Notices

Knowledge and best practice in this f eld are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identif ed, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Dedication to Seventh Edition

Mentor, Colleague, Friend

On behalf of the worldwide community of clinical laboratorians, we are pleased to dedicate this edition of the Tietz Fundamentals of Clinical Chemistry and Molecular Diagnostics to Professor Norbert W. Tietz, Ph.D. Through his many scientific, educational, and editorial efforts, Professor Tietz has had a significant and worldwide impact on the profession, practice, and teaching of clinical laboratory medicine.

Professor Tietz is internationally known for creating and subsequent editing of one of the first books produced for clinical laboratorians, the internationally acclaimed Fundamentals of Clinical Chemistry. It was the first modern textbook that integrated clinical chemistry with the basic medical sciences and pathophysiology. Dr. Tietz also edited the first edition of the Textbook of Clinical Chemistry, a reference text that bridges the gap between the clinical laboratory and medical management by relating pathophysiology to analytical results in health and disease. He has also edited the Clinical Guide to Laboratory Tests and the Applied Laboratory Medicine.

In summary, Professor Tietz has been and continues to be a strong advocate of clinical chemistry, and through his energetic scientific, educational, and editorial efforts he has encouraged countless clinical chemists, clinical pathologists, and medical technologists to advance their profession by linking progress in laboratory medicine with the practice of medicine. The name of Tietz is synonymous with the profession and practice of quality laboratory medicine. It is our distinct pleasure to dedicate this edition of the Fundamentals of Clinical Chemistry and Molecular Diagnostics to an individual who has had such a significant impact on our profession and our careers.

Foreword

As a practitioner and instructor of clinical chemistry for over 20 years, I have observed many innovative changes in the clinical laboratory, from implementation of new analytical techniques to dependence on laboratory informatics to the inclusion of molecular testing and its unique practice standards. I have worked with the editors and publishers of Tietz Fundamentals of Clinical Chemistry and Molecular Diagnostics as consulting editor for three editions and have followed each edition as they reflect the numerous advances in laboratory science. In the area of education, such updates are crucial for informing students of what they should expect in their careers as professional laboratorians or as other practitioners in health care. As with previous editions, the seventh edition of Tietz Fundamentals of Clinical Chemistry and Molecular Diagnostics presents information that today's clinical chemistry students and practicing laboratorians must know to succeed in this discipline and in the contemporary world of pathology.

The true purpose of education must go beyond providing the knowledge necessary to be successful in a particular field. It must also stimulate and encourage students to investigate knowledge beyond that presented in the formal classroom setting. The highly regarded authors of the seventh edition of Tietz Fundamentals of Clinical Chemistry and Molecular Diagnostics excel at presenting essential knowledge. Their updates and revisions of traditional topics and the addition of new chapters, such as "Pharmacogenetics" and "Genomes and Nucleic Acid Alterations," provide interesting and indispensable material for the active learner. To inspire students to seek information beyond that provided in the various chapters, the seventh edition provides end-of-chapter multiple-choice questions that encourage continued review and study. Updated websites within each chapter offer further sources of data to increase understanding of the subject matter. Thought-provoking figures that illustrate chapter concepts and innovative algorithms that provide a unique way of examining diagnostic issues have been added to this edition.

For both the educator and the student, improved and testable objectives have been designed and related Test Bank questions have been added, revised, or modified. For the laboratory science student, the professional laboratorian, and the practicing pathologist, this textbook serves as an outstanding resource for (1) the study of basic laboratory operations, (2) understanding clinical chemistry analytes, and (3) comprehending fundamental pathophysiology. The last chapter "Reference Information for the Clinical Laboratory" provides an excellent source of reference intervals for analytes of clinical relevance. As with previous editions of Tietz Fundamentals of Clinical Chemistry and Molecular Diagnostics, this textbook provides something of interest for anyone who is involved in the field of medical laboratory science.

It is a privilege and an honor to have been invited to take part in the continuation of such a quality endeavor as this exceptional textbook. To observe and comment on its continued growth and maturation is both rewarding and stimulating. I find it truly fulfilling to know that students, educators, managers, and pathologists use this text as a primary resource in the classroom, laboratory, and clinic for information regarding the field of clinical chemistry. Maintaining the highest standards of quality while providing crucial contemporary information that is both concise and readable, this volume continues in the tradition of excellence set by previous editions of Tietz Fundamentals of Clinical Chemistry and Molecular Diagnostics.

Barbara G. Sawyer, Ph.D., M.L.S.(A.S.C.P.)^{CM},
M.B.(A.S.C.P.)^{CM}
Professor, Clinical Laboratory Science/Molecular Pathology

Preface

As the discipline of clinical laboratory science and medicine has evolved and expanded, each new edition of Tietz Fundamentals of Clinical Chemistry has been revised to reflect these changes. The seventh edition of this series is no exception, as we have made significant revisions in its format and content. First, reflecting the effect that molecular diagnostics has had and continues to have on the practice of clinical chemistry and laboratory medicine, we have retitled the seventh edition as Tietz Fundamentals of Clinical Chemistry and Molecular Diagnostics. Consequently, chapters have been added on the topic of molecular diagnostics and many of the other updated chapters now include discussions of genetic testing and descriptions of the genetic basis of diseases.

Second, 47 new authors along with 53 veterans from the sixth edition have joined our company of subject-matter experts to revise and produce chapters that reflect the state-of-the-art in their respective fields. Consequently, this new edition covers many new topics and updates information on older ones. With these changes, the seventh edition now contains 50 chapters that are grouped into sections entitled (I) Principles of Laboratory Medicine, (II) Analytical Techniques and Instrumentation, (III) Analytes, (IV) Pathophysiology, (V) Molecular Diagnostics, and (VI) Reference Information.

Third, learning tools have been added or expanded. For example, a set of objectives and a list of key terms and definitions were included at the beginning of each chapter. (Note: in each chapter key terms are listed in alphabetical order in a bold red font and again when each appears for the first time in their respective chapter.) At the end of each chapter, a list of review questions has been added to assist students in the review of the salient points covered in each chapter. At the end of the book, we have combined the keywords and definitions into a Glossary. Of note, many of these key words and definitions were obtained, in whole or in part, from the 32nd edition of Dorland's Illustrated Medical Dictionary, with permission kindly granted by Elsevier.

As with the sixth edition, we have relied on information technology to prepare and produce the seventh edition. For example, each chapter was submitted and edited via Elsevier's "Electronic Manuscript Submission System." In addition, many of the figures, especially those that included chemical structures, were drawn or revised by Ed Ashwood using ChemWindows software. This resulted in a uniform representation of chemical structures and facilitated the integration of figures within the text while reducing errors. Readers will note that references to web-based sources of information are found throughout the text.

To assist us in preparing the seventh edition, we again invited Barbara G. Sawyer, Ph.D., to join our editorial team as an educational consultant. Because of her experience with using Fundamentals as a teaching text and her perspective as an educator, Professor Sawyer's advice and assistance were again very useful to us as we produced the seventh edition.

We appreciate the opportunity provided us by Elsevier to prepare the seventh edition of Tietz Fundamentals of Clinical Chemistry. It has been an exciting, challenging, and educational experience. We trust that this edition will live up to the reputation and success of its distinguished predecessors. We have enjoyed working with the team of dedicated authors that have spent many hours preparing comprehensive chapters that are authoritative and timely. We thank them sincerely and believe that they have enabled us to produce a textbook that is reflective of the diverse, technical, and practical nature of the current practice of clinical laboratory science and medicine.

We have also benefited from and enjoyed working with the Elsevier staff, especially Sonya Seigafuse, Executive Content Strategist; Ellen Wurm-Cutter, Content Development Manager; and Rachel E. McMullen and Andrea Campbell, Senior Project Managers. Their patience, cooperation, advice, and professional dedication are gratefully acknowledged.

Finally, we thank our valued colleague Ed Ashwood for his years of work as an editor of this book's predecessors. The current product continues to benefit from his many contributions.

Contents

PART I PRINCIPLES OF LABORATORY MEDICINE

1 Clinical Chemistry, Molecular Diagnostics, and Laboratory Medicine, 1
David E. Bruns, M.D., François A. Rousseau, M.D., and Carl A. Burtis, Ph.D.
- Laboratory Medicine, 1
- Clinical Chemistry and Laboratory Medicine, 2
- Molecular Diagnostics, 3
- Ethical Issues in Laboratory Medicine, 3
- Review Questions, 5

2 Selection and Analytical Evaluation of Methods—With Statistical Techniques, 6
Kristian Linnet, M.D., Ph.D. and James C. Boyd, M.D.
- Method Selection, 7
- Basic Statistics, 8
- Basic Concepts in Relation to Analytical Methods, 11
- Analytical Goals, 15
- Method Comparison, 16
- Monitoring Serial Results, 28
- Traceability and Measurement Uncertainty, 28
- Software Packages, 30
- Review Questions, 31

3 Clinical Evaluation of Methods, 33
Edward R. Ashwood, M.D. and David E. Bruns, M.D.
- Sensitivity and Specificity, 33
- Receiver Operating Characteristic Plots, 34
- Probabilistic Reasoning, 35
- Prevalence, 35
- Predictive Values, 35
- Odds Ratio, 36
- Likelihood Ratio, 36
- Bayes' Theorem, 36
- Combination Testing, 37
- Methods of Assessing Diagnostic Accuracy, 38
- Review Questions, 38

4 Evidence-Based Laboratory Medicine, 40
Christopher P. Price, Ph.D., F.R.S.C., F.R.C.Path. Patrick M.M. Bossuyt, Ph.D., and David E. Bruns, M.D.
- Evidence-Based Medicine—What Is It?, 41
- Evidence-Based Medicine and Laboratory Medicine, 42
- Information Needs in Evidence-Based Laboratory Medicine, 43
- Characterization of Diagnostic Accuracy Tests, 44
- Outcomes Studies, 45
- Systematic Reviews of Diagnostic Tests, 48
- Economic Evaluations of Diagnostic Testing, 50
- Clinical Practice Guidelines, 53
- Clinical Audit, 56
- Applying the Principles of Evidence-Based Laboratory Medicine in Routine Practice, 57
- Review Questions, 58

5 Establishment and Use of Reference Values, 60
Gary L. Horowitz, M.D.
- Establishment of Reference Values, 61
- Use of Reference Values, 67
- Review Questions, 70

6 Specimen Collection, Processing, and Other Preanalytical Variables, 72
Doris M. Haverstick, Ph.D., D.A.B.C.C., and Amy R. Groszbach, M.E.D., M.L.*T.*, M.B.(A.S.C.P.)^{CM}
- Types of Specimens, 73
- Handling of Specimens for Analysis, 81
- Review Questions, 88

7 Quality Management, 90
George G. Klee, M.D., Ph.D. and James O. Westgard, Ph.D.
- Fundamentals of Total Quality Management, 91
- Implementing TQM, 93
- Personnel Competency and Training, 94
- The Total Testing Process, 94
- Control of Preanalytical Variables, 95
- Control of Analytical Variables, 96
- External Quality Assessment and Proficiency Testing Programs, 102

New Quality Initiatives, 103
Review Questions, 105

8 Principles of Basic Techniques and Laboratory Safety, 107
Stanley F. Lo, Ph.D., D.A.B.C.C., F.A.C.B.
Concept of Solute and Solvent, 108
Units of Measurement, 109
Chemicals, 111
Reference Materials, 112
Basic Techniques and Procedures, 113
Review Questions, 127

PART II ANALYTICAL TECHNIQUES AND INSTRUMENTATION

9 Optical Techniques, 129
L.J. Kricka, D.Phil., F.A.C.B., C.Chem., F.R.S.C., F.R.C.Path. and Jason Y. Park, M.D., Ph.D., F.C.A.P.
Photometry and Spectrophotometry, 131
Instrumentation, 133
Refectance Photometry, 138
Atomic Absorption Spectrophotometry, 138
Fluorometry, 139
Phosphorimetry, 146
Luminometry, 146
Nephelometry and Turbidimetry, 147
Review Questions, 149

10 Electrochemistry and Chemical Sensors, 151
Paul D'Orazio, Ph.D. and Mark E. Meyerhof, Ph.D.
Potentiometry, 152
Voltammetry/Amperometry, 158
Conductometry, 162
Coulometry, 163
Optical Chemical Sensors, 163
Biosensors, 164
Review Questions, 169

11 Electrophoresis, 171
Lindsay A.L. Bazydlo, Ph.D. and James P. Landers, Ph.D.
Basic Concepts and Definitions, 172
Theory of Electrophoresis, 172
Description of Technique, 172
Types of Electrophoresis, 175
Technical Considerations, 180
Review Questions, 181

12 Chromatography, 183

Basic Concepts, 184
Separation Mechanisms, 187
Planar Chromatography, 189
Column Chromatography, 190
Qualitative and Quantitative Analyses, 198
Review Questions, 200

13 Mass Spectrometry, 202
Alan L. Rockwood, Ph.D., D.A.B.C.C., Thomas M. Annesley, Ph.D., and Nicholas E. Sherman, Ph.D.
Basic Concepts and Definitions, 203
Instrumentation, 205
Clinical Applications, 213
Review Questions, 214

14 Enzyme and Rate Analyses, 216
Renze Bais, Ph.D., F.F.Sc. (R.C.P.A.) and Mauro Panteghini, M.D.
Basic Principles, 217
Enzyme Kinetics, 223
Analytical Enzymology, 229
Review Questions, 234

15 Immunochemical Techniques, 236
L.J. Kricka, D.Phil., F.A.C.B., C.Chem., F.R.S.C., F.R.C.Path. and J.Y. Park, M.D., Ph.D., F.C.A.P.
Basic Concepts and Definitions, 237
Antigen-Antibody Binding, 238
Qualitative Methods, 240
Quantitative Methods, 242
Other Immunochemical Techniques, 252
Review Questions, 252

16 Automation, 254
James C. Boyd, M.D. and Charles D. Hawker, Ph.D., M.B.A., F.A.C.B.
Basic Concepts, 255
Automation of Analytical Processes, 255
Integrated Automation for the Clinical Laboratory, 263
Practical Considerations, 267
Other Areas of Automation, 269
Review Questions, 270

17 Point-of-Care Instrumentation, 272
Christopher P. Price, Ph.D., F.R.S.C., F.R.C.Path. and Andrew St. John, Ph.D., F.F.Sc. (R.C.P.A.)
Analytical and Technological Considerations, 273
Implementation and Management Considerations, 280
Review Questions, 284

PART III ANALYTES

18 Amino Acids, Peptides, and Proteins, 286
Glen L. Hortin, M.D., Ph.D.
Amino Acids, 287
Peptides and Proteins, 292
Analysis of Proteins, 293
Plasma and Serum Proteins, 299
Review Questions, 317

19 Serum Enzymes, 318
Mauro Panteghini, M.D. and Renze Bais, Ph.D., F.F.Sc. (R.C.P.A.)
Basic Concepts, 319

Clinical Chemistry, Molecular Diagnostics, and Laboratory Medicine

CHAPTER 1

David E. Bruns, M.D., Francois A. Rousseau, M.D., and Carl A. Burtis, Ph.D.

Objectives

1. Define the following terms:
   - Core laboratory
   - Ethics
   - Laboratory medicine
   - Molecular diagnostics
   - Pharmacogenetics
2. List and explain six reasons for performing a laboratory test.
3. Describe the field of laboratory medicine, including subdisciplines, information handling, and ethical issues.
4. State the contribution of epidemiology to the field of clinical chemistry.
5. State the applications of molecular diagnostics in laboratory medicine.
6. List and explain five ethical issues that confront laboratorians; state the critical importance of maintaining confidentiality in the laboratory.
7. Evaluate a possible confidentiality or conflict of interest issue and determine whether it is an ethics violation.

Key Words and Definitions

Core laboratory A laboratory that provides all of the high-volume and emergency testing in many hospitals.

Ethics Rules or standards governing the conduct of an individual or the members of a profession.

Laboratory medicine A component of laboratory science that is involved in the selection, provision, and interpretation of diagnostic testing of individual specimens.

Laboratory testing A process conducted in a clinical laboratory to rule in or rule out a diagnosis, to select and monitor disease treatment, to provide a prognosis, to screen for a disease, or to determine the severity of and monitor a physiological disturbance.

Molecular diagnostics Use of molecular biology techniques for the purposes of prevention, diagnosis, and follow-up or prognosis of disease; and selection, optimization, and monitoring of therapies.

In this chapter, we begin with a general discussion to introduce the field of laboratory medicine and the disciplines of clinical chemistry (or clinical biochemistry) and molecular diagnostics. This will include a discussion of the meaning of the term laboratory medicine and the relationships among (1) clinical chemistry, (2) molecular diagnostics, (3) laboratory medicine, and (4) evidence-based laboratory medicine. The concepts introduced in this chapter are developed in the remaining chapters of this book.

The chapter concludes with a discussion on the ethical issues that clinical chemists/biochemists face in the practice of their profession and issues that they will face in the future.

Laboratory Medicine

The term **laboratory medicine** refers to the discipline involved in the (1) selection, (2) provision, and (3) interpretation of diagnostic testing that uses primarily samples from patients. This discipline includes (1) research, (2) administration, (3) teaching activities, and (4) clinical service. Testing in laboratory medicine may be directed at (1) confirming a clinical suspicion, which may include making, or ruling in, a diagnosis, (2) excluding, or ruling out, a diagnosis, (3) assisting in selection, optimization, and monitoring of treatment, (4) providing a prognosis, (5) screening for disease in the absence of clinical

signs or symptoms, and (6) establishing and monitoring the severity of a physiological disturbance (Box 1-1).

The field of laboratory medicine includes clinical chemistry and its traditional subdisciplines (including toxicology and drug monitoring, endocrine and organ function testing, and "biochemical" and "molecular" genetics) and areas such as microbiology, hematology, hemostasis and thrombosis, blood banking (transfusion medicine), immunology, and identity testing (Box 1-2). In some parts of the world, laboratory medicine also encompasses cytology and anatomic pathology (histopathology). In recent years, molecular diagnostics has become an increasingly important part of all of the specialties of laboratory medicine. Information management and interpretation (including laboratory informatics) are key aspects of the laboratory medicine service, as are activities concerned with maintaining quality, such as (1) quality control, (2) proficiency testing, (3) audit, (4) benchmarking, and (5) clinical governance. Closer links with patients are increasingly attained through the use of telemedicine and tele-healthcare, which includes facets of laboratory medicine such as (1) analytical testing, (2) the use of clinical decision support systems, and (3) informatics.

BOX 1-1 Uses of Testing in the Clinical Laboratory

- Confirming a clinical suspicion (which could include making a diagnosis)
- Excluding a diagnosis
- Assisting in selection, optimization, and monitoring of treatment
- Providing a prognosis
- Screening for disease in the absence of clinical signs or symptoms
- Establishing and monitoring the severity of a physiological disturbance

BOX 1-2 Disciplines of the Modern-Day Clinical Laboratory

- Biochemical Genetics
- Cancer Diagnostics
- Clinical Chemistry/Biochemistry
- Clinical Hematology
- Clinical Immunology
- Cytogenetics
- Drug Monitoring
- Endocrinology Testing
- Hemostasis/Thrombosis (Coagulation) Testing
- Identity Testing
- Infectious Disease Testing
- Information Technology
- Laboratory Management
- Microbiology
- Molecular Cytogenetics
- Molecular Diagnostics
- Nutrition
- Organ Transplantation
- Organ Function Testing
- Pharmacogenetics
- Proteomics
- Quality Management
- Toxicology
- Trace Elements
- Transfusion Medicine (Blood Banking)

Clinical Chemistry and Laboratory Medicine

The ties between clinical chemistry and other areas of laboratory medicine have deep roots. Individuals working primarily in the area of clinical chemistry/biochemistry have developed tools and methods that have become part of the fabric of laboratory medicine beyond the clinical chemistry laboratory. Examples include (1) the theory and practice of reference intervals (see Chapter 5), (2) the use of both (internal) quality control and proficiency testing (see Chapter 7), (3) the introduction of automation into the clinical laboratory (see Chapter 16), and (4) concepts of diagnostic testing (see Chapters 3 and 4). From physician and patient perspectives, no distinction is evident among these specialties, and invariably the repertoire of more than one specialty will be called upon when a clinical decision is made. Examples of clinical scenarios that require tests from multiple laboratory areas include the diagnosis and management of many diseases and the management of patients in intensive care (see Chapters 33 through 45).

Boundaries between and among the parts of the clinical laboratory have become more blurred with increasing emphasis on the use of chemical and "molecular" (nucleic acid) testing. Molecular diagnostic testing has evolved beyond human genetic testing—an area in which clinical chemists have long been active. Now, clinical chemists in "molecular" laboratories contribute their expertise in laboratory medicine to infectious disease testing, cancer diagnostics, and identity testing—activities that formerly were associated primarily or solely with, respectively, clinical microbiology, hematology, and blood bank laboratories. Successful contributions by clinical chemists to these areas require an understanding of the principles of laboratory medicine and close collaboration with clinical microbiologists, hematologists, and others who have specialized expertise in those areas of laboratory medicine.

The relationship between the clinical chemist and laboratory medicine has evolved further with the advent of **"core" laboratories**. These laboratories provide all of the high-volume and emergency testing in many hospitals. Their efficient and reliable operation depends on automation (see Chapter 16), computers, and high levels of quality control and quality management (see Chapter 7). Clinical chemists, who have long been active in these areas, have assumed increasing responsibility in core laboratories and thus have become more involved in areas such as hematology, coagulation, urinalysis, and even microbiology. Thus a new type of "clinical chemist" has emerged, and again the functions require a broader knowledge of laboratory medicine and greater collaboration with other specialists.

A virtual merger of clinical chemistry and laboratory medicine has been suggested in many ways. For example, journals in the field of clinical chemistry publish articles in all of the areas of laboratory medicine. The current logo of the American Association for Clinical Chemistry reads, "AACC—Improving Healthcare through Laboratory Medicine." Moreover, the

International Federation of Clinical Chemistry Societies is now called the International Federation of Clinical Chemistry and Laboratory Medicine (IFCC). Being active in the field of laboratory medicine today requires, more often than not, familiarity with core concepts in several if not all of the subdisciplines of the field.

During the past two decades, the field of clinical chemistry has been profoundly influenced by new activities in the fields of clinical epidemiology and evidence-based medicine (see Chapter 4). Clinical epidemiologists have developed study designs to quantify the diagnostic accuracy (as opposed to analytical accuracy) of tests developed in laboratory medicine (see Chapter 3). Moreover, they have introduced methods that are used to evaluate the effects and value of **laboratory testing** in healthcare (see Chapter 2). These developments are expected to play an increasing role in the selection and interpretation of tests. Thus Chapter 4 of this book is devoted to evidence-based laboratory medicine.

Molecular Diagnostics

Molecular diagnostics is defined as the use of the techniques of molecular biology for the purpose of prevention, diagnosis, follow-up, or prognosis of disease. Molecular diagnostics has impacted all fields of laboratory medicine and has delivered several new diagnostic tools of proven clinical utility. After the discovery of DNA as the repository of genetic information in the 1950s, the development of molecular biology methods to study DNA and RNA in the 1970s and 1980s, and the invention of the polymerase chain reaction (PCR) in 1985, analysis of nucleic acids and molecular biology methods have been used to decipher many biological processes of the living cell (see Chapters 46 to 49) in normal and disease states. These discoveries naturally led to the development of the discipline of molecular diagnostics, which entered the realm of laboratory medicine in multiple forms and in multiple fields. Molecular diagnostics has been applied to the study of the constitutive genome (e.g., inherited diseases, histocompatibility, identity assessment, pharmacogenetics; see Chapter 46) and to the study of acquired states (e.g., infectious diseases, grafting, and pregnancy). Molecular diagnostic methods can be qualitative or quantitative in nature, depending on the clinical need.

The field of molecular diagnostics is characterized by very rapidly evolving technology (as the result of massive investments in the human genome project and endeavors that followed), as well as by a rapidly increasing variety of potential clinical applications. Of note, the advent of massively parallel nucleic acid sequencing is opening a wide spectrum of potential new diagnostic applications, where tens to hundreds of millions of different molecules are characterized and quantified in a single experiment and supported by high throughput clinical bioinformatic data analyses. Chapters 47, 48, and 49 provide an overview, respectively, of the Principles of Molecular Biology, Nucleic Acid Techniques and Applications, and Genome and Nucleic Acid Alterations.

One field in which molecular diagnostics has made a significant impact is the study of hematopoietic malignancies such as malignant lymphomas and leukemias. Easy access to malignant cells through a blood or bone marrow sample allowed the development of molecular biomarkers to refine the diagnosis of such tumors. These include genetic rearrangements that are specific to certain types of malignancies and are associated with the aggressiveness and prognosis of the malignancy and, hence, are useful tools for orienting treatment. Further, once the molecular signature of the patient's tumor has been identified, quantitative assays allow monitoring of response to therapy and aid in detection of residual disease in the event of a relapse and confirmation of durable remissions.

Pharmacogenetics (see Chapter 46), or the study of variation in drug metabolism between individuals, has been a field of intensive work and increasing interest because studying the genomic DNA from a patient is simpler than measuring the activity of enzymes in tissues that are not easily accessible but are involved in drug activation and metabolism.

Apart from the study of tissues and nucleated cells, molecular diagnostics has been applied to the study of plasma nucleic acids (or circulating nucleic acids; see Chapter 47). Plasma nucleic acid analysis has been made possible by the discovery that cells in the body release DNA and RNA into the extracellular compartment and ultimately into the bloodstream, where they can be detected and analyzed. Because of their short half-life in the circulation (less than 24 hours), plasma nucleic acids provide a measure of processes that are ongoing at the time of blood sampling. Such processes include the presence of nucleic acids from abnormal tissue (tumor nucleic acids) or the existence of nonhost nucleic acids (microorganisms, graft–donor, and the fetus during pregnancy). It is expected that molecular diagnostic analysis of plasma nucleic acids will enter routine clinical practice for various indications with the appearance of a high-quality evidence base for their clinical utility.

Ethical Issues in Laboratory Medicine

As in other branches of medicine, practitioners in laboratory medicine are faced with ethical issues, often on a daily basis; examples are listed in Box 1-3. The definition of **ethics** varies, but in this chapter, the following definition is relevant: "The rules or standards governing the conduct of an individual or the members of a profession (e.g., laboratory medicine)." Specific ethical issues that pertain to the practice of laboratory medicine include but are not limited to (1) confidentiality of genetic information and patient medical information, (2) allocation

BOX 1-3 Ethical Issues in Clinical Chemistry and Molecular Diagnostics

- Confidentiality of genetic information
- Confidentiality of patient medical information
- Allocation of resources
- Codes of conduct
- Publishing issues
- Conflict of interest

of healthcare resources, (3) codes of conduct, (4) publishing issues, and (5) conflict of interest.

Confidentiality of Genetic Information

Prominent in the news in the first and second decades of this millennium has been the issue of confidentiality of genetic information. Legislation was considered necessary to prevent denial of health insurance or employment to people found by DNA testing to be at risk of disease. Less appreciated is the fact that the issue of confidentiality of clinical laboratory data predated DNA testing. In fact, many non-DNA tests, old and new, also carry information about risks of illness and death. Clinical laboratorians have long been responsible for maintaining the confidentiality of all laboratory results—a situation made even more critical with the advent of increasingly powerful genetic testing.

Confidentiality of Patient Medical Information

Because new medical tests are constantly needed, laboratory physicians and scientists spend a great deal of time and effort developing new diagnostic tests or evaluating them for use in a specific setting. This process requires use of patient samples and may involve use of patient medical information.[3] Ethical judgments are required regarding the type of informed consent that is needed from patients for use of their samples and clinical information. Clinical laboratory physicians and scientists often serve on institutional review boards that examine proposed research on human subjects. In these discussions, ethical concepts such as equipoise and confidentiality are central to decision making.

Allocation of Healthcare Resources

Because resources are finite, clinical laboratorians must make ethically responsible decisions about allocation of resources in the clinical laboratory and beyond. When a trade-off exists between cost and quality (of testing reagents or analyzers, for example), ethical issues may need to be considered: What is best for patients generally? How can the most good be done with the available resources?

Business Ethics

For laboratorians in business, the newly appreciated area of business ethics comes into play. One example, recently epitomized by scandals associated with names such as Madoff and Enron, involves the area of accounting—a human endeavor that in the public mind had not been much associated with concerns about ethics.

Codes of Conduct

Most professional organizations publish a Code of Conduct that requires adherence by their members. For example, the American Association for Clinical Chemistry (AACC) has published Ethical Guidelines (http://www.aacc.org/about/ethics/Pages/default.aspx#; accessed June 26, 2013) that require AACC members to endorse principles of ethical conduct in their professional activities, including (1) selection and performance of clinical procedures, (2) research and development, (3) teaching, (4) management, (5) administration, and (6) other forms of professional service.

Publishing Issues

Publication of documents having high scientific integrity depends on authors, editors, and reviewers all working in concert in an environment governed by high ethical standards.[2]

Authors are responsible for honest and complete reporting of original data produced in ethically conducted research studies. Practices such as fraud, plagiarism, and falsification or fabrication of data are unacceptable! The International Committee of Medical Journal Editors (ICMJE)[7] and the Committee on Publication Ethics (COPE)[5] have published policies that address such behavior. Other practices to be avoided include redundant publication, and inappropriate credit for authorship; in addition, ethical policies require that factors that might influence the interpretation of a study must be revealed. Most journals now have conflict of interest policies for both authors and journal editors. For example, Clinical Chemistry requires that authors complete a full disclosure form upon manuscript submission. Annually, the Editor and Associate Editors are also required to complete such a form (http://www.clinchem.org/; accessed June 26, 2013).

Conflict of Interest

Concern has been raised over the interrelationships between practitioners in the medical field and commercial suppliers of drugs, devices, equipment, etc., to the medical profession.[8] These concerns led the National Institutes of Health (NIH) in 1995 to require official institutional review of financial disclosure by researchers and management of situations in which disclosure indicates potential conflict of interest and/or conflict of effort in research. In 2009, the Institute of Medicine (IOM) issued a report[6] that questioned inappropriate relationships between pharmaceutical and device companies and physicians and other healthcare professionals.[8] Similarly, the relationships between clinical laboratorians and manufacturers and providers of diagnostic equipment and supplies have been scrutinized.

As a consequence of these concerns and as a result of the enactment of various laws designed to prevent fraud, abuse, and waste in Medicare, Medicaid, and other federal programs, professional organizations that represent manufacturers of in vitro diagnostics (IVD) and other device and healthcare companies have published Codes of Ethics. For example, the Advanced Medical Technology Association (AdvaMed) has revised and published its Code of Ethics that became effective July 1, 2009.[1] Topics discussed in this revised Code include (1) gifts and entertainment, (2) consulting arrangements and royalties, (3) reimbursement for testing, and (4) education. Similarly, the European Diagnostic Manufacturers Association (EDMA) has published its Code of Ethics.[4] In Part A of this document, topics discussed include (1) member-sponsored product training and education, (2) supporting third-party educational conferences, (3) sales and promotional meetings, (4) financial arrangements for consultants (5) gifts, (6) provision of reimbursements and other economic information, and (7) donations for charitable and philanthropic purposes.

Both documents address demands from regulators while nurturing the unique role that laboratorians and other healthcare professionals play in developing and refining new technology.[8]

In closing, it is our opinion that practitioners of clinical chemistry, molecular diagnostics, and laboratory medicine have before them a future full of promises and challenges. New insight into disease and its treatment is exploding, and these insights are based in sciences that are at the heart of the clinical laboratory. The clinical laboratory is the place of translation of these insights into effective healthcare. We honor the important role of ethical laboratory professionals in these efforts and have endeavored to provide in this book chapters prepared by expert authors that help to define the evidence base and the knowledge base of the profession.

Review Questions

1. The clinical laboratory discipline that is used most often to assess inherited disease through study of the constitutive genome is:
   a. transfusion services.
   b. clinical chemistry.
   c. molecular diagnostics.
   d. hematology.
2. The study of the genetic variation between individuals in their ability to metabolize drugs is referred to as:
   a. pharmacogenetics.
   b. molecular diagnostics.
   c. clinical chemistry.
   d. epidemiology.
3. When a practitioner in clinical chemistry has an inappropriate personal relationship with a commercial supplier of medical supplies and chemistry analyzers, there may be a potential issue with:
   a. publication development.
   b. confidentiality.
   c. selection of treatment.
   d. conflict of interest.
4. "Molecular testing" involves the clinical analysis of:
   a. atoms and molecules.
   b. nucleic acids.
   c. cellular components of blood.
   d. the physical structure of compounds.
5. Which one of the following is not considered an ethical issue facing a clinical laboratorian?
   a. Allocation of resources
   b. Conflicts of interest
   c. Discussion of one's salary
   d. Maintenance of confidentiality

CHAPTER

2 Selection and Analytical Evaluation of Methods—With Statistical Techniques*

Kristian Linnet, M.D., D.M.Sc., and James C. Boyd, M.D.

Objectives

1. Define the following:
   - Analytical measurement range
   - Bias
   - Clinical sensitivity
   - Clinical specificity
   - Coefficient of variation
   - Correlation coefficient
   - Difference plot
   - Error model
   - Frequency distribution
   - Gaussian probability distribution
   - Limit of detection
   - Linearity
   - Mean
   - Median
   - Population
   - Precision
   - Random error
   - Random sample
   - Regression analysis
   - Sample
   - Standard deviation
   - Systematic error
   - Student t distribution
   - Trueness
   - Uncertainty
2. List and describe three criteria that must be considerations in laboratory method selection, including the specific parameters involved in each criterion.
3. Compare population and sample mean, population parameter and sample statistic, and population standard deviation and sample standard deviation, including a description of each, symbols used to express these, how they are calculated, and the information they provide.
4. State the connection of the following concepts to analytical methods:
   - Accuracy
   - Analytical sensitivity
   - Analytical specificity
   - Calibration
   - Limit of detection
   - Linearity
   - Precision
   - Repeatability
   - Reproducibility
5. List two common approaches used to objectively analyze data in a methods comparison study.
6. Describe the components of a difference plot, including the plot's use in method comparison and how the plot is interpreted.
7. Discuss assessment of error in an objective analysis of data in method comparison, including how error occurrence relates to an assay's performance characteristics, the difference between random and systematic error, what causes error, and how error is evaluated in a difference plot.
8. For the following types of analyses, list the components of the analysis, its application in method comparison, how it is computed, how outliers affect it, and how the results are interpreted:
   - Deming regression
   - Nonparametric regression
   - Ordinary least-squares regression
   - Regression
9. Describe the calibration hierarchy, including the tracing of values of routine clinical chemistry measurements to a primary reference, how the values are obtained, and the methods involved; draw a calibration hierarchy given a specific analyte.
10. Discuss the concept of uncertainty in relation to clinical laboratory results, including the components of the standard uncertainty formula and two ways in which uncertainty is assessed.
11. Given appropriate values, state the formula and calculate the following:
    - Coefficient of variation
    - Coefficient of variation percent
    - Deming regression
    - Linear regression
    - Population mean
    - Precision analyses
    - Standard deviation
    - Standard uncertainty

Key Words and Definitions

Analyte The substance being analyzed in an analytical procedure.

Analytical sensitivity The ability of an analytical method to assess small variations in the concentration of analyte.

Analytical specificity The ability of an assay procedure to determine specifically the concentration of the target analyte in the presence of potentially interfering substances or factors in the sample matrix.

Bias In an analytical method, the difference between the average value and the true value that is expressed numerically and is inversely related to the trueness.

*The authors gratefully acknowledge the original contributions by Theodore Peters, Robert O. Kringle, and David D. Koch on which portions of this chapter are based.

Key Words and Definitions—cont'd

Calibration In relation to analytical methods, a function that describes the relationship between instrument signal and concentration of analyte.

Commutability The equivalence of the mathematical relationships between the results of different measurement procedures for a reference material and for representative samples from healthy and diseased individuals.

Difference plot A bias plot that shows the dispersion of observed differences between the measurements of two methods as a function of the average concentration of the measurements; also referred to as a "Bland-Altman plot."

Limit of detection An assay characteristic defined as the lowest value that significantly exceeds the measurements of a blank sample.

Matrix In relation to analytical methods, human serum that contains analytes.

Measuring interval The analyte concentration range over which measurements are within the declared tolerances for imprecision and bias; also referred to as "reportable range."

Method comparison Comparison of measurements by two methods that is carried out objectively using statistical procedures and graphics displays.

Ordinary least-squares regression (OLR) analysis A method used to estimate the unknown parameters in a linear regression assessment performed to minimize the sum of squared vertical distances between observed responses and responses predicted by linear approximation.

Population In relation to analytical methods, the complete set of all observations that might occur as the result of performing a particular procedure according to specified conditions.

Random error Error that arises from imprecision of measurement of the type that is described by a Gaussian distribution (e.g., caused by pipetting variability, signal variability).

Reference measurement procedure A procedure of highest analytical quality that has been shown to yield values having an uncertainty of measurement commensurate with its intended use, especially in assessing the trueness of other measurement procedures for the same quantity and in characterizing reference materials.

Regression analysis A statistical analysis that compares measurement relations between two analytical methods.

Systematic error Error in measurement that arises from calibration bias or nonspecificity of an assay and, in the course of a number of analyses of the same analyte, remains constant (y-intercept deviation from zero) or varies in a proportional way (slope deviation from unity) based on the analyte concentration.

Traceability In relation to analytical methods, a concept based on a chain of comparisons of measurements that lead to a known reference value done to ensure reasonable agreement between measurements of routine methods.

Trueness A qualitative term that describes the closeness of agreement between the average value obtained from a large series of results of measurements and a true value.

Uncertainty A parameter associated with the result of a measurement that characterizes the dispersion of the values that could reasonably be attributed to the measure and, or, more briefly, uncertainty is a parameter characterizing the range of values within which the value of the quantity being measured is expected to lie.

The introduction of new or revised methods is a common task for laboratorians working in the clinical laboratory (Figure 2-1). In practice, a new or revised method must be selected carefully and its performance evaluated thoroughly in the laboratory before it is adopted for routine use. The establishment of a new method may also involve an evaluation of the features of the automated analyzer on which the method will be implemented.

Method evaluation in the clinical laboratory is influenced strongly by guidelines (e.g., see the Clinical and Laboratory Standard Institute [CLSI; www.clsi.org/; accessed July 6, 2013] and the International Organization for Standardization [ISO; www.iso.org/; accessed July 6, 2013]). In addition, meeting laboratory accreditation requirements has become an important aspect of the method selection and evaluation process. This chapter presents an overview of considerations in the method selection process, followed by sections on basic statistics, method evaluation, and method comparison. A list of abbreviations used in this chapter is provided in Box 2-1.

Method Selection

Optimal method selection involves consideration of (1) medical usefulness, (2) analytical performance, and (3) practical criteria.

Medical Usefulness Criteria

The selection of appropriate methods for clinical laboratory assays is a vital part of rendering optimal patient care, and advances in patient care are frequently based on the use of new or improved laboratory tests.

Ascertaining what is necessary clinically from a laboratory test is the first step in selecting a candidate method (see Figure 2-1). Key parameters, such as desired turnaround time and necessary clinical utility for an assay, often are derived from discussions between laboratorians and clinicians. When new diagnostic assays are introduced, reliable estimates of clinical **sensitivity** and **specificity** must be obtained by reviewing the literature or by conducting a clinical outcome study. With established **analytes** (the substances analyzed in an analytical procedure), a common scenario is the replacement of an older, labor-intensive method with a newer, automated assay that is more economical for daily use.

Analytical Performance Criteria

In evaluating the performance characteristics of a candidate method, (1) precision, (2) accuracy (trueness), (3) analytical range, (4) detection limit, and (5) analytical specificity are of prime importance. The sections in this chapter on method

evaluation and comparison contain outlines of these concepts and of their assessment. The estimated performance parameters for a method are related to quality goals that ensure acceptable medical use of the test results (see section, "Analytical Goals"). From a practical point of view, the "ruggedness" of the method in routine use is of importance.

When a new clinical analyzer is included in the overall evaluation process, various instrumental parameters also require evaluation, including (1) pipetting precision, (2) specimen-to-specimen carryover, (3) reagent-to-reagent carryover, (4) detector imprecision, (5) time to first reportable result, (6) on-board reagent stability, (7) overall throughput, (8) mean time between instrument failures, and (9) mean time to repair. Information on most of these parameters should be available from the instrument manufacturer.

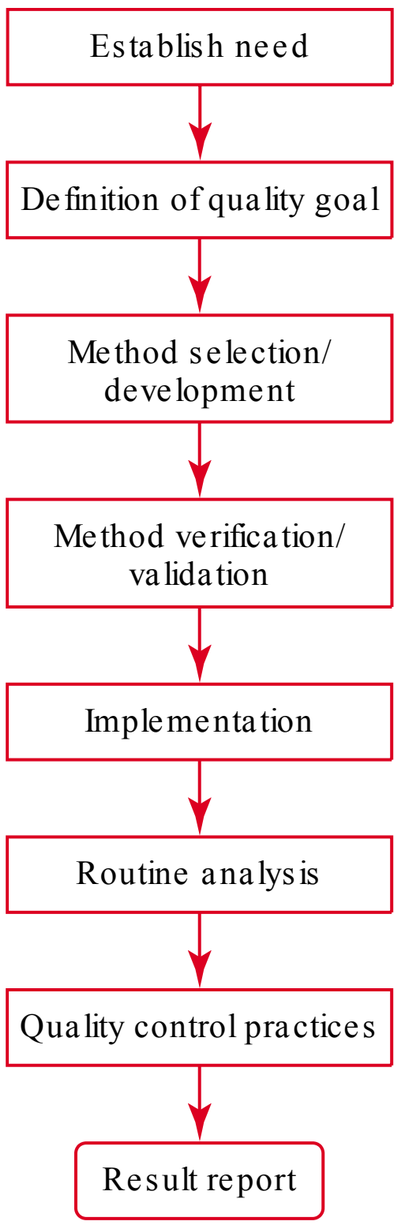

Figure 2-1 Flow diagram that illustrates the process of introducing a new method into routine use. The diagram highlights the key steps of method selection, method evaluation, and quality control.

BOX 2-1 Abbreviations

CI	Confidence interval
CV	Coefficient of variation (=SD/x, where x is the concentration)
CV%	= CV100%
CV_A	Analytical coefficient of variation
CV_{RB}	Random bias coefficient of variation
ISO	International Organization for Standardization
OLR	Ordinary least-squares regression analysis
SD	Standard deviation
SEM	Standard error of the mean = SD/√N)
SD_A	Analytical standard deviation
SD_{RB}	Random bias standard deviation
x_m	Mean

Other (Practical) Criteria

Various categories of candidate methods may be considered. New methods described in the scientific literature may require "in-house" development. Commercial kit methods, on the other hand, are ready for implementation in the laboratory, often in a "closed" analytical system on a dedicated instrument. When prospective methods are reviewed, attention should be given to the following:

1. The principle of the assay, with original references
2. The detailed protocol for performing the test
3. The composition of reagents and reference materials, the quantities provided, and their storage requirements (e.g., space, temperature, light, and humidity restrictions) applicable both before and after the original containers are opened
4. The stability of reagents and reference materials (e.g., their shelf life)
5. Technologist time and required skills
6. Possible hazards and appropriate safety precautions according to relevant guidelines and legislation
7. The type, quantity, and disposal of waste generated
8. Specimen requirements such as conditions for collection, specimen volume requirements, the necessity for anticoagulants and preservatives, and necessary storage condition
9. The reference interval of the method, including information on how it was derived, typical values obtained in health and disease, and the necessity of determining a reference interval for one's own institution (see Chapter 5 for details on how to generate a reference interval)
10. Instrumental requirements and limitations
11. Cost-effectiveness
12. Computer platforms and interfacing to the laboratory information system
13. The availability of technical support, supplies, and service

Other considerations should be taken into account. For example, is there sufficient space, electrical power, cooling, and plumbing for a new instrument? Does the projected workload match with the capacity of a new instrument? Is the test repertoire of a new instrument sufficient? What is the method of calibration, and what is its frequency? Is staffing of the laboratory sufficient or is training required? What are the appropriate choices of quality control procedures and proficiency testing? What is the estimated cost of performing an assay using the proposed method, including the costs of calibrators, quality control specimens, and technologists' time?

Basic Statistics

In this section, fundamental statistical concepts and techniques are introduced in the context of typical analytical investigations. The basic concepts of populations, samples, parameters,

statistics, and probability distributions are defined and illustrated. Two important probability distributions, Gaussian and Student t, are introduced and discussed.

Frequency Distribution

A graphical device for displaying a large set of data is the *frequency distribution*, also called a histogram. Figure 2-2 shows a frequency distribution displaying the results of serum γ-glutamyltransferase (GGT) measurements of 100 apparently healthy 20- to 29-year-old men. The frequency distribution is constructed by dividing the measurement scale into cells of equal width, counting the number, n_i, of values that fall within each cell, and drawing a rectangle above each cell whose area (and height, because all cell widths are equal) is proportional to n_i. In this example, the selected cells were 5 to 9, 10 to 14, 15 to 19, 20 to 24, 25 to 29, and so on, with 60 to 64 being the last cell. The ordinate axis of the frequency distribution gives the number of values falling within each cell. When this number is divided by the total number of values in the data set, the relative frequency in each cell is obtained.

Often, the position of a subject's value within a distribution of values is useful medically. The nonparametric approach is used to determine directly the percentile of a given subject. When N subjects have been ranked according to their values, the n-percentile, $Perc_n$, may be estimated as the value of the (N[n/100] + 0.5) ordered observation. In cases of a noninteger value, interpolation is carried out between neighboring values.

Population and Sample

The purpose of analytical work is to obtain information and draw conclusions about characteristics of one or more populations of values. In the GGT example, the interest involves the location and spread of the population of GGT values for 20- to 29-year-old healthy men. Thus a working definition of a **population** is the complete set of all observations that might occur as a result of performing a particular procedure according to specified conditions.

Most populations of interest in clinical chemistry are infinite in size and so are impossible to study in their entirety. Usually a subgroup of observations is taken from the population as a basis on which conclusions can be formed about the population characteristics. The group of observations that has actually been selected from the population is called a sample. For example, the 100 GGT values represent a sample from a respective population. However, a sample is used to study the characteristics of a population only if it has been properly selected. For instance, if the analyst is interested in the population of GGT values over various lots of materials and some time period, the sample must be selected to be representative of these factors as well as of the age, sex, and health factors. Consequently, exact specification of the population(s) of interest is necessary before a plan can be designed for obtaining the sample(s).

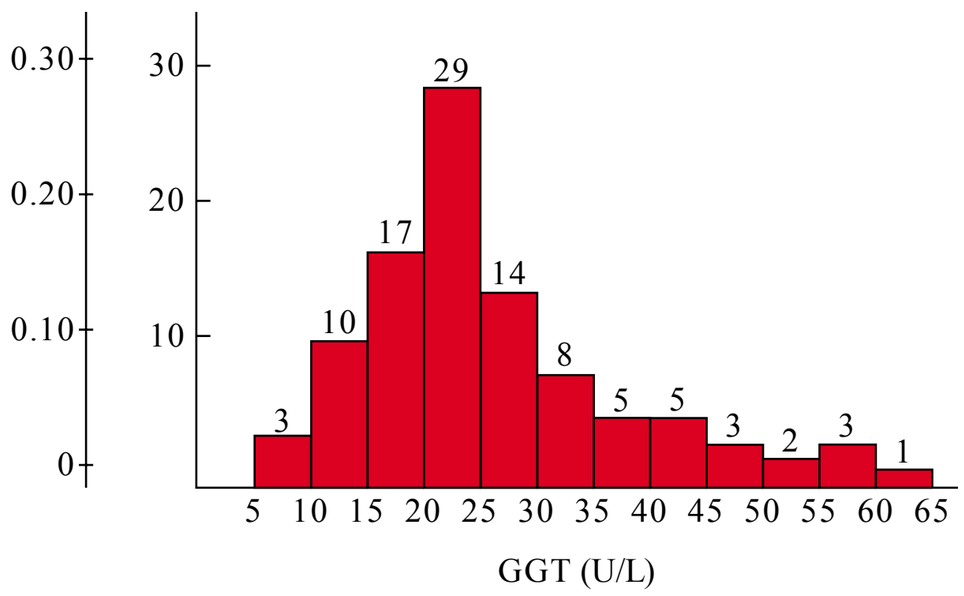

Figure 2-2 Frequency distribution of 100 γ-GGT values.

Probability and Probability Distributions

Consider again the frequency distribution in Figure 2-2. In addition to the general location and spread of the GGT determinations, other useful information is easily extracted from this frequency distribution. For instance, 96% (96 of 100) of the determinations are less than 55 U/L, and 91% (91 of 100) are greater than or equal to 10 but less than 50 U/L. Because the cell interval is 5 U/L in this example, statements like these can be made only to the nearest 5 U/L. A larger sample would allow a smaller cell interval and more refined statements. For a sufficiently large sample, the cell interval is made so small that the frequency distribution is approximated by a continuous, smooth curve like that shown in Figure 2-3. In fact, if the sample is large enough, we can consider this a close representation of the true population *frequency distribution*. In general, the functional form of the population frequency distribution curve of a variable x is denoted by f(x).

The population frequency distribution allows us to make probability statements about the GGT of a randomly selected member of the population of healthy 20- to 29-year-old men. For example, the probability $Pr(x > x_a)$ that the GGT value x of a randomly selected 20- to 29-year-old healthy man is greater than some particular value x_a is equal to the area under the population frequency distribution to the right of x_a. If $x_a = 58$, then from Figure 2-3, $Pr(x > 58) = 0.05$. Similarly, the probability $Pr(x_a < x < x_b)$ that x is greater than x_a but less than x_b is equal to the area under the population frequency distribution between x_a and x_b. For example, if $x_a = 9$ and $x_b = 58$, then from Figure 2-3, $Pr(9 < x < 58) = 0.90$. Because the population frequency distribution provides all information about the probabilities of a randomly selected member of the population, it is called the probability distribution *of* the population. Although the true probability distribution is never exactly

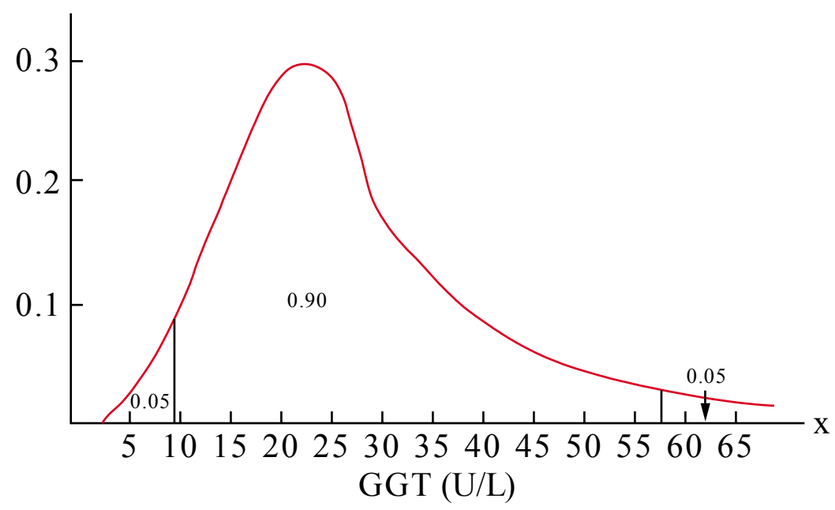

Figure 2-3 Population frequency distribution of γ-GGT values.

known in practice, it is approximated with a large sample of observations.

Parameters: Descriptive Measures of a Population

Any population of values can be described by measures of its characteristics. A parameter is a constant that describes some particular characteristic of a population. Although most populations of interest in analytical work are infinite in size, for the following definitions we shall consider the population to be of finite size N, where N is very large.

One important characteristic of a population is its central location. The parameter most commonly used to describe the central location of a population of N values is the population mean (μ):

$$\mu = \frac{\sum x_i}{N}$$

An alternative parameter that indicates the central tendency of a population is the median, which is defined as the 50th percentile, $Perc_{50}$.

Another important characteristic of a population is the dispersion of values about the population mean. A parameter very useful in describing this dispersion of a population of N values is the population variance σ^2 (sigma squared):

$$\sigma^2 = \frac{\sum (x_i - \mu)^2}{N}$$

The population standard deviation σ, the positive square root of the population variance, is a parameter frequently used to describe the population dispersion in the same units (e.g., mg/dL) as the population values.

Statistics: Descriptive Measures of the Sample

As was noted earlier, the clinical laboratorian usually has available only a few observations from the population of interest. A statistic is a value calculated from the observations in a sample to describe a particular characteristic of that sample. The sample mean x_m is the arithmetic average of a sample, which is an estimate of μ. Likewise, the sample standard deviation (SD) is an estimate of σ, and the coefficient of variation (CV) is the ratio of the SD to the mean multiplied by 100%. The equations used to calculate x_m, SD, and CV, respectively, are as follows:

$$x_m = \frac{\sum x_i}{N}$$

$$SD = \sqrt{\frac{\sum (x_i - x_m)^2}{N-1}} = \sqrt{\frac{\sum x_i^2 - \frac{(\sum x_i)^2}{N}}{N-1}}$$

$$CV = \frac{SD}{x_m} \times 100\%$$

where x_i is an individual measurement, and N is the number of sample measurements.

Random Sampling

A random selection from a population is one in which each member of the population has an equal chance of being selected. A random sample is one in which each member of the sample is considered to be a random selection from the population of interest. Although much of statistical analysis and interpretation depends on the assumption of a random sample from some fixed population, actual data collection often does not satisfy this assumption. In particular, for sequentially generated data, it is often true that observations adjacent to each other tend to be more alike than observations separated in time. A sample of such observations cannot be considered a sample of random selections from a fixed population. Fortunately, precautions can usually be taken in the design of an investigation to validate approximately the random sampling assumption.

The Gaussian Probability Distribution

The Gaussian probability distribution, which is illustrated in Figure 2-4, is of fundamental importance in statistics for several reasons. As was mentioned earlier, a particular analytical value x will not usually be equal to the true value μ of the specimen being measured. Rather, associated with this particular value x will be a particular measurement error, $\varepsilon = x - \mu$, which is the result of many contributing sources of error. These measurement errors tend to follow a probability distribution like that shown in Figure 2-4, where the errors are symmetrically distributed, with smaller errors occurring more frequently than larger ones, and with an expected value of 0. This important fact is known as the central limit *effect for* distribution *of* errors: If a measurement error ε is the sum of many independent sources of error ($\varepsilon_1, \varepsilon_2, \ldots, \varepsilon_k$), several of which are major contributors, the probability distribution of the measurement error ε will tend to be Gaussian as the number of sources of error becomes large.

Another reason for the importance of the Gaussian probability distribution is that many statistical procedures are based on the assumption of a Gaussian distribution of values; this approach is commonly referred to as parametric. Furthermore, these procedures usually are not seriously invalidated by departures from this assumption. Finally, the magnitude

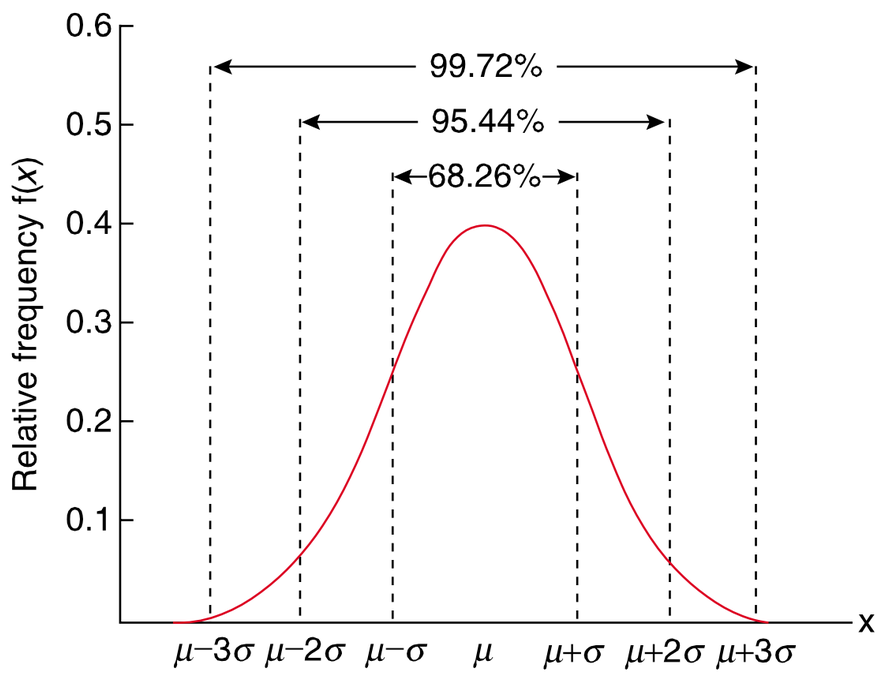

Figure 2-4 The Gaussian probability distribution.

of the uncertainty associated with sample statistics can be ascertained on the basis of the fact that many sample statistics computed from large samples have a Gaussian probability distribution.

The Gaussian probability distribution is completely characterized by its mean μ and variance σ^2. The notation $N(\mu,\sigma^2)$ is often used for the distribution of a variable that is Gaussian with mean μ and variance σ^2. Probability statements about a variable x that follows an $N(\mu,\sigma^2)$ distribution are usually made by considering the variable z:

$$z = \frac{x - \mu}{\sigma}$$

which is called the standard Gaussian variable. The variable z has a Gaussian probability distribution with $\mu = 0$ and $\sigma^2 = 1$, that is, z is N(0,1). The probability that x is within 2σ of μ [i.e., $Pr(|x - \mu| < 2\sigma) =$] is 0.9544. Most computer spreadsheet programs can be used to calculate probabilities for all values of z.

Student t Probability Distribution

To determine probabilities associated with a Gaussian distribution, it is necessary to know the population standard deviation σ. In actual practice, σ is often unknown, so we cannot calculate z. However, if a random sample is taken from the Gaussian population, it is possible to calculate the sample SD, substitute SD for σ, and compute the value t:

$$t = \frac{x - \mu}{SD}$$

Under these conditions, the variable t has a probability distribution called the Student t distribution. The t distribution is really a family of distributions depending on the degrees of freedom (ν_n) for the sample standard deviation. Several t distributions from this family are shown in Figure 2-5. When the size of the sample and the degrees of freedom for SD are infinite, there is no uncertainty in SD, and so the t distribution is identical to the standard Gaussian distribution. However, when the sample size is small, the uncertainty in SD causes the t distribution to have greater dispersion and heavier tails than the standard Gaussian distribution, as illustrated in Figure 2-5. Most computer spreadsheet programs can calculate probabilities for all values of t, given the degrees of freedom for SD.

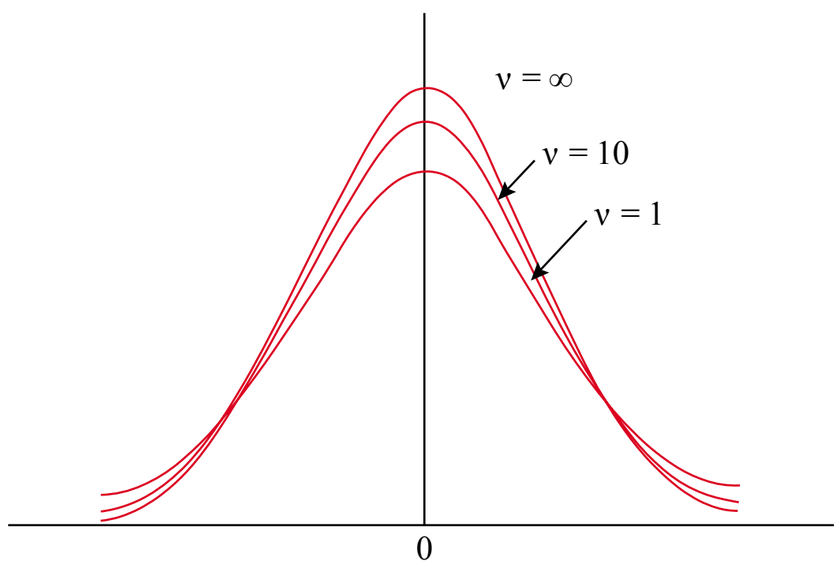

Figure 2-5 The t probability distribution for ν = 1, 10, and ∞.

Suppose that the distribution of fasting serum glucose values in healthy men is known to be Gaussian and to have a mean of 90 mg/dL. Suppose also that σ (SD) is unknown and that a random sample of size 20 from the healthy men yielded a sample SD = 10.0 mg/dL. Then, to find the probability Pr(x > 105), we proceed as follows:

1. $t_a = (x_a - \mu)/SD = (105 - 90)/10 = 1.5$
2. $Pr(t > t_a) = Pr(t > 1.5) = 0.08$, approximately, from a t distribution with 19 degrees of freedom
3. $Pr(x > 105) = 0.08$

The Student t distribution is commonly used in significance tests, such as the comparison of sample means or testing of whether a regression slope differs significantly from 1. Descriptions of these tests are found in statistics textbooks and in the Tietz Textbook of Clinical Chemistry, 3rd edition, pages 274 to 287.

Basic Concepts in Relation to Analytical Methods

This section defines the basic concepts used in this chapter: (1) calibration, (2) trueness (accuracy), (3) precision, (4) linearity, (5) limit of detection, and (6) others.

Calibration

The **calibration** function is the relation between instrument signal (y) and concentration of analyte (x), i.e.,

$$y = f(x)$$

The inverse of this function, also called the measuring function, yields the concentration from response:

$$x = f^{1}(y)$$

This relationship is established by measurement of samples with known amounts (the quantity) of analyte (calibrators). One may distinguish between solutions of pure chemical standards and samples with known amounts of analyte present in the typical **matrix** that is to be measured (e.g., human serum). The first situation applies typically to a **reference measurement procedure,** which is not influenced by matrix effects, and the second case corresponds typically to a field method that often is influenced by matrix components and so preferably is calibrated using the relevant matrix. Calibration functions may be linear or curved and in the case of immunoassays often of a special form (e.g., modeled by the four-parameter logistic curve; see Chapter 15). In the case of curved calibration functions, nonlinear regression analysis is applied to estimate the relationship, or a logit transformation is performed to produce a linear form. An alternative, model-free approach is to estimate a smoothed spline curve, which often is performed for immunoassays. The only requirement is that there should be a monotonic relationship between signal and analyte concentration over the analytical measurement range. Otherwise the possibility of error occurs (e.g., the hook effect in noncompetitive immunoassays), caused by a decreasing signal response at very high concentrations.

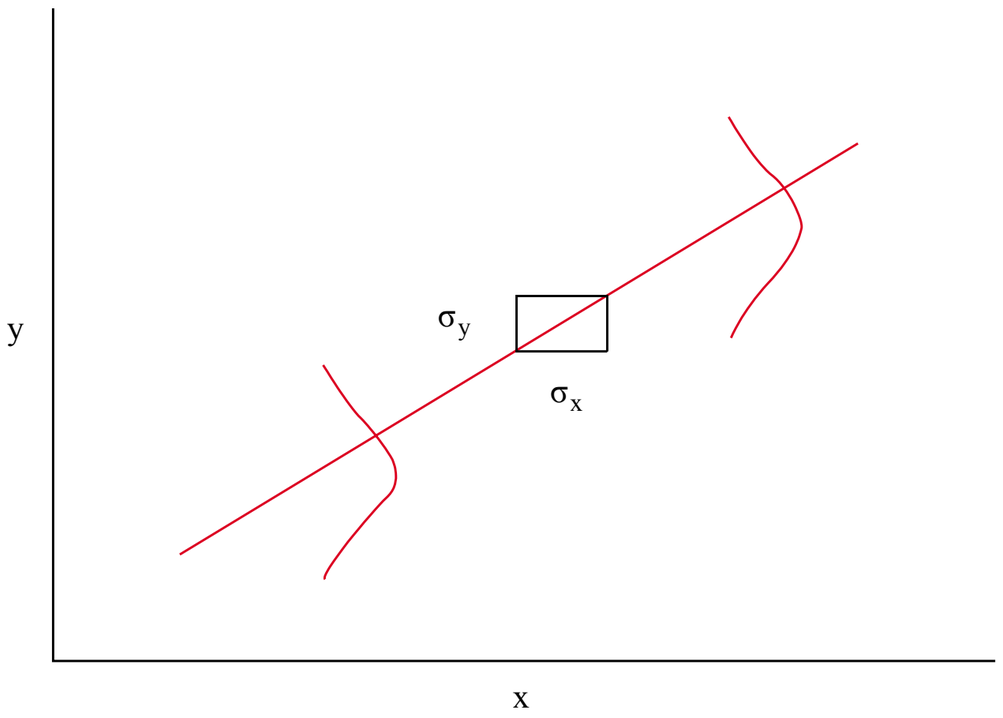

Figure 2-6 Relation between concentration (x) and signal response (y) for a linear calibration curve. The dispersion in signal response (σ_y) is projected onto the x-axis, giving rise to assay imprecision (σ_x).

The precision of the analytical method depends on the stability of the instrument response for a given amount of analyte. In principle, a random dispersion of instrument signal at a given concentration transforms into dispersion on the measurement scale as schematically shown (Figure 2-6). The detailed statistical aspects of calibration are rather complex, but some approximate relations are reviewed here. If the calibration function is linear, and the imprecision of the signal response is the same over the analytical measurement range, the analytical standard deviation (SD_A) of the method tends to be constant over the analytical measurement range (see Figure 2-6). If the imprecision increases proportionally to the signal response level, the analytical SD of the method tends to increase proportionally to the concentration level (x), which means that the relative imprecision, CV, is constant over the analytical measurement range—supposing that the intercept of the calibration line is zero.

In modern, automated clinical chemistry instruments/systems, the relation between analyte concentration and signal is often very stable, so that calibration is necessary infrequently (e.g., at intervals of several months). However, in traditional chromatographic analysis (e.g., high-performance liquid chromatography [HPLC]), it is customary to calibrate each analytical series (run), which means that calibration is carried out daily.

Trueness and Accuracy

Trueness of measurement is defined as closeness of agreement between the average value obtained from a large series of results of measurements and a true value.[5] The difference between the average value (strictly, the mathematical expectation) and the true value is the **bias,** which is expressed numerically and so is inversely related to trueness. Trueness in itself is a qualitative term that is expressed as, for example, low, medium, or high. From a theoretical point of view, the exact true value is not available, and instead an "accepted reference value" is considered, which is the "true" value that is determined in practice.[5] Trueness also is evaluated by comparison of measurements by a given (field) method and a reference method. Such an evaluation may be carried out by parallel measurements of a set of patient samples or by measurements of reference materials (see traceability and uncertainty). The ISO has introduced the trueness expression as a replacement for the term "accuracy," which now has gained a slightly different meaning. Accuracy is the closeness of the agreement between the result of a measurement and a true concentration of the analyte. Accuracy is thus influenced by both bias and imprecision and in this way reflects the total error. Accuracy, which in itself is a qualitative term, is inversely related to the "uncertainty" of measurement, which is quantified as described later (Table 2-1).

In relation to trueness, the concepts (1) recovery, (2) drift, and (3) carryover may also be considered. Recovery is the fraction or percentage increase of concentration that is measured in relation to the amount added. Recovery experiments are typically carried out in the field of drug analysis. One may distinguish between extraction recovery, which often is interpreted as the fraction of compound that is carried through an extraction process, and the recovery measured by the entire analytical procedure, in which the addition of an internal standard compensates for losses in the extraction procedure. A recovery close to 100% is a prerequisite for a high degree of trueness, but it does not ensure unbiased results because possible nonspecificity against matrix components is not detected in a recovery experiment. Drift is caused by instrument or reagent instability over time, so that calibration becomes biased. Assay carryover also must be close to zero to ensure unbiased results.

TABLE 2-1 An Overview of Qualitative Terms and Quantitative Measures Related to Method Performance

Qualitative Concept	Quantitative Measure
Trueness	**Bias**
Closeness of agreement of mean value with "true value"	A measure of the systematic error
Precision	**Imprecision (SD)**
Repeatability (within run)	A measure of the dispersion of random errors
Intermediate precision (long term)	
Reproducibility (interlaboratory)	
Accuracy	**Error of Measurement**
Closeness of agreement of a single measurement with "true value"	Comprises both random and systematic influences

Precision

Precision has been defined as the closeness of agreement between independent results of measurements obtained under stipulated conditions.[5] The degree of precision is usually expressed on the basis of statistical measures of imprecision, such as SD or CV, which thus are inversely related to precision. Imprecision of measurements is solely related to the **random error** of measurements and has no relation to the trueness of measurements.

Precision is specified as follows[5]:

Repeatability: closeness of agreement between results of successive measurements carried out under the same conditions (i.e., corresponding to within-run precision).

Reproducibility: closeness of agreement between results of measurements performed under changed conditions of measurements (e.g., time, operators, calibrators, reagent lots). Two specifications of reproducibility are often used: total or between-run precision in the laboratory, often termed intermediate precision, and interlaboratory precision (e.g., as observed in external quality assessment schemes [EQAS]) (see Table 2-1).

The total standard deviation (σ_T) may be split into within-run and between-run components by using the principle of analysis of variance components (variance is the squared SD):

$$\sigma_T^2 = \sigma_{\text{Within-run}}^2 + \sigma_{\text{Between-run}}^2$$

In laboratory studies of analytical variation, it is estimates of imprecision that are obtained. The more observations, the more certain are the estimates. Commonly the number 20 is given as a reasonable number of observations. To estimate both within-run imprecision and total imprecision, a common approach is to measure duplicate control samples in a series of runs. For example, one may measure a control in duplicate for more than 20 runs, in which case 20 observations are present with respect to both components. Here one may notice that the dispersion of the means (x_m) of the duplicates is given as

$$\sigma_{x_m}^2 = \sigma_{\text{Within-run}}^2/2 + \sigma_{\text{Between-run}}^2$$

From the 20 sets of duplicates, we may derive the within-run SD using the shortcut formula:

$$SD_{\text{Within-run}}^2 = \sum d_i^2/(2 \times 20)$$

where d_i refers to the difference between the ith set of duplicates. When estimating SDs, the concept degrees of freedom (df) is used. In a simple situation, the number of degrees of freedom equals N − 1. For N duplicates, the number of degrees of freedom is N(2 − 1) = N. Thus both variance components are derived in this way. The advantage of this approach is that the within-run estimate is based on several runs, so that an average estimate is obtained rather than only an estimate for one particular run, if all 20 observations had been obtained in the same run. The described approach is a simple example of a variance component analysis.

There is nothing definitive about the selected number of 20. Generally, the estimate of the imprecision improves as more observations become available. In Table 2-2, factors corresponding to the 95% confidence intervals (CIs) are given as a function of sample size for simple SD estimation according to the X^2 distribution. These factors provide guidance on the validity of estimated SDs for precision. Suppose we have estimated the imprecision to an SD of 5.0 on the basis of N = 20 observations. From Table 2-2, we get the 2.5 and 97.5 percentiles:

$$5.0 \times 0.76 < \sigma < 5.0 \times 1.46$$

TABLE 2-2 Factors Corresponding to 95% CI Limits for an SD (the number of degrees of freedom is N − 1)

	95% CI	
N	Lower	Upper
20	0.760	1.460
30	0.797	1.346
40	0.819	1.283
50	0.835	1.243
60	0.848	1.217
70	0.857	1.198
80	0.865	1.183
90	0.872	1.171
100	0.878	1.161
150	0.898	1.128
200	0.911	1.109
250	0.919	1.096
300	0.926	1.087

Precision Profile

Precision often depends on the concentration of analyte being considered. A presentation of precision as a function of analyte concentration is the precision profile, which usually is plotted in terms of SD or CV as a function of analyte concentration (Figure 2-7, A-C). Some typical examples may be considered. First, the SD may be constant and independent of the concentration, as it often is for analytes with a limited range of values (e.g., electrolytes). When the SD is constant, the CV varies inversely with the concentration and is high in the lower part of the range and low in the high part of the range. For analytes with extended ranges (e.g., hormones), the SD frequently increases as the analyte concentration increases. If a proportional relationship exists, the CV is constant. This is may often apply approximately over a large part of the analytical measurement range. Actually, this relationship is anticipated for measurement error arising because of imprecise volume dispensing. Often a more complex relationship exists. Not infrequently, the SD is relatively constant in the low range, so that the CV increases in the area approaching the detection limit. At intermediate concentrations, the CV may be relatively constant and perhaps may decline somewhat at increasing concentrations.

Linearity

Linearity refers to the relationship between measured and expected values over the range of analytical measurements. Linearity may be considered in relation to actual or relative analyte concentrations. In the latter case, a dilution series of a sample may be studied. This is is often carried out for immunoassays, in which case it is investigated to find out whether the measured concentration declines as expected according to the dilution factor. Dilution is usually carried out with the appropriate sample matrix (e.g., human serum [individual or pooled serum]).

Evaluation of linearity may be carried out in various ways. A simple, but subjective, approach is to visually assess whether

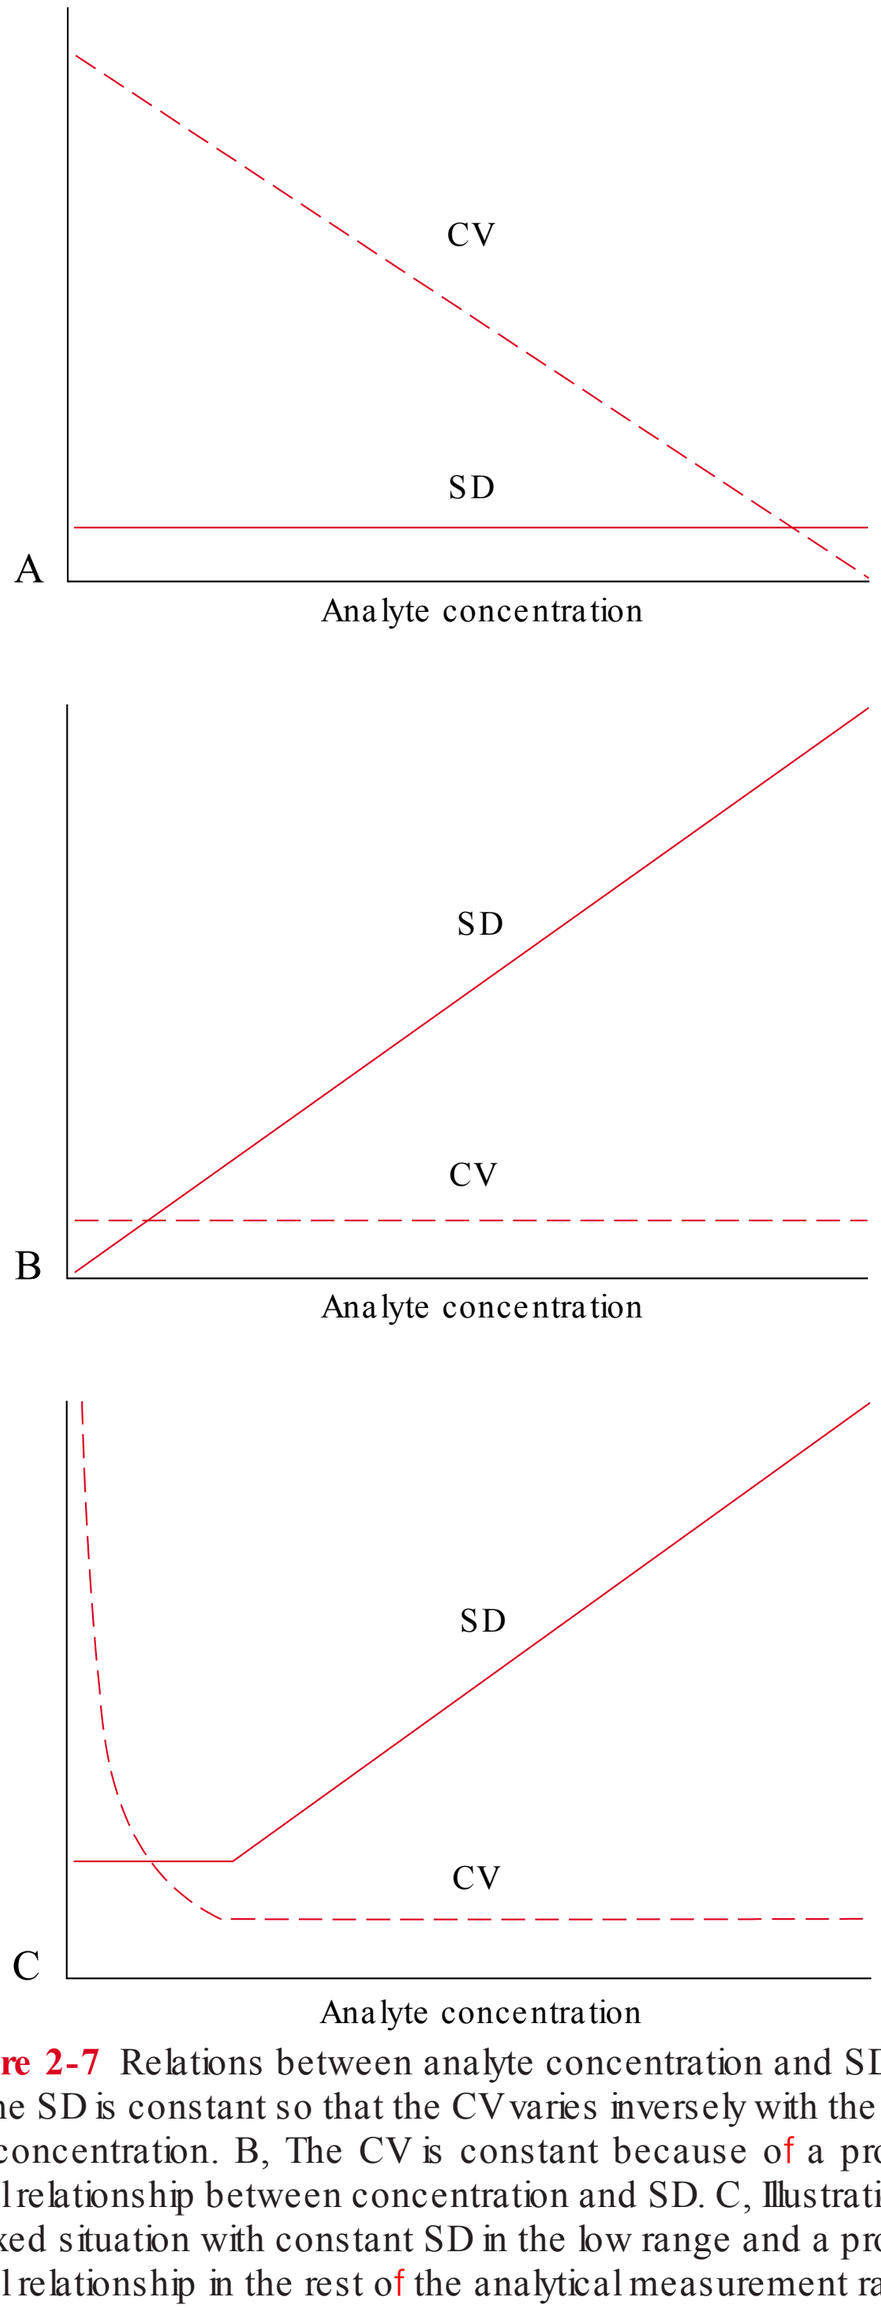

Figure 2-7 Relations between analyte concentration and SD/CV. A, The SD is constant so that the CV varies inversely with the analyte concentration. B, The CV is constant because of a proportional relationship between concentration and SD. C, Illustration of a mixed situation with constant SD in the low range and a proportional relationship in the rest of the analytical measurement range.

the relationship between measured and expected concentrations is linear or not. A more formal evaluation may be carried out on the basis of statistical tests. Various principles may be applied here. When repeated measurements are available at each concentration, the random variation between measurements and the variation around an estimated regression line may be evaluated statistically (by an F-test). T is approach has been criticized because it only relates the magnitude of random and **systematic error** without taking the absolute deviations from linearity into account. When significant nonlinearity is found, it may be useful to explore nonlinear alternatives to the linear regression line (i.e., polynomials of higher degrees).[2]

Another commonly applied approach for detecting nonlinearity is to assess the residuals of an estimated regression line and test for whether positive and negative deviations are randomly distributed. T is is carried out by a runs test (see "Regression Analysis" section). An additional consideration for evaluating dilution curves is whether or not an estimated regression line passes through zero. Furthermore, testing for linearity is related to assessment of trueness over the analytical measurement range. T e presence of linearity is a prerequisite for a high degree of trueness. A CLSI guideline suggests procedure(s) for assessment of linearity.[2]

Analytical Measurement Range and Limits of Quantif cation

T e analytical measurement range (**measuring interval**, reportable range) is the analyte concentration range over which measurements are within declared tolerances for imprecision and bias of the method. Taking drug assays as an example, requirements for a CV% of less than 15% and a bias of less than 15% are common. T e measurement range then extends from the lowest concentration (lower limit of quantification [LloQ]) to the highest concentration (upper limit of quantification [UloQ]) for which these performance specifications are fulfilled.

T e LloQ is medically important for many analytes. T yroid-stimulating hormone (TSH) is a good example. As assay methods improved, lowering the LloQ, low TSH results could be distinguished from the lower limit of the reference interval, making the test useful for the diagnosis of hyperthyroidism.

T e **limit of detection** (LoD) is another characteristic of an assay. T e LoD may be defined as the lowest value that significantly exceeds the measurements of a blank sample. T us the limit has been estimated on the basis of repeated measurements of a blank sample and has been reported as the mean plus 2 or 3 SDs of the blank measurements. In the interval from LoD up to LloQ, one should report a result as "detected" but not provide a quantitative result. More complicated approaches for estimation of the LoD have been suggested.[12]

Analytical Sensitivity

T e detection limit of a method should not be confused with its so-called analytical sensitivity. **Analytical sensitivity** is the ability of an analytical method to assess small variations in the concentration of analyte. T is is often expressed as the slope of the calibration curve. However, in addition to the slope of the calibration function, the random variation of the calibration function should be taken into account. In fact, analytical sensitivity depends on the ratio between the SD of the calibration function and the slope. As was mentioned previously, the smaller the random variation of the instrument response and the steeper the slope, the greater is the ability to distinguish small differences in analyte concentration. T us, analytical sensitivity depends on the precision of the method.

Analytical Specificity and Interference

Analytical specificity is the ability of an assay procedure to determine specifically the concentration of the target analyte in the presence of potentially interfering substances or factors in the sample matrix (e.g., hyperlipemia, hemolysis, bilirubin, anticoagulants, antibodies, degradation products). Also, in the context of a drug assay, specificity is of relevance in relation to drug metabolites. Interference from hyperlipemia, hemolysis, and bilirubin is generally concentration dependent and is often quantified as a function of the concentration of the interfering compound. In relation to immunoassays, interference from proteins (usually heterophilic antibodies) should be recognized.

Analytical Goals

Setting goals for analytical quality is based on various principles, and a hierarchy has been suggested on the basis of a consensus conference on the subject[14] (Table 2-3). The top level of the hierarchy specifies goals on the basis of clinical outcome in specific clinical settings, which is a logical principle.

However, analytical goals related to biological variation have attracted considerable interest.[7] Originally, focus was on imprecision, and it was suggested that the analytical SD (σ_A) should be less than half the intraindividual biological variation, $\sigma_{Within\text{-}B}$. The rationale for this relation is the principle of adding variances. If a subject is undergoing monitoring of an analyte, random variation from measurement to measurement consists of both analytical and biological components of variation. The total SD for the random variation during monitoring then is determined by the relation

$$\sigma_T^2 = \sigma_{Within\text{-}B}^2 + \sigma_A^2$$

where the biological component includes the preanalytical variation. If σ_A is equal to or less than half the $\sigma_{Within\text{-}B}$ value, σ_T exceeds $\sigma_{Within\text{-}B}$ by less than 12%. Thus, analytical imprecision only adds limited random noise in a monitoring situation.

In addition to imprecision, goals for bias should be considered. The allowable bias is related to the width of the reference interval, which is determined by combined within- and between-subject biological variations, in addition to the analytical variation. On the basis of considerations concerning the included percentage in an interval in the presence of analytical bias, it has been suggested that

$$\text{Bias} < 0.25\left(\sigma_{Within\text{-}B}^2 + \sigma_{Between\text{-}B}^2\right)^{0.5}$$

where $\sigma_{Between\text{-}B}$ is the between-subject biological SD component.

Another principle that has been used is relating assay goals to the limits set by professional bodies (e.g., the bias goal of 3% for serum cholesterol [originally 5%] set by the National Cholesterol Education Program). Ricos and colleagues have published a comprehensive listing of data on biological variation along with a database that is available at www.westgard.com/guest17.htm (accessed July 6, 2013).

	B. Data from current publications on methodology

Qualitative Methods

Qualitative methods, which currently are gaining in use in the form of point-of-care testing (POCT), are designed to distinguish between results below and above a predefined cutoff value (see Chapter 17). Notice that the cutoff point should not be confused with the detection limit. These tests are assessed primarily on the basis of their ability to correctly classify results in relation to the cutoff value.

The probability of classifying a result as positive (exceeding the cutoff) is called clinical sensitivity (see Chapter 3). Classifying a result as negative (below the cutoff) is termed clinical *specificity*. Determination of clinical sensitivity and specificity is based on comparison of test results with a "gold" standard. The gold standard may be an independent test that measures the same analyte, but it may also be a clinical diagnosis determined by definitive clinical methods (e.g., radiographic testing, follow-up, outcomes analysis). Clinical sensitivity and specificity may be given as a fraction or as a percentage after multiplication by 100. Standard errors of estimates are derived from the binomial distribution.

One approach for determining the recorded performance of a test in terms of clinical sensitivity and specificity is to determine the true concentration of analyte using an independent reference method. The closer the concentration is to the cutoff point, the larger are the expected error frequencies. Actually the cutoff point is defined in such a way that for samples having a true concentration exactly equal to the cutoff point, 50% of the results will be positive and 50% will be negative. Concentrations above and below the cutoff point at which repeated results are 95% positive or 95% negative, respectively, have been called the "95% interval" for the cutoff point for that method (notice that this is not a CI; Figure 2-8).[4] Thus in an evaluation of a qualitative test, it is important to specify in detail the composition of the samples. A CLSI guideline on the topic[4] recommends that samples should be prepared with

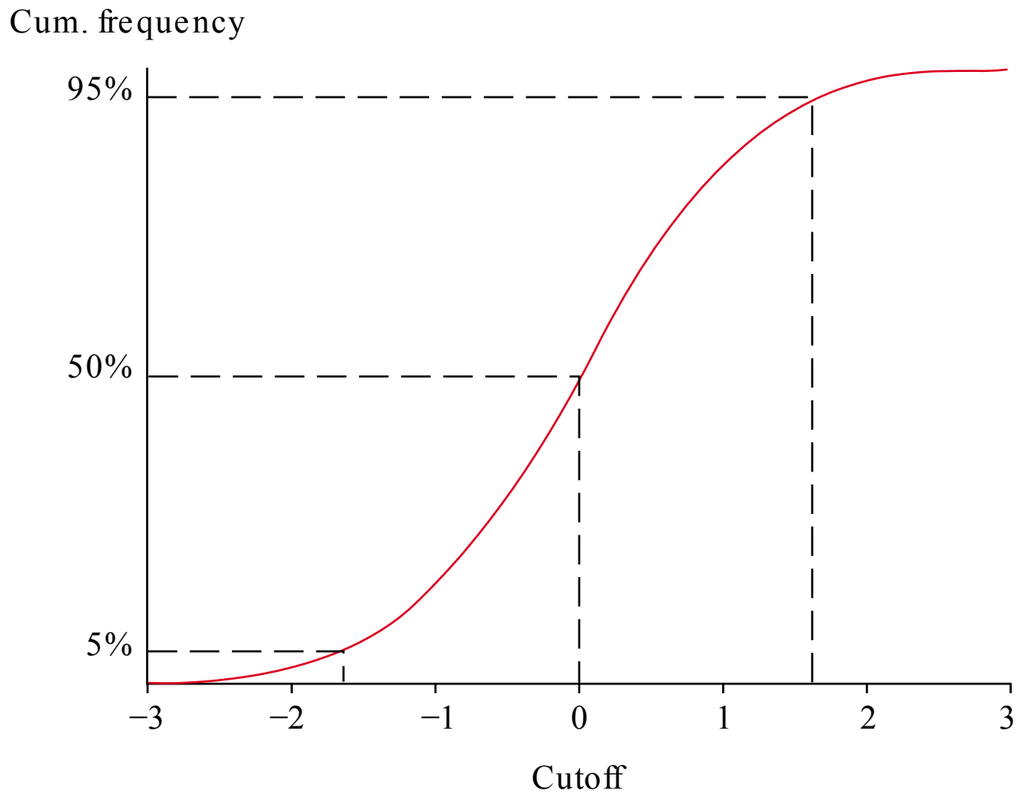

Figure 2-8 Cumulative frequency distribution of positive results. The x-axis indicates concentrations standardized to zero at the cutoff point (50% positive results) with unit SD.

a concentration equal to the cutoff point and with concentrations 20% below and above the cutoff point. Twenty replicate measurements are then carried out at each concentration, and the percentages of positive and negative results are recorded. On the basis of these measurements, it is possible to judge whether the 95% interval for the cutoff point is within or outside this interval. In relation to the suggested procedure, one should be aware of the limitations associated with repeated measurements of pools. Measurements of individual patient samples with the specified concentrations are preferable to get a true impression of possible matrix effects.

Method Comparison

Comparison of measurements by two methods is a frequent task in the laboratory. Preferably, parallel measurements of a set of patient samples should be undertaken. To prevent artificial matrix-induced differences, fresh patient samples are the optimal material. A nearly even distribution of values over the analytical measurement range is also preferable. In an ordinary laboratory, comparison of two field methods will be the most frequently occurring situation. Less commonly, comparison of a field method with a reference method is undertaken. When two field methods are compared, the focus is on observed differences. In this situation, it is not possible to establish that one set of measurements is the correct one and then consider deviation of the other set of measurements from the presumed correct concentrations. Rather, the question is whether the new method can replace the existing one without a general change in measurement concentration. To carry out a formal, objective analysis of the data, a statistical procedure with graphics display should be applied. Commonly used approaches include (1) a difference (bias) plot, which shows differences as a function of the average concentration of the measurements (Bland-Altman plot); and (2) a regression analysis. In the following, a general error model is presented, and statistical approaches are demonstrated.

Basic Error Model

The occurrence of measurement error is related to the performance characteristics of the assay. It is important to distinguish between (1) pure, random measurement errors, which are present in all measurement procedures, and (2) errors related to incorrect calibration and nonspecificity of the assay. A reference measurement procedure is associated only with pure, random error, whereas a routine method typically has some additional bias related to errors in calibration and limitations with regard to specificity. An erroneous calibration function gives rise to a systematic error, whereas nonspecificity yields an error that typically varies from sample to sample. The error related to nonspecificity thus has a random character, but in contrast to the pure measurement error, it is not reduced by repeated measurements of a sample. Although errors related to nonspecificity for a group of samples look like random errors, for the individual sample this type of error is a bias. Because this bias varies from sample to sample, it has been called a sample-related random bias. In the following section, various error components are incorporated into a formal error model.

Measured Value, Target Value, Modified Target Value, and True Value

Upon taking into account that an analytical method measures analyte concentrations with some random measurement error, one has to distinguish between the actual, measured value and the average result we would obtain if the given sample was measured an infinite number of times. If the method is a reference method without bias and nonspecificity, we have the following, simple relationship:

$$x_i = X_{Truei} + \varepsilon_i$$

where x_i represents the measured value, X_{Truei} is the average value for an infinite number of measurements, and ε_i is the deviation of the measured value from the average value. If we were to undertake repeated measurements, the average of ε_i would be zero and the SD would equal the analytical SD (σ_A) of the reference measurement procedure. Pure, random measurement error will usually be Gaussian distributed.

In the case of a routine method, the relationship between the measured value for a sample and the true value becomes more complicated:

$$x_i = X_{Truei} + \text{Cal-Bias} + \text{Random-Bias}_i + \varepsilon_i$$

The Cal-Bias term (calibration bias) is a systematic error related to the calibration of the method. This systematic error may be a constant for all measurements corresponding to an offset error, or it may be a function of the analyte concentration (e.g., corresponding to a slope deviation in the case of a linear calibration function). The Random-Bias_i term is a bias that is specific for a given sample in relation to nonspecificity of the method. It may arise because of codetermination of substances that vary in concentration from sample to sample. For example, a chromogenic creatinine method codetermines some other components with creatinine in serum. Finally, we have the random measurement error term ε_i.

If we performed an infinite number of measurements of a specific sample by the routine method, the random measurement error term ε_i would be zero. The cal-bias and the random-biasi, however, would be unchanged. Thus, the average value of an infinite number of measurements would equal the sum of the true value and these bias terms. This average value may be regarded as the target value ($X_{Targeti}$) of the given sample for the routine method. We have

$$X_{Targeti} = X_{Truei} + \text{Cal-Bias} + \text{Random-Bias}_i$$

As has been mentioned, calibration bias represents a systematic error component in relation to the true values measured by a reference measurement procedure. In the context of regression analysis, this systematic error corresponds to the intercept and the slope deviation from unity when a routine method is compared with a reference measurement procedure (outlined in detail later). It is convenient to introduce a modified target value expression ($X'_{Targeti}$) for the routine method to delineate this systematic calibration bias, so that

$$X'_{Targeti} = X_{Truei} + \text{Cal-Bias}$$

Thus, for a set of samples measured by a routine method, the $X_{Targeti}$ values are distributed around the respective $X'_{Targeti}$ values with an SD, which is called σ_{RB}.

If the method is a reference method without bias and nonspecificity, the target value and the modified target value equal the true value, that is,

$$X_{Targeti} = X'_{Targeti} = X_{Truei}$$

The error model is outlined in Figure 2-9.

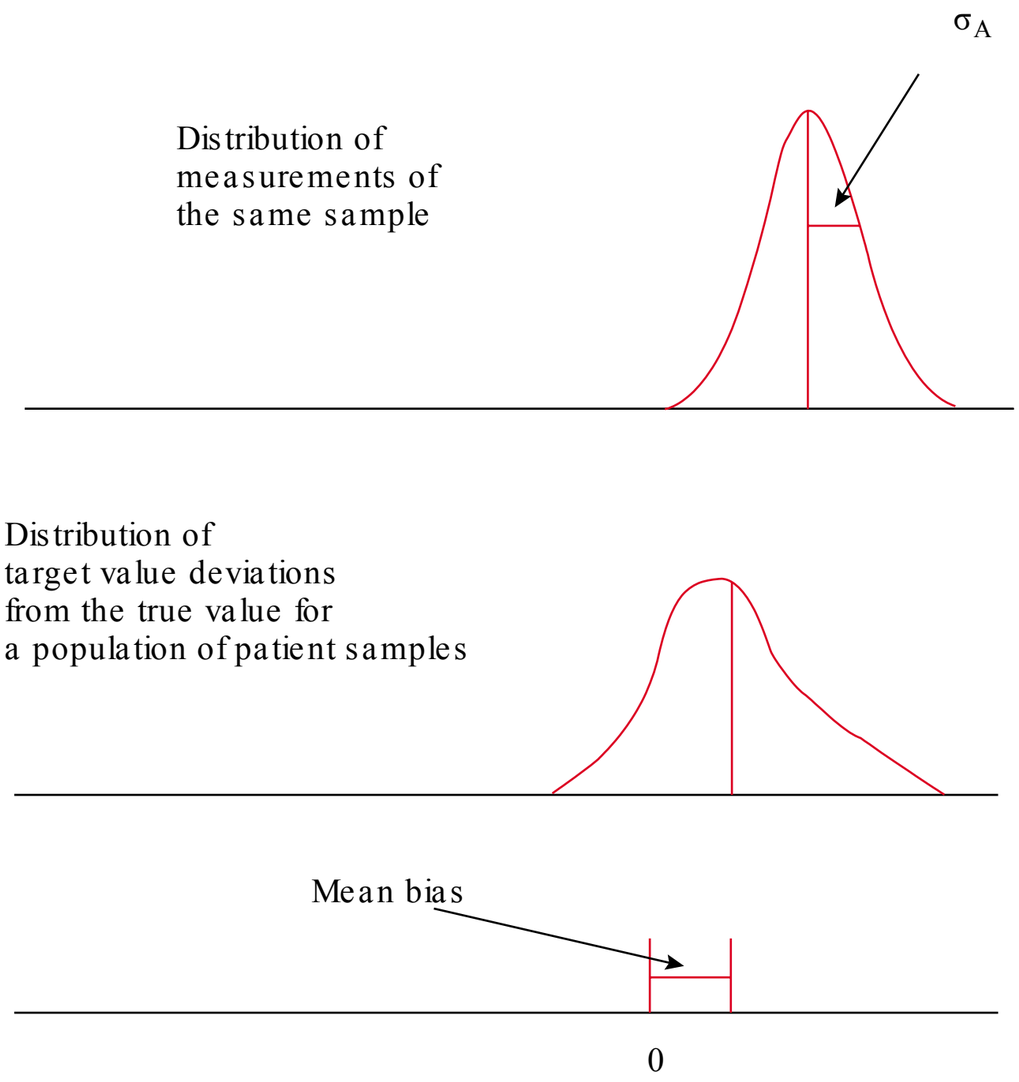

Figure 2-9 Outline of basic error model for measurements by a feld method. Upper part: The distribution of repeated measurements of the same sample, representing a Gaussian distribution around the target value (vertical line) of the sample with a dispersion corresponding to the analytical standard deviation, σ_A. Middle part: Schematic outline of the dispersion of target value deviations from the respective true values for a population of patient samples. A distribution of an arbitrary form is displayed. The vertical line indicates the mean of the distribution. Lower part: The distance from zero to the mean of the target value deviations from the true values represents the calibration bias (Mean bias = Cal-Bias) of the method.

Calibration Bias and Random Bias

For an individual measurement, the total error is the deviation of x_i from the true value, that is,

$$\text{Total error of } x_i = \text{Cal-Bias} + \text{Random-Bias}_i + \varepsilon_i$$

Estimation of the bias terms requires parallel measurements between the method in question and a reference method as outlined in detail later. With regard to calibration bias, one should be aware of the possibility of lot-to-lot variation in analytical kit sets. The manufacturer should provide documentation on this lot-to-lot variation because often it will not be possible for the individual laboratory to investigate a sufficient number of lots to assess this variation. Lot-to-lot variation will show up as a calibration bias that changes from lot to lot.

The previous exposition defines the total error in somewhat broader terms than is often seen. A traditional total error expression is

$$\text{Total error} = \text{Bias} + 2\ SD_A,$$

which often is interpreted as the calibration bias plus 2 SD_A. If a one-sided statistical perspective is taken, the expression is modified to Bias + 1.65 SD_A, indicating that 5% of results are located outside the limit. If a lower percentage is desired, the multiplication factor is increased accordingly, supposing a normal distribution. Interpreting the bias as identical with the calibration bias may lead to an underestimation of the total error.

Random bias related to sample-specific interferences may take several forms. It may be a regularly occurring additional random error component, perhaps of the same order of magnitude as the analytical error. In this context, it is natural to quantify the error in the form of an SD or coefficient of variation. The most straightforward procedure is to carry out a **method comparison** study based on a set of patient samples in which one of the methods is a reference method, as outlined later. For example, it has been found that for the Jaffe creatinine method, the random bias constituted 80% of the total random error. This is relatively high amount should be interpreted in light of the limited specificity of the Jaffe creatinine measurement principle.

Another form of sample-related random interference is more rarely occurring gross errors, which typically are seen in the context of immunoassays and are related to unexpected antibody interactions (see “Interference” section). Such an error usually will show up as an outlier in method comparison studies. A well-known source is the occurrence of heterophilic antibodies. Outliers should not just be discarded from the data analysis procedure. Outliers must be investigated to identify their cause, which may be an important limitation in using a given method. Supplementary studies may help to clarify

such random sample-related interferences and may provide specifications for the assay that limit its application in certain contexts (e.g., with regard to samples from certain patient categories).

Mistakes or Clerical Errors

Another reason for outliers in method comparison studies and in daily practice is mistakes (sometimes termed blunders) or clerical errors. In the past, this type of error usually arose in relation to manual transfer of results. Today, this kind of error typically is related to computer errors originating at interfaces between computer systems. Errors on test order forms or errors related to handling of order forms appear to occur relatively frequently (1% to 5% of recorded cases have been revealed in systematic studies). In the postanalytical phase, inappropriate interpretation may take place (e.g., in relation to erroneous reference intervals).

Method Comparison Data Model

We here consider our error model in relation to the method comparison situation. For a given sample measured by two analytical methods, 1 and 2, we have

$$x1_i = X1_{Targeti} + \varepsilon 1_i = X_{Truei} + \text{Cal-Bias}1 + \text{Random-Bias}1_i + \varepsilon 1_i$$

$$x2_i = X2_{Targeti} + \varepsilon 2_i = X_{Truei} + \text{Cal-Bias}2 + \text{Random-Bias}2_i + \varepsilon 2_i$$

From this general model, we may study some typical situations. First, comparison of a routine method with a reference method will be treated. Second, the more frequently occurring situation—the comparison of two routine methods—is considered.

Comparison of a Routine Method With a Reference Method

The process of comparing the performance of a routine method with that of a reference method begins with considering that method 1 is a reference method. In this case, the bias components per definition disappear, and we have the following situation:

$$x1_i = X1_{Targeti} + \varepsilon 1_i = X_{Truei} + \varepsilon 1_i$$

$$x2_i = X2_{Targeti} + \varepsilon 2_i = X_{Truei} + \text{Cal-Bias}2 + \text{Random-Bias}2_i + \varepsilon 2_i$$

The paired differences become

$$(x2_i - x1_i) = \text{Cal-Bias}2 + \text{Random-Bias}2_i + (\varepsilon 2_i - \varepsilon 1_i)$$

We thus have an expression consisting of a constant term (the calibration bias of method 2) and two random terms. The random bias term is distributed around the calibration bias according to an undefined distribution. The second random term is a difference between two random measurement errors that are independent and, commonly, Gaussian distributed. Under these assumptions, the differences between random measurement errors are also random and Gaussian. However, we remind the reader that the SD for analytical methods often depends on the concentration level, as mentioned earlier. For analytes with a wide analytical measurement range (e.g., some hormones), both random matrix-related interferences and analytical SDs are likely to depend on the measurement concentration, often in a roughly proportional manner. It may then be more useful to evaluate the relative differences—$(x2_i - x1_i)/[(x2_i + x1_i)/2]$—and accordingly express calibration and random bias and analytical error as proportions. An alternative is to partition the total analytical measurement range into segments (e.g., three parts), and consider calibration bias, random bias, and analytical error separately for these segments. The segments may preferably be divided in relation to important decision concentrations (e.g., in relation to reference interval limits or treatment decision concentrations or both).

Comparison of Two Routine Methods

In the comparison of two routine methods, the paired differences become

$$(x2_i - x1_i) = (\text{Cal-Bias}2 - \text{Cal-Bias}1) + (\text{Random-Bias}2_i - \text{Random-Bias}1_i) + (\varepsilon 2_i - \varepsilon 1_i)$$

The expression again consists of a constant term, the difference between the two calibration biases, and two random terms. The first random term is a difference between two random bias components that may or may not be independent. If the two routine methods are based on the same measurement principle, the random bias terms are likely to be correlated. For example, two chromogenic methods for creatinine are likely to be subject to interference from the same chromogenic compounds present in a given serum sample. Alternatively, chromogenic and enzymatic creatinine methods are subject to different types of interfering compounds, and the random bias terms may be relatively independent. In the $\varepsilon 2_i - \varepsilon 1_i$ term, the same relationships as described above are likely to apply. One may notice that the general form of the expressed differences is the same in the two situations. Thus the same general statistical principles apply. In the following sections, we will consider the distribution of differences under various circumstances as well as the measurement relations between methods 1 and 2 on the basis of regression analysis.

Planning a Method Comparison Study

In the planning phase of a method comparison study, several points require attention, including (1) the number of samples necessary, (2) the distribution of analyte concentrations (preferably uniform over the analytical measurement range), and (3) the representativeness of the samples. To address point (3), samples from relevant patient categories should be included, so that possible interference phenomena will be discovered. Practical aspects related to storage and treatment of samples (e.g., container) and possible artifacts induced by storage (e.g., freezing of samples) and addition of anticoagulants should be considered. Comparison of measurements preferably should be undertaken over several days (e.g., at least 5 days), so that the comparison of methods does not become dependent on the performance of methods in one particular analytical run. Finally, ethical aspects (e.g., informed consent from patients whose samples will be used) should be considered in relation to existing legislation.

When the comparison protocol is considered, various guidelines may be consulted. The CLSI Evaluation Protocol (EP) guidelines give advice on various aspects. For example, the CLSI guideline EP9-A2-IR, "Method Comparison and Bias Estimation Using Patient Samples,"[3] suggests measurement of 40 samples in duplicate by each method when a new method is introduced in the laboratory as a substitute for an established one.[10] Additionally, it is proposed that the vendor of an analytical test system should have made a comparison study based on at least 100 samples measured in duplicate by each method. The principle of a more demanding requirement for vendors appears reasonable. This initial validation should be comprehensive to disclose the performance of the assay system in detail. Then the requirement for the ordinary user may be more modest. The CLSI EP15-A2 guideline, "User Verification of Performance for Precision and Trueness," suggests a more condensed approach based on a bias or **difference plot,** which does not involve regression analysis and can be carried out using 20 samples. Although these general guidelines on sample size are useful, additional aspects are important. The probability of detecting rarely occurring interferences showing up as outliers should be taken into account when the necessary sample size is considered. Finally, in relation to evaluation of automated methods, special consideration should be given to the sample sequence to evaluate drift, carryover, and nonlinearity (e.g., by a multifactorial design).

Difference (Bland-Altman) Plot

This procedure was originally introduced by Bland and Altman for comparison of measurements in clinical medicine, but the procedure has been adopted also in clinical chemistry.[1] The Bland-Altman plot is usually understood as a plot of the differences against average results of the methods. Thus the difference plot in this version provides information on the relation between differences and concentration, which is useful in evaluating whether problems exist at certain ranges (e.g., in the high range) as the result of nonlinearity of one of the methods. It may also be of interest to observe whether differences tend to increase proportionally with the concentration, or whether they are independent of concentration. The underlying error model outlined previously applies also to the difference plot.

The basic version of the difference plot consists of plotting the differences against the average of the measurements. If one set of measurements is without random measurement error, one may plot the differences against this value. Figure 2-10 shows the plot for an example consisting of N = 65 samples measured by two drug assay methods. The interval ± 2 SD of the differences is often delineated around the mean difference that corresponds to the mean and the 2.5 and 97.5 percentiles.

A constant mean bias over the analytical measurement range changes the average concentration away from zero. The presence of random matrix-related interferences increases the width of the distribution. If the mean bias depends on the concentration or if the dispersion varies with the concentration, or both, the relations become more complex, and the interval mean ± 2 SD of the differences may not fit very well as a 95% interval throughout the analytical measurement range.

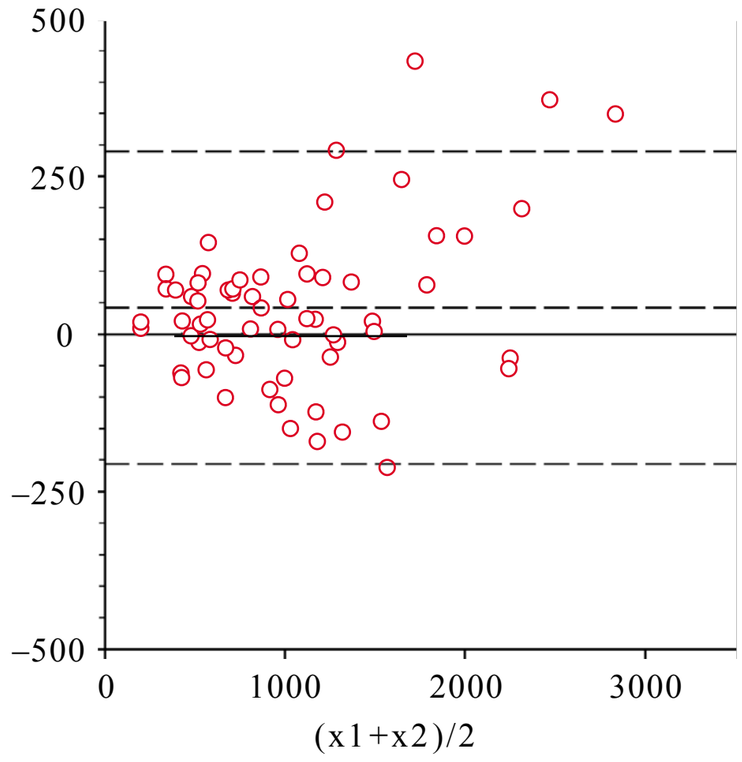

Figure 2-10 Bland-Altman plot of differences for the drug comparison example. The differences are plotted against the average concentration. The mean difference (42 nmol/L) with ±2 SD of differences is shown (dashed lines).

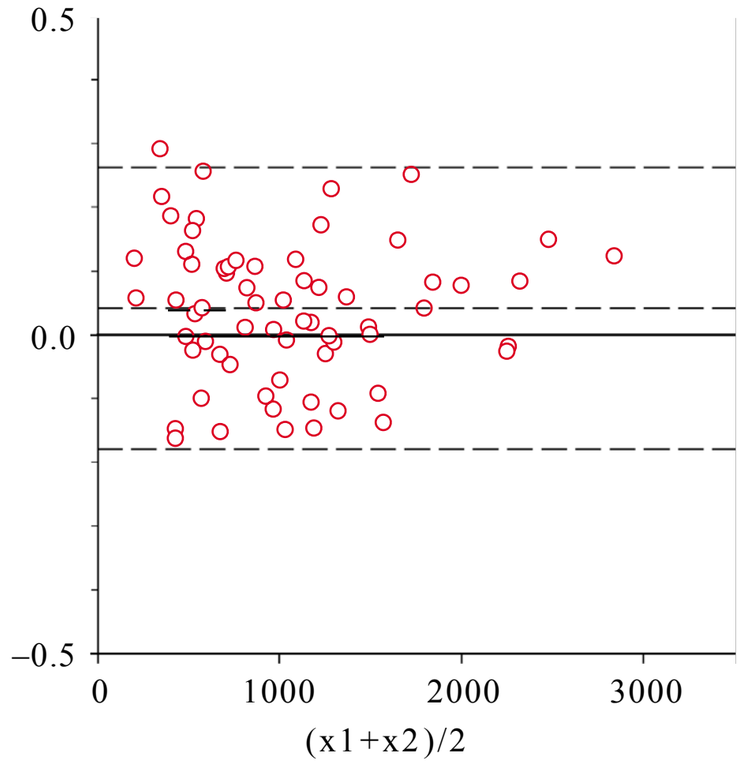

Figure 2-11 Bland-Altman plot of relative differences for the drug comparison example. The differences are plotted against the average concentration. The mean relative difference (0.042) with ±2 SD of relative differences is shown (dashed lines).

In the displayed Bland-Altman plot for drug assay comparison data, there is a tendency toward increasing scatter with increasing concentration, which is a reflection of increasing random error with the concentration level. Thus a plot of the relative differences against the average concentration is of relevance (Figure 2-11). Now there is a more homogeneous dispersion of values agreeing with the estimated limits for the dispersion (i.e., the relative mean difference $\pm t_{0.025(N-1)}\, SD_{RelDif}$).

Difference (Bland-Altman) Plot With Specified Limits

In many situations where a routine method is being considered for implementation, it may be desired primarily to verify whether differences in relation to the existing method are located within given specified limits rather than estimating the distribution of differences. For example, one may set limits corresponding to ±15% as clinically acceptable and desire that most (e.g., 95% of differences) are located within this interval.

TABLE 2-4 Lower Bounds (One-Sided 95% CI) of Observed Proportions (%) of Results Located Within Specified Limits for Paired Differences That Are in Accordance With the Hypothesis of at Least 95% of Differences Being Within the Limits

N	Observed Proportions
20	85
30	87
40	90
50	90
60	90
70	90
80	91
90	91
100	91
150	92
200	93
250	93
300	93
400	93
500	93
1000	94

By counting, it may be determined whether the expected proportion of results is within the limits (i.e., 95%). One may accept percentages that do not deviate significantly from the supposed percentage at the given sample size derived from the binomial distribution (Table 2-4). For example, if 50 paired measurements have been performed in a method comparison study, and if it is observed that 46 of the results (92%) are within the specified limits (e.g., ±15%), the study supports that the achieved goal has been reached because the lower boundary for acceptance is 90%. It is clear that a reasonable number of observations should be obtained for the assessment to have an acceptable power.

When appropriate limits are considered for a comparison study, one should be aware of the error components of the comparison method. Suppose an imprecision corresponding to an analytical coef cient of variation (CV_A) of 5% is allowed for the new method, and a bias of up to ±3% in relation to the comparison method is reasonable. If the CV_A of the comparison method is 4%, the limits for the differences become $\pm[3\% + 2(5^2 + 4^2)^{0.5}]$ (i.e., ±15.8% [supposing a 95% interval]). Note that here we have ignored the possibility of random matrix-related interferences.

Regression Analysis

Regression analysis is commonly applied in comparing the results of analytical method comparisons. Typically an experiment is carried out in which a series of paired values is collected when a new method is compared with an established method. T is series of paired observations ($x1_i$, $x2_i$) is then used to establish the nature and strength of the relationship between the tests. Regression analysis has the advantage that it allows the relation between target values for the two compared methods to be studied over the full analytical measurement range. If the systematic difference between target values (i.e., the calibration bias difference between the two methods or the systematic error) is related to the analyte concentration, such a relationship may not be clearly shown when the previously mentioned types of difference plots are used. In linear regression analysis, it is assumed that the systematic difference between target values is modeled as a constant systematic difference (intercept deviation from zero) combined with a proportional systematic difference (slope deviation from unity), usually related to a discrepancy with regard to calibration of the methods (Figure 2-12). In situations with constant SDs of random errors, unweighted regression procedures are used (i.e., **ordinary least-squares [OLR]** and Deming regression analyses). For cases with SDs that are proportional to the measurement level, the corresponding weighted regression procedures are optimal.

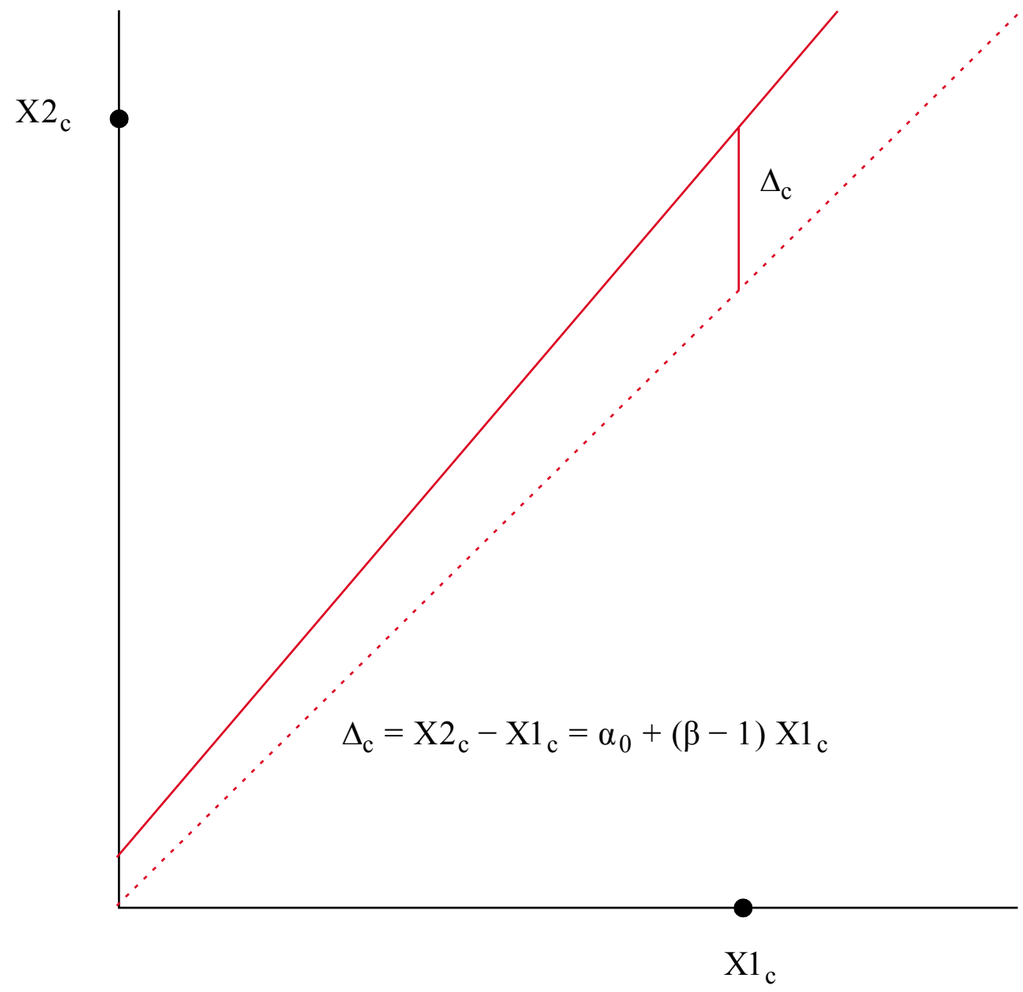

Figure 2-12 Illustration of the systematic difference $_c$ between two methods at a given level $X1_c$ according to the regression line. The difference is a result of a constant systematic difference (intercept deviation from zero) and a proportional systematic difference (slope deviation from unity). The dotted line represents the diagonal X2 = X1.

Error Models in Regression Analysis

As was outlined previously, we distinguish between the measured value (x_i) and the target value ($X_{Targeti}$) of a sample subjected to analysis by a given method. In linear regression analysis, we assume a linear relationship between values devoid of random error of any kind. In statistical terminology, a so-called structural relationship is assumed. T us, to operate with a linear relationship between values without random measurement error and sample-related random bias, we assume a linear relationship between the modified target values:

$$X2'_{Targeti} = \alpha_0 + \beta X1'_{Targeti}$$

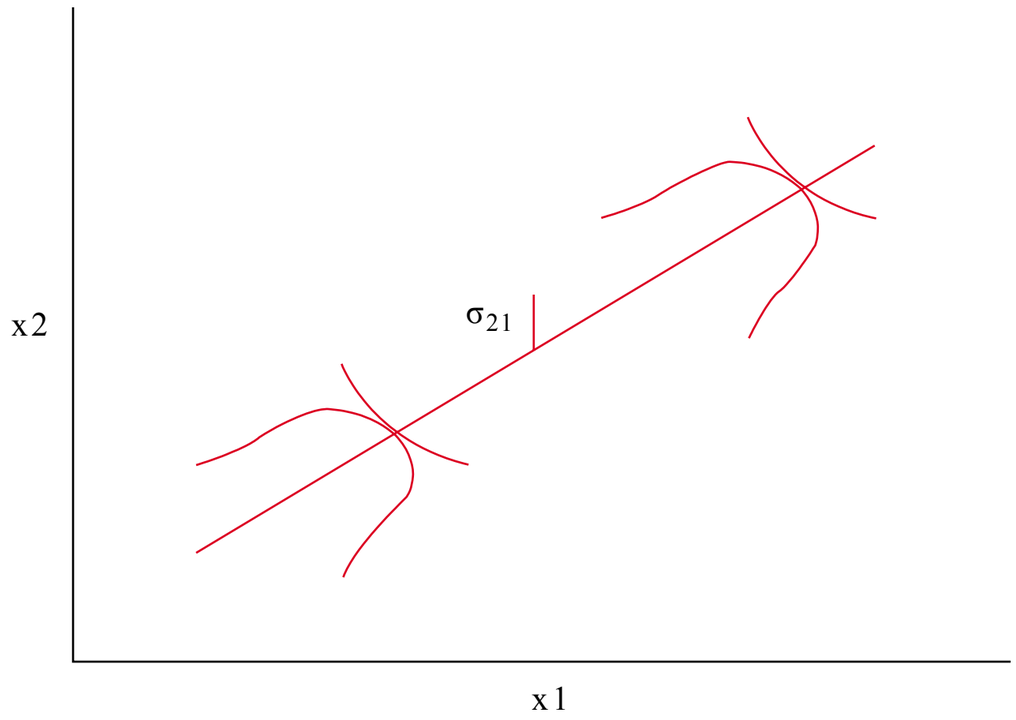

Figure 2-13 Outline of the relation between x1 and x2 values measured by two methods subject to random error with constant SDs over the analytical measurement range. A linear relationship between the target values ($X1'_{Targeti}$, $X2'_{Targeti}$) is presumed. The $x1_i$ and $x2_i$ values are Gaussian distributed around $X1'_{Targeti}$ and $X2'_{Targeti}$, respectively, as schematically shown. σ_{21} (σ_{yx}) is demarcated.

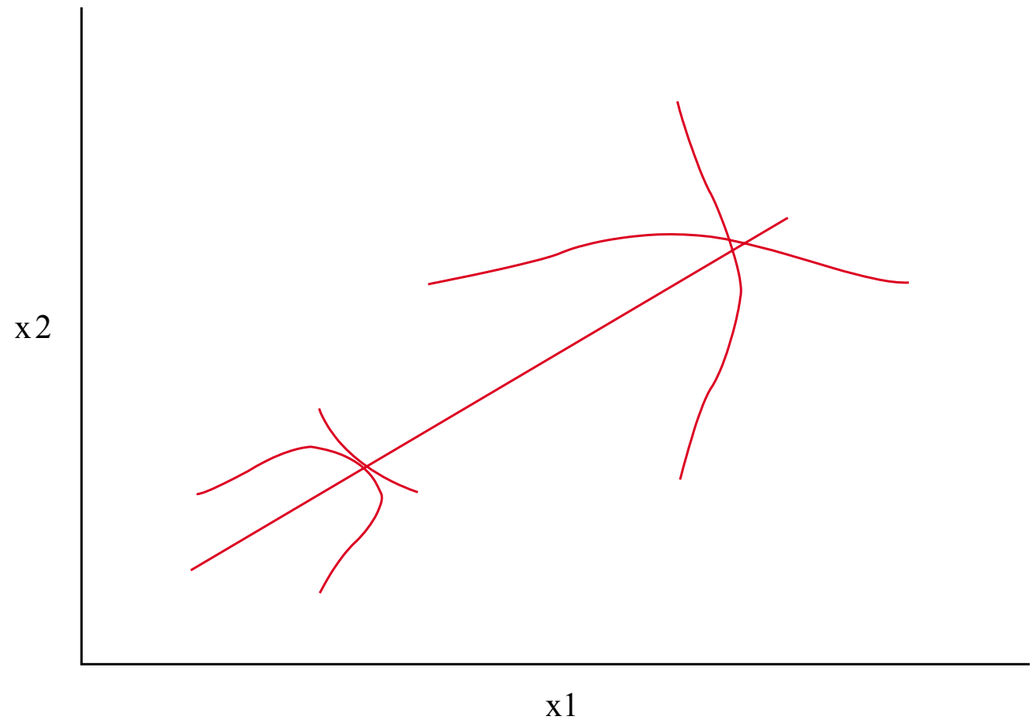

Figure 2-14 Outline of the relation between x1 and x2 values measured by two methods subject to proportional random errors. A linear relationship between the target values is assumed. The $x1_i$ and $x2_i$ values are Gaussian distributed around $X1'_{Targeti}$ and $X2'_{Targeti}$, respectively, with increasing scatter at higher concentrations as schematically shown.

In this model, α_0 corresponds to a constant difference with regard to calibration, and $(\beta - 1)$ is a proportional deviation. Thus, the systematic error or calibration difference between the measurements corresponds to

$$X2'_{Targeti} - X1'_{Targeti} = \alpha_0 + (\beta - 1)\, X1'_{Targeti}$$

Because of sample-related random interferences and measurement imprecision (of the type described by a Gaussian distribution, e.g., caused by pipetting variability, signal variability), individually measured pairs of values ($x1_i$, $x2_i$) will be scattered around the line expressing the relationship between $X1'_{Targeti}$ and $X2'_{Targeti}$. Figure 2-13 outlines schematically how the random distribution of x1 and x2 values occurs around the regression line. We have

$$x1_i = X1_{Targeti} + \varepsilon 1_i = X1'_{Targeti} + \text{Random-Bias}1_i + \varepsilon 1_i$$

$$x2_i = X2_{Targeti} + \varepsilon 2_i = X2'_{Targeti} + \text{Random-Bias}2_i + \varepsilon 2_i$$

The random error components may be expressed as SDs, and generally we assume that sample-related random bias (SD σ_{RB}) and analytical imprecision (SD σ_A) are independent for each analyte, yielding the relations

$$\sigma^2_{x1} = \sigma^2_{RB1} + \sigma^2_{A1}$$

$$\sigma^2_{x2} = \sigma^2_{RB2} + \sigma^2_{A2}$$

where σ^2_{x1} and σ^2_{x2} are the total SDs of the distributions of x1i and x2i around their respective modified target values, $X1'_{Targeti}$ and $X2'_{Targeti}$. The sample-related random bias components for methods 1 and 2 may not necessarily be independent. They also may not be Gaussian distributed, contrary to the analytical components. Thus when a regression procedure is applied, the explicit assumptions to take into account should be considered. In situations without random bias components of any significance, the relationships simplify to

$$\sigma^2_{x1} = \sigma^2_{A1}$$

$$\sigma^2_{x2} = \sigma^2_{A2}$$

In this situation, it usually is assumed that the error distributions are Gaussian, and estimates of the analytical SDs may be available from quality control data.

Another methodological problem concerns the question of whether the dispersion of sample-related random bias and the analytical imprecision are constant or change with the analyte concentration, as considered previously in the difference plot sections. In cases with a considerable range (e.g., a decade or longer), this phenomenon should be taken into account when a regression analysis is applied. Figure 2-14 schematically shows how dispersions may increase proportionally with concentration.

Deming Regression Analysis and Ordinary Least-Squares Regression Analysis (Constant SDs)

To reliably estimate the relationship between modified target values (i.e., a_0 for α_0 and b for β), a regression procedure taking into account errors in both x1 and x2 is preferable (a situation termed the Deming approach; see Figure 2-13). Although the OLR procedure is commonly used in method comparison studies, it does not take errors in x1 into account but is based on the assumption that only the x2 measurements are subject to random error (Figure 2-15). In the Deming procedure, the sum of squared distances from measured sets of values ($x1_i$, $x2_i$) to the regression line is minimized at an angle determined by the ratio between SDs for the random variations of x1 and x2. It is possible to prove theoretically that, given Gaussian error distributions, this estimation procedure is optimal. It should here be

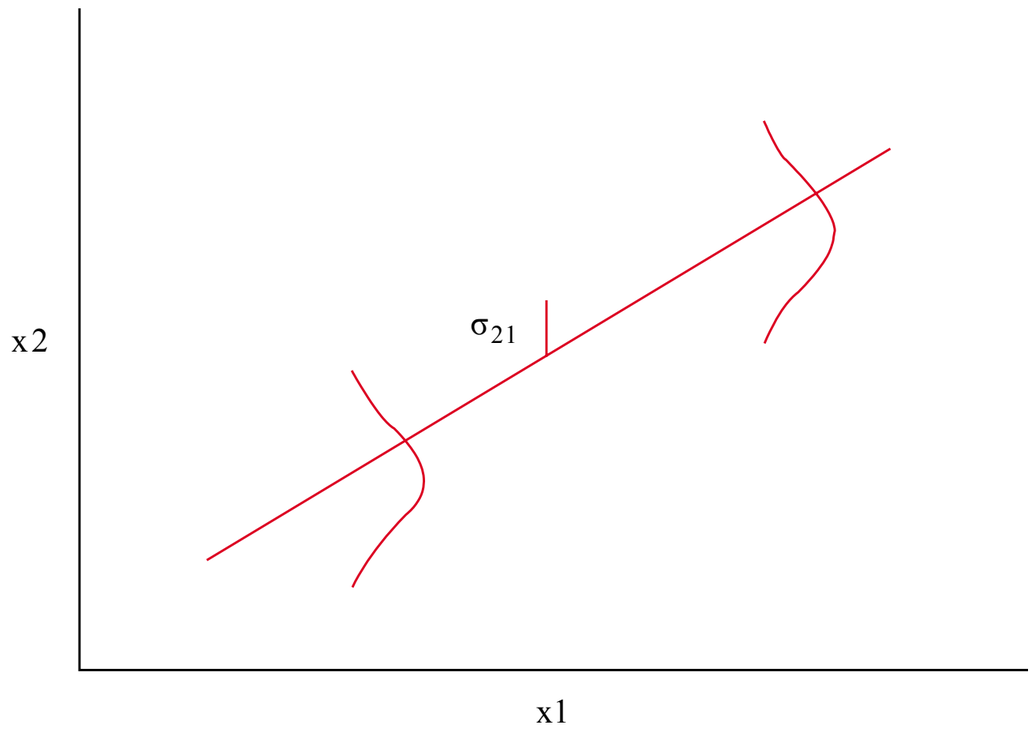

Figure 2-15 The model assumed in ordinary OLR. The x2 values are Gaussian distributed around the line with constant SD over the analytical measurement range. The x1 values are assumed to be without random error. σ_{21} (σ_{yx}) is shown.

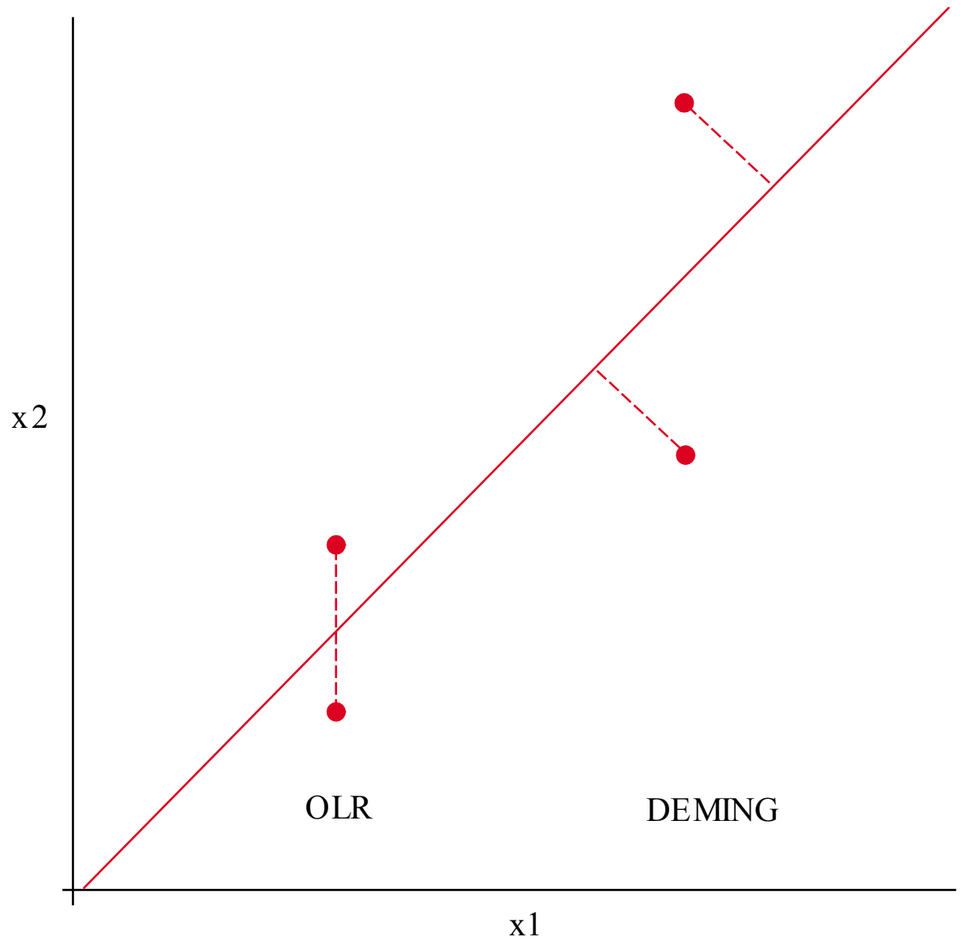

Figure 2-16 In OLR, the sum of squared deviations from the line is minimized in the vertical direction. In Deming regression analysis, the sum of squared deviations is minimized at an angle to the line depending on the random error ratio. Here the symmetric case is displayed with orthogonal deviations. (Reproduced with permission from Linnet K. The performance of Deming regression analysis in case of a misspecifed analytical error ratio, Clin Chem 1998;44:1024–1031 [Figure 1].)

noted that it is the error distributions that should be Gaussian, not the dispersion of values over the measurement range. T is is often misunderstood. In Figure 2-16, the symmetrical case is illustrated with a regression slope of 1 and equal SDs for the random variations of x1 and x2, in which case the sum of squared distances is minimized orthogonally in relation to the line.

OLR is not recommended except in special situations. In OLR, the sum of squared distances is minimized in the vertical direction to the line (see Figure 2-16). It is possible to prove theoretically that neglect of the random error in x1 induces a downward biased slope estimate

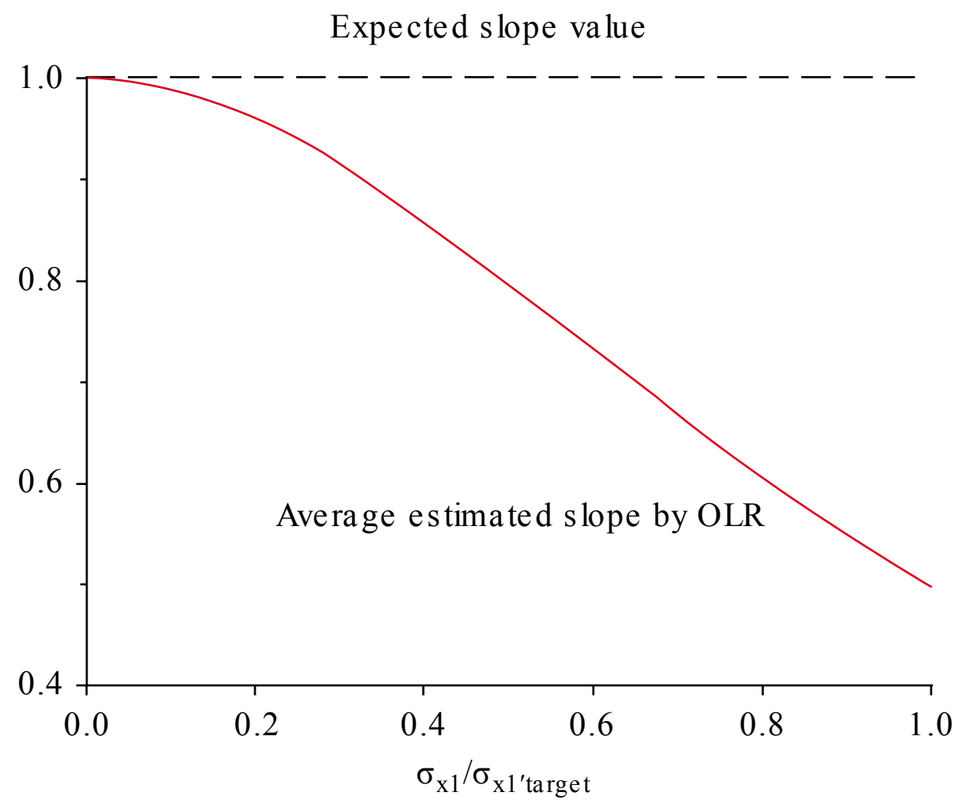

Figure 2-17 Relations between the true (expected) slope value and the average estimated slope by OLR. The bias of the OLR slope estimate increases negatively for increasing ratios of the SD random error in x1 to the SD of the X1 target value distribution.

$$\beta' = \beta\left[\sigma^2_{x1'target} \Big/ \left(\sigma^2_{x1'target} + \sigma^2_{x1}\right)\right]$$
$$= \beta \Big/ \left[1 + \left(\sigma_{x1}/\sigma_{X1'target}\right)^2\right]$$

where $\sigma_{X1'target}$ is the SD of X1′ target values. T e magnitude of the bias depends on the ratio between the SD for the random error in x1 and the SD of the X1′ target values. Figure 2-17 shows the bias as a function of the ratio of the random error SD to the SD of the X1′ target value dispersion. For a ratio up to 0.1, the bias is less than 1%. At a ratio of 0.33, the bias amounts to 10%; it increases further for increasing ratios. In a given case, one takes the analytical SD (e.g., from quality control data) and divides by the SD of the measured x1 values, which approximately equals the SD of X1′ target values. As an example, a typical comparison study for two serum sodium methods may be associated with a downward directed slope bias of about 10% (Figure 2-18).

In the example presented previously, the ratio of the analytical SD to the SD of the target value distribution is large because of the tight physiological regulation of electrolyte concentrations, which means that the biological variation is limited. Most other types of analytes exhibit wider distributions, and the ratio of error to target value distribution is smaller. For example, for analytes with a distribution of longer than 1 decade and an analytical error corresponding to a CV of 5% at the middle of the analytical measurement range, the OLR slope bias amounts to about −1%.

Computation Procedures for OLR and Deming Regression

Assuming no errors in x1 and a Gaussian error distribution of x2 with constant SD throughout the analytical measurement range, OLR is the optimal estimation procedure as developed by Carl Friedrich Gauss in the eighteenth century. Given

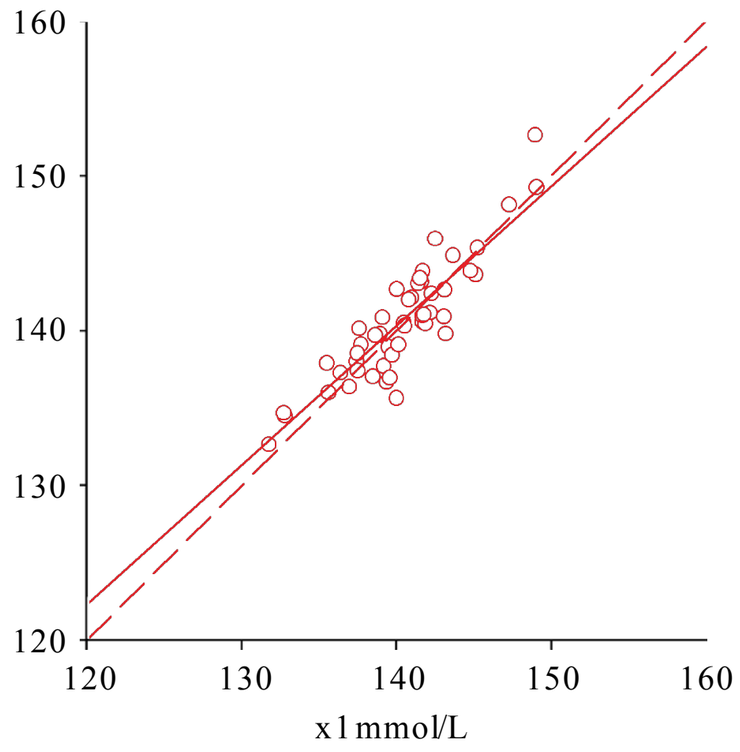

Figure 2-18 Simulated comparison of two sodium methods. The solid line indicates the average estimated OLR line, and the dotted line is the identity line. Even though there is no systematic difference between the two methods, the average OLR line deviates from the identity line corresponding to a downward slope bias of about 10%.

errors in both x1 and x2, the Deming approach is the method of choice.[10] It should be noted for these parametric procedures that only the error distributions must be Gaussian or normal. The least-squares principle does not presume normality to be applied, but it is optimal under normality conditions, and the nominal Type I errors for the associated statistical tests for slope and intercept hold true under this assumption. The procedures are generally robust toward deviations from normality, but they are sensitive toward outliers because of the squaring principle. Finally, the distributions of the target values of x1 and x2 do not have to be Gaussian. A uniform distribution over the analytical measurement range is generally of advantage, but the distribution may in principle take any form. For both procedures, we may evaluate the SD of the dispersion in the vertical direction around the line (commonly denoted $SD_{y\bullet x}$ and here given as SD_{21}). We have

$$SD_{21} = \left[\sum \left(x2_i - X2'_{Targetesti}\right)^2 / (N-2)\right]^{0.5}$$

Further discussion regarding the interpretation of SD_{21} will be given later.

To compute the slope in Deming regression analysis, the ratio between the SDs of the random errors of x1 and x2 is necessary, that is,

$$\lambda = \left(\sigma^2_{RB1} + \sigma^2_{A1}\right) / \left(\sigma^2_{RB2} + \sigma^2_{A2}\right)$$

SD_As are estimated from duplicate sets of measurements as

$$SD^2_{A1} = (1/2N) \sum (x1_{2i} - x1_{1i})^2$$

$$SD^2_{A2} = (1/2N) \sum (x2_{2i} - x2_{1i})^2$$

or they may be available from quality control data.

If a specific value for λ is not available and the two field methods that are compared are likely to be associated with random error levels of the same order of magnitude, λ is set to 1. The Deming procedure is generally relatively insensitive to a misspecification of the λ value.

Formulas for computing slope (β), intercept (α_0), and their standard errors are available from other sources[10,11] and will not be repeated here. Commonly available software packages for performing regression analysis by both methods will be reviewed later.

Evaluation of the Random Error Around an Estimated Regression Line

The estimated slope and intercept provide an estimate of the systematic difference or error between two methods over the analytical measurement range. Additionally, an estimate of the random error is important. As has been mentioned, it is commonplace to consider the dispersion around the line in the vertical direction, which is quantified as $SD_{y\bullet x}$ (here denoted SD_{21}). SD_{21} has originally been introduced in the context of OLR, but it may as well be considered in relation to Deming regression analysis.

Interpreting $SD_{y\bullet x}$ (SD_{21}) With Random Errors in Both x1 and x2

With regard to σ_{21}, we have here without sample-related random interferences

$$\sigma^2_{21} = \beta^2 \sigma^2_{A1} + \sigma^2_{A2}$$

Thus σ_{21} reflects the random error in both x1 (with a rescaling) and x2. Often β is close to unity, and in this case σ^2_{21} becomes approximately the sum of the individual squared SDs. This is relation holds true for both Deming and OLR analyses. Frequently, OLR is applied in situations associated with random measurement error in both x1 and x2, and in these situations σ_{21} reflects the errors of both.

The presence of sample-related random interferences in both x1 and x2 gives the following expression:

$$\sigma^2_{21} = \left[\beta^2 \sigma^2_{A1} + \sigma^2_{A2}\right] + \left[\beta^2 \sigma^2_{RB1} + \sigma^2_{RB2}\right]$$

Thus the σ_{21} value is influenced by the slope value, the analytical error components σ_{A1} and σ_{A2} (grouped in the first bracket) and σ_{RB1} and σ_{RB2} (grouped in the second bracket). In many cases, the slope is close to unity, in which case we have simple addition of the components. As has been mentioned, the matrix-related random interferences may not be independent. In this case, simple addition of the components is not correct because a covariance term should be included. However, in a real case, we estimate the combined effect corresponding to the bracket term. Information on the analytical components is usually available, either from duplicate sets of measurements or from quality control data. On this basis, the combined random bias term in the second bracket is derived by subtracting the analytical components from σ_{21}. Overall, it is possible to judge whether the total random error is acceptable or not. The systematic

difference is adjusted for relatively easily by rescaling of one of the sets of measurements. However, if the random error term is very large, such rescaling does not ensure equivalency of measurements with regard to individual samples. Thus it is important to assess both the systematic difference and the random error when deciding whether a new field method can replace an existing one. In a roughly symmetrical situation with a slope close to unity and two field methods of presumed equal specificity and precision, the total random error expressed as SD_{21} may be subdivided into component errors associated with each test by dividing with the square root of two. One may then assess the random error levels in relation to stated goals.

Assessment of Outliers

The principle of minimizing the sum of squared distances from the line makes the described regression procedures sensitive toward outliers, and an assessment of the occurrence of outliers should be carried out routinely. The distance from a suspected outlier to the line is recorded in SD units, and rejection of the outlier is performed if the distance exceeds a predetermined limit (e.g., 3 or 4 SD units). In the case of OLR, the SD unit equals SD_{21}, and the vertical distance is considered. For Deming regression analysis, the unit is the SD of the deviation of the points from the line at an angle determined by the error variance ratio, λ. A plot of these deviations, a so-called residuals plot, conveniently illustrates the occurrence of outliers.[10,11] Figure 2-19, A, illustrates a Deming regression analysis example with occurrence of an outlier and the associated residuals plot (B), which clearly shows the outlier pattern. In this example, the residuals plot was standardized to unit SD. In this example with an outlier limit of 4 SD units, the outlier was rejected and a reanalysis was undertaken. In this example, rejection of the outlier changed the slope from 1.14 to 1.03. With regard to outliers, these measurements should not just be rejected automatically; the reason for their presence should be investigated as a method limitation (e.g., possibly a nonspecificity for the analyte).

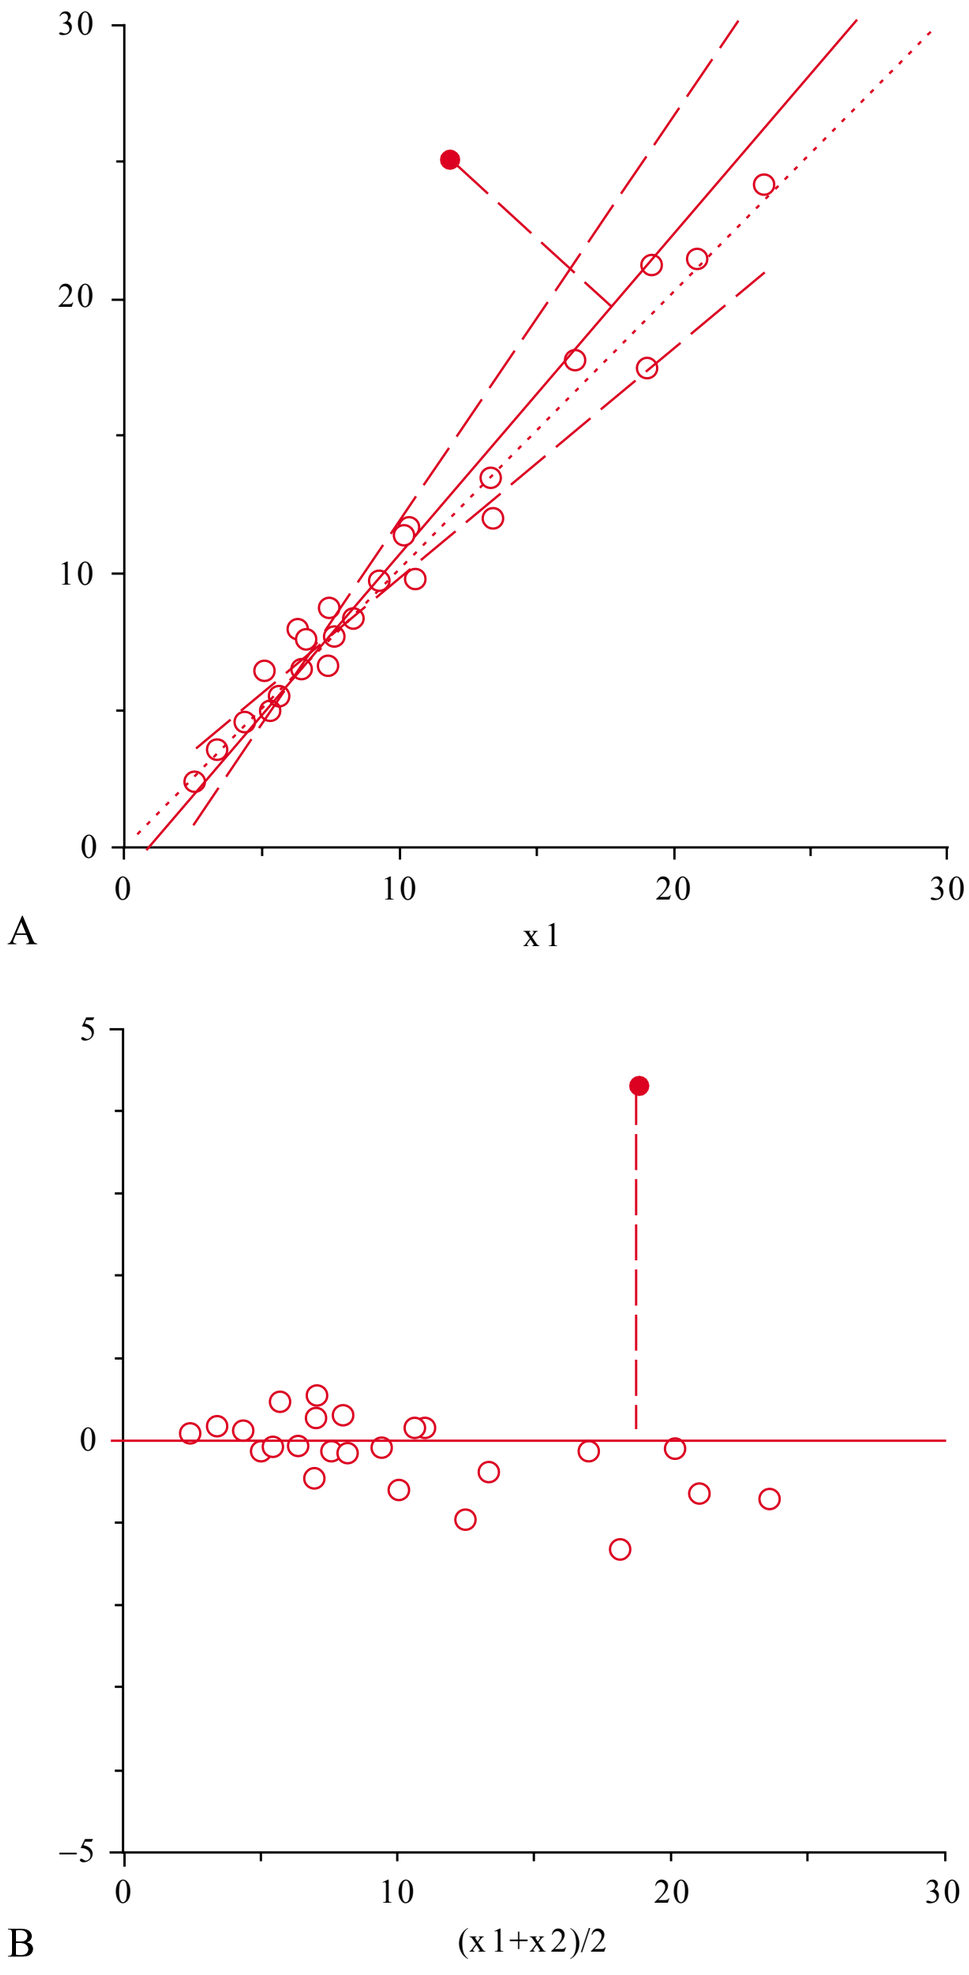

Figure 2-19 A, A scatter plot with the Deming regression line (solid line) with an outlier (filled point). The dotted straight line is the diagonal, and the curved dashed lines demarcate the 95% confidence region. B, Standardized residuals plot with indication of the outlier.

The Correlation Coefficient

In addition to outlining the random error components related to regression analysis, some comments on the correlation coefficient may be appropriate. The ordinary correlation coefficient ρ, also called the Pearson product moment correlation coefficient, is estimated as r from sums of squared deviations for x1 and x2 values as follows:

$$r = p/[uq]^{0.5}$$

where

$$p = \sum (x1_i - x1_m)(x2_i - x2_m)$$

$$u = \sum (x1_i - x1_m)^2 \quad q = \sum (x2_i - x2_m)^2$$

and

$$x1_m = \sum x1_i/N \quad x2_m = \sum x2_i/N$$

Theoretically, ρ is related to the ratio between the SDs of the distributions of target values ($\sigma_{X1'target}$ and $\sigma_{X2'target}$) and the associated independent total random error components (σ_{x1} and σ_{x2})

$$\rho = \sigma_{X1'target}\sigma_{X2'target} \Big/ \left[\left(\sigma^2_{X1'target} + \sigma^2_{x1} \right) \left(\sigma^2_{X2'1target} + \sigma^2_{x2} \right) \right]^{0.5}$$

The total random error components comprise both imprecision error and sample-related random interferences (i.e., $\sigma^2_{x1} = \sigma^2_{A1} + \sigma^2_{RB1}$ and $\sigma^2_{x2} = \sigma^2_{A2} + \sigma^2_{RB2}$). Thus ρ is a relative indicator of the amount of dispersion around the regression

line. If the range of values is narrow, ρ tends to be low and vice versa for a wide range of values. For example, consider simulated examples, where the random errors of x1 and x2 are the same, but the width of the distributions of target values differs (Figure 2-20, A and B). In (A), the target values are uniformly distributed over the range 1 to 3, and in (B), the range is 1 to 6. The random error SD is presumed constant, and it is in both cases set to 0.15 for both x1 and x2, corresponding to a CV of 5% at level 3. Given sets of 50 paired measurements, the correlation coefficient is 0.93 in case (A) and 0.99 in case (B). Further, a single point located outside the range of the rest of the observations exerts a strong influence (Figure 2-20, C). In (C), 49 of the observations are distributed within the range 1 to 3 with a single point located apart from the others around the value 6, other factors being equal. The correlation coefficient here takes an intermediate value, 0.97. Thus a single point located away from the rest has a strong influence (a so-called influential point). Notice that it is not an outlying point, just an aberrant point with regard to the range.

Although σ_{21} is the relevant measure for random error in method comparison studies, ρ is still incorrectly used as a supposed measure of agreement between two methods. It should be noted that a systematic difference due to a difference with regard to calibration is expressed not through ρ but solely in the form of an intercept (α_0) deviation from zero and/or a slope (β) deviation from unity. Thus even though the correlation coefficient is very high, a considerable calibration bias may be noted between the measurements of two methods.

Regression Analysis in Case of Proportional Random Errors

As has been discussed in relation to the precision profile, for analytes with wide ranges (e.g., 1 or several decades), the SD_A is seldom constant. Rather, a proportional relationship may apply. This is may also be true for the random bias components. In this situation, the regression procedures described previously still may be used, but they are not optimal because the standard errors of slope and intercept become larger than is the case when a weighted form of regression analysis is applied. The optimal approaches are weighted forms of regression analysis that take into account the relationship between random error and analyte concentration.[10,11] Given a proportional relationship, a weighted procedure assigns larger weights to observations in the low range; low-range observations are more precise than measurements at higher concentrations that are subject to larger random errors. More specifically, weights are applied in the computations that are inversely proportional to the squared SDs (variances) that express the random error. In the weighted modification of the Deming procedure, distances from (x1i, x2i) to the line are inversely weighted according to the squared SDs at a given concentration (Figure 2-21). The regression procedures are most conveniently performed using dedicated software.

Testing for Linearity

Dividing systematic error into a constant and a proportional component depends on the assumption of linearity,

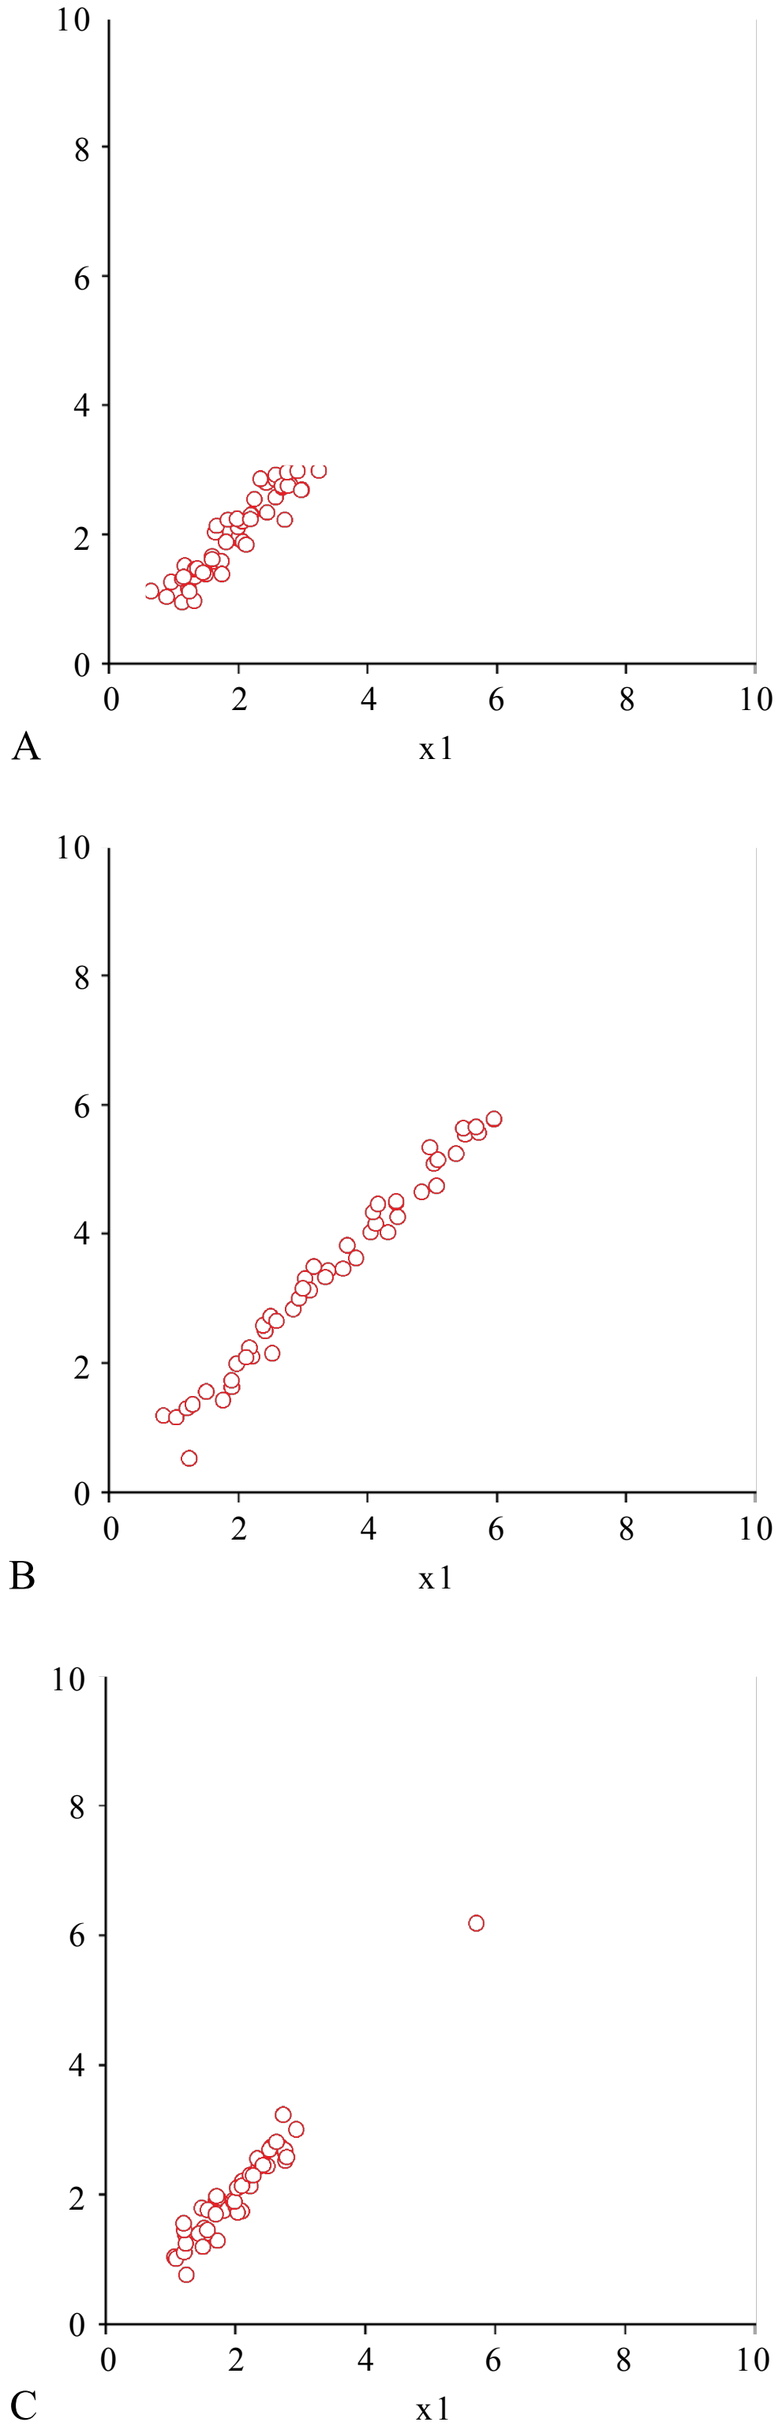

Figure 2-20 Scatter plots illustrating the effect of the range on the value of the correlation coefficient ρ. A, The target values are uniformly distributed over the range 1 to 3 with random errors of both x1 and x2 corresponding to an SD of 5% of the target value at 3 (constant error SDs). B, The range is extended to 1 to 6 with the same random error levels. The correlation coefficient equals 0.93 in A and 0.99 in B. In C, the effect of a single aberrant point is shown. Forty-nine of the target values are distributed over the range 1 to 3 with a single point at 6. The correlation coefficient is 0.97.

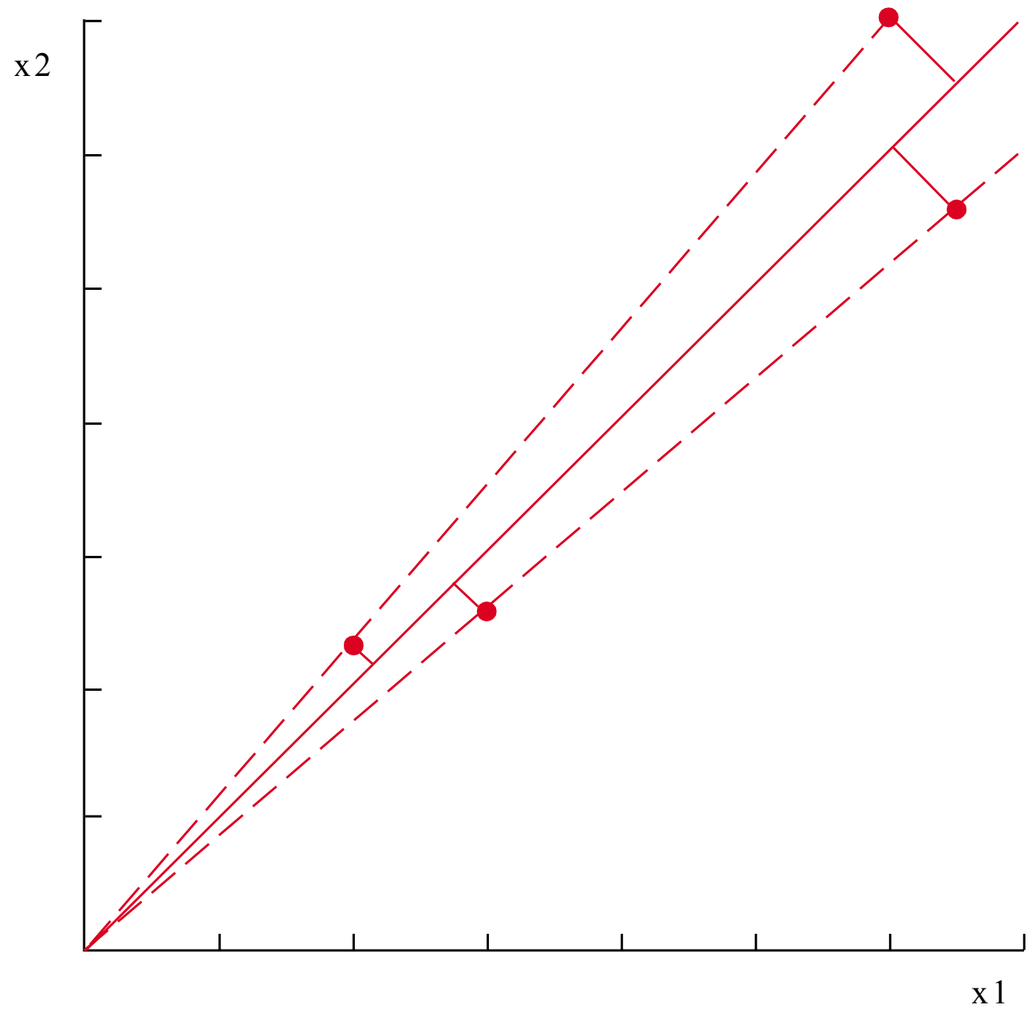

Figure 2-21 Distances from data points to the line in weighted Deming regression, assuming proportional random errors in x1 and x2. The symmetrical case is illustrated with equal random errors and a slope of unity, yielding orthogonal projections onto the line. (From Linnet K. Necessary sample size for method comparison studies based on regression analysis, Clin Chem 1999;45:882-94.)

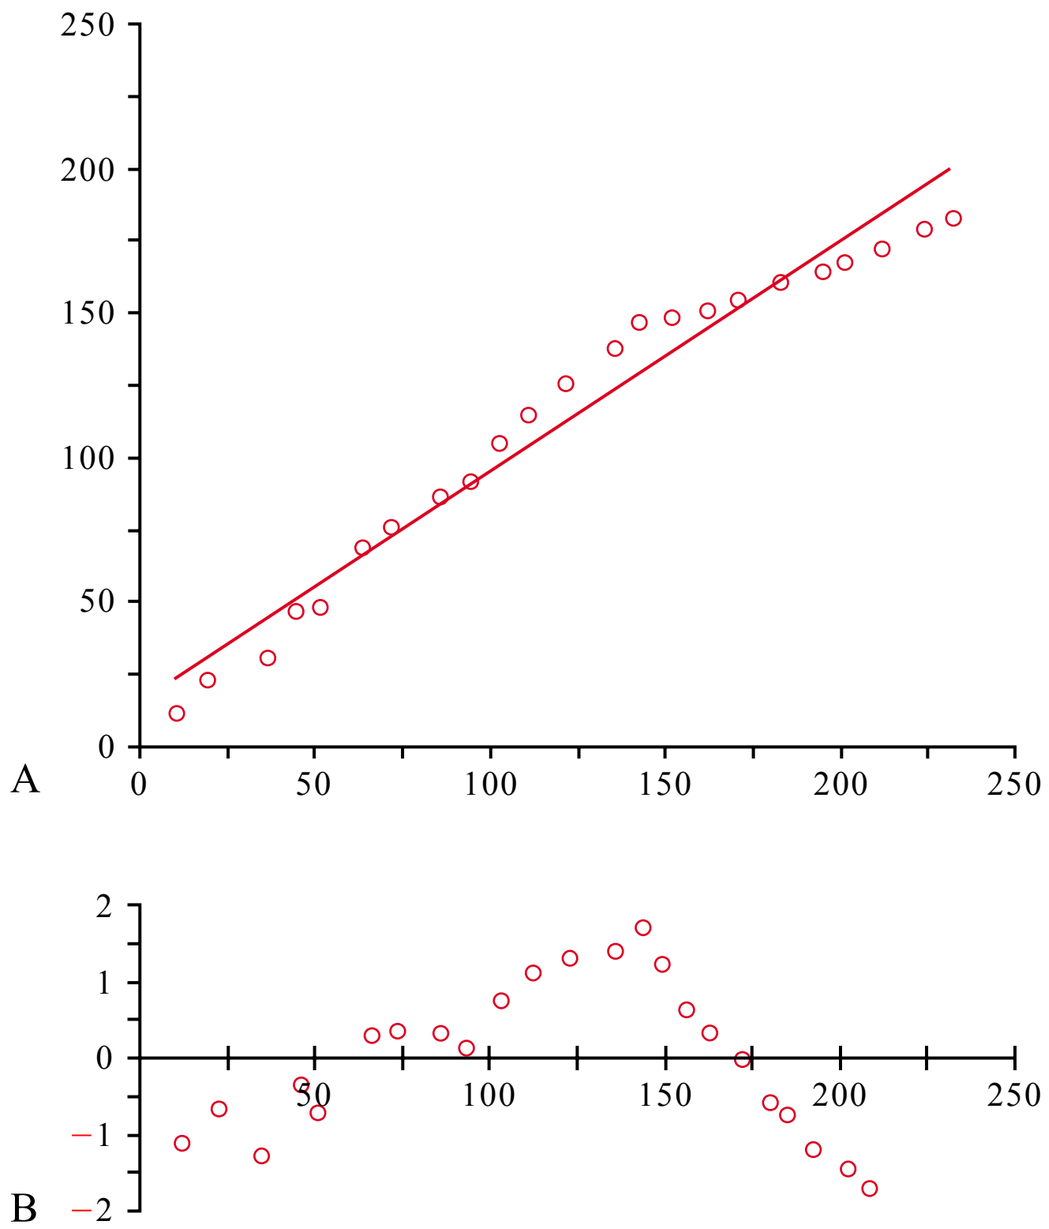

Figure 2-22 Top, Scatter plot showing an example of nonlinearity in the form of downward deviating x2 values at the upper part of the range. Bottom, Plot of residuals showing the effect of nonlinearity. At the upper end of the analytical measurement range, a sequence (run) of negative residuals is present from x = 150 to 200.

which should be tested. A convenient test is a runs test, which in principle assesses whether negative and positive deviations from the points to the line are randomly distributed over the analytical measurement range. The term run here relates to a sequence of deviations with the same sign. Consider for example the situation with a downward trend of x2 values at the upper end of the analytical measurement range (Figure 2-22, A). The standardized deviations from the line (i.e., the residuals) will tend to be negative in this area instead of being randomly distributed above and below the line[10] (Figure 2-22, B). Given a sufficient number of points, such a sequence will turn out to be statistically significant in a runs test.

Nonparametric Regression Analysis (Passing-Bablok)

The slope and the intercept may be estimated by a nonparametric procedure, which is robust to outliers and requires no assumptions of Gaussian error distributions.[13] Note, however, that parametric regression procedures do not presume Gaussian distributions of x1 and x2 values over the measurement range, but only of the error distributions. Thus the main advantage of the nonparametric procedure is its robust performance in the presence of outliers. The method takes measurement errors for both x1 and x2 into account, but it presumes that the ratio between random errors is related to the slope in a fixed manner:

$$\lambda = \left(SD_{RB1}^2 + SD_{A1}^2\right) \Big/ \left(SD_{RB2}^2 + SD_{A2}^2\right) = 1/\beta^2$$

Otherwise, a biased slope estimate is obtained.[10] The procedure may be applied both in situations with random errors with constant SDs and in cases with proportional SDs. The method is not as efficient as the corresponding parametric procedures (i.e., Deming and weighted Deming procedures).[10,11] Slope and intercept with CIs are provided, together with Spearman's rank correlation coefficient. A software program is required for the procedure.

Interpretation of Systematic Differences Between Methods Obtained on the Basis of Regression Analysis

A systematic difference between two methods is identified if the estimated intercept differs significantly from zero, or if the slope deviates significantly from 1. This is decided on the basis of t-tests:

$$t = (a_0 - 0)/SE(a_0)$$

$$t = (b - 1)/SE(b)$$

$SE(a_0)$ and $SE(b)$ are the standard errors of the estimated intercept α_0 and the slope b, respectively. In practice, standard errors are derived by a computerized resampling principle called the jackknife procedure, which is carried out using appropriate software[10] (see section Software Packages).

Having estimated a_0 and b, we have the estimate of the systematic difference between the methods, D_c, at a selected concentration, $X1'_{Targetc}$:

$$D_c = X2'_{Targetestc} - X1'_{Targetc} = a_0 + (b - 1)\, X1'_{Targetc}$$

$X2'_{Targetestc}$ is the estimated X2′ target value at $X1'_c$. Note that D_c refers to the systematic difference (i.e., the difference between modified target values corresponding to a calibration difference). The standard error of D_c is derived by the jackknife procedure using a software program. By evaluating the standard error throughout the analytical measurement range, a confidence region for the estimated line is displayed. If method comparison is performed to assess the calibration to a reference measurement procedure, correction of a significant systematic difference $Delta_c$ will often be performed by recalibration [$x2_{rec} = (x1 - a_0)/b$]. The associated standard uncertainty is the standard error of $Delta_c$. Even though the intercept and the slope are not significantly different from zero and 1, respectively, the combined expression $Delta_c$ may be significantly different from zero.

Example of Application of Regression Analysis (Weighted Deming Analysis)

Application of weighted Deming regression analysis may be illustrated by the comparison of drug assays example (N = 65 [x1, x2] measurements). As was outlined previously, in this example, the random error of the differences increases with the concentration, suggesting that the weighted form of Deming regression analysis is appropriate. Figure 2-23 shows (A) the estimated regression line with 95% confidence bands and (B) a plot of residuals. The nearly homogeneous scatter in the residuals plot supports the assumed proportional random error model and the assumption of linearity. The slope estimate (1.014) is not significantly different from 1 (95% CI, 0.97 to 1.06), and the intercept is not significantly different from zero (95% CI, −6.7 to 47.4) (Table 2-5). A runs test for linearity does not contradict the assumption of linearity. The amount of random error is quantified in the form of the SD_{21} proportionality factor equal to 0.11 or 11%. In the present example with a slope close to unity and two routine methods with assumed random errors of about the same magnitude, we divide the random error by the square root of two and get $CV_{x1} = CV_{x2} = 7.8\%$. Quality control data in the laboratory have provided CV_As of 6.1% and 7.2% for methods 1 and 2, respectively. Thus in this example, the random error may be attributed largely to analytical error. The assay principle is HPLC for both methods, which generally is a rather specific measurement principle, and considerable random bias effects are not expected in this case. If one or both of the assays had been immunoassays, the situation might have been different.

In the table, the estimated systematic differences at the limits of the therapeutic interval (300 and 2000 nmol/L) are displayed (24.6 and 48.9 nmol/L, respectively). This is corresponds to percentage values of 8.2% and 2.4%, respectively. The estimated standard errors by the jackknife procedure yield the 95% CIs as shown in the table. At the low concentration, the difference is significant (95% CI: 5.7 to 44 nmol/L does not include zero), which is not the case at the high level (95% CI, −19 to 117 nmol/L). Even though the intercept and slope estimates separately are not significantly different from the null hypothesis values of zero and 1, respectively, the combined difference $Delta_c$ is significant at low concentrations in this example. If the

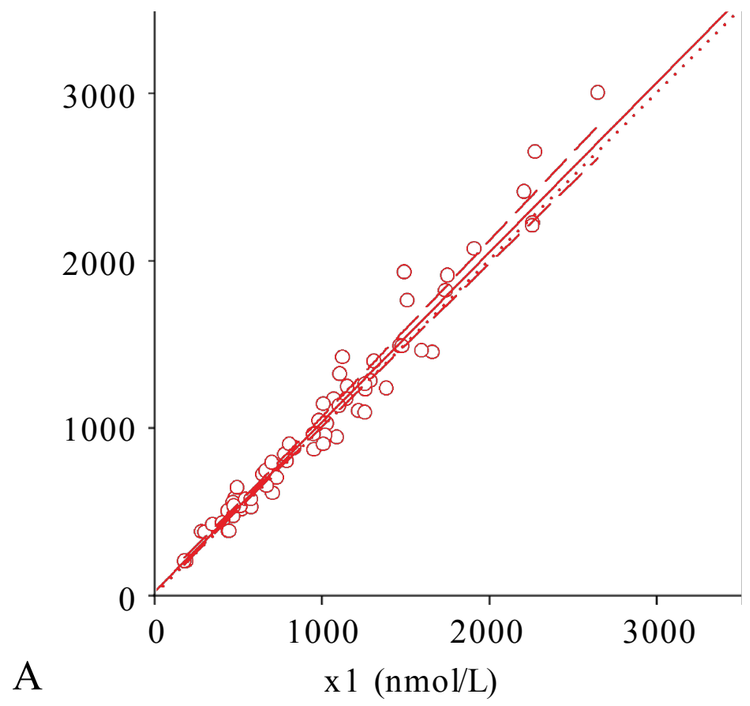

Figure 2-23 An example of weighted Deming regression analysis for the comparison of drug assays. A, The solid line is the estimated weighted Deming regression line, the dashed curves indicate the 95% confdence region, and the dotted line is the line of identity. B is a plot of residuals standardized to unit SD. The homogeneous scatter supports the assumed proportional error model and the assumption of linearity.

TABLE 2-5 Results of Weighted Deming Regression Analysis for the Comparison of Drug Assays Example, N = 65 (x1, x2) Measurements

	Estimate	Standard Error (SE)	95% CI
Slope (b)	1.014	0.022	0.97 to 1.06
Intercept (a_0)	20.3	13.5	−6.7 to 47.4
Weighted correlation coefficient	0.98		
SD_{21} proportionality factor	0.11		
Runs test for linearity	NS		
$Delta_c = X_2 - X_1$ at $X_c = 300$	24.6	9.5	5.72 to 43.6
$Delta_c = X_2 - X_1$ at $X_c = 2000$	48.9	34.2	−19.3 to 117

difference is considered of medical importance and both methods are to be used simultaneously in the laboratory, recalibration of one of the methods might be considered.

Discussion of Application of Regression Analysis

Generally, it is recommended that Deming or weighted Deming regression analysis should be used with a type of regression analysis that is based on a correct error model. Most published method evaluations are based on unweighted regression analysis; here the use of unweighted analysis is considered in the setting of proportional random errors.

Basically, the Deming procedure provides unbiased estimates of slope and intercept when SDs vary, provided that their ratio is constant throughout the analytical measurement range. T is aspect is important and indicates that generally the estimates of slope and intercept are reliable in this frequently encountered situation. However, applying the unweighted Deming analysis in cases of proportional SD_As is less ef cient than applying the weighted approach. For uniform distributions of values with range ratios from 2 to 100, 1.2 to 3.7 times as many samples are necessary to obtain the same uncertainty of the slope estimated by the unweighted compared with the weighted approach.[11] T us the larger the range ratio, the more inef cient is the unweighted method.

Monitoring Serial Results

An important aspect in clinical chemistry is monitoring of disease or treatment (e.g., tumor markers in case of cancer, drug concentrations in case of therapeutic drug monitoring). To assess changes in a rational way, the various imprecision components have to be taken into account.[7,8] Biological within-subject variations ($SD_{Within\text{-}B}$) and preanalytical (SD_{PA}) and analytical variations (SD_A) all have to be recognized. Assuming that preanalytical variation is already included in the estimated within-subject variation SD, a total SD (SD_T) is estimated by:

$$SD_T^2 = SD_{Within\text{-}B}^2 + SD_A^2$$

T e limit for statistically significant changes then is $k\sqrt{2}$ SD_T, where k depends on the desired probability level. When a two-sided 5% level is given, k is 1.96. T e corresponding one-sided factor is 1.65. If a higher probability level is desired, k should be increased.

Traceability and Measurement Uncertainty

As was outlined previously in the error model sections, laboratory results are influenced by systematic and random errors of various kinds. Obtaining agreement of measurements between laboratories or agreement over time in a given laboratory often is problematic.

Traceability

To ensure reasonable agreement between measurements of routine methods, the concept of traceability comes into focus. **Traceability** is based on an unbroken chain of comparisons of measurements leading to a known reference value

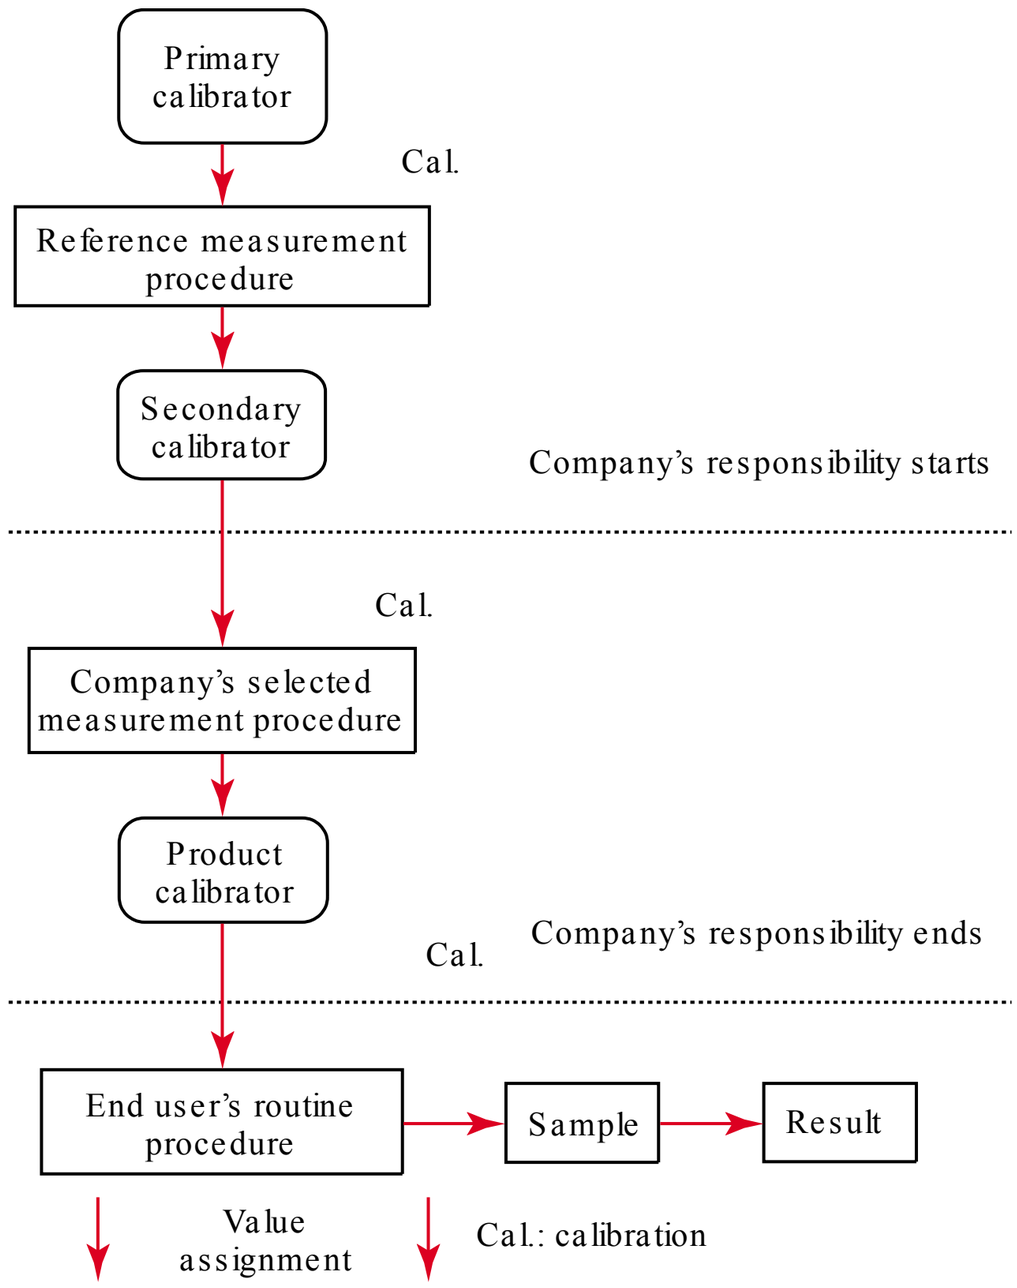

Figure 2-24 The calibration hierarchy from a reference measurement procedure to a routine method. The uncertainty increases from top to bottom.

(Figure 2-24).[15] A hierarchical approach for tracing the values of routine clinical chemistry measurements to reference measurement procedures was proposed by Tietz and has been adapted by the ISO.[9] For well-established analytes, a hierarchy of methods exists with a reference measurement procedure at the top, selected measurement procedures at an intermediate level, and finally routine measurement procedures at the bottom. A reference measurement procedure is a fully understood procedure of highest analytical quality containing a complete uncertainty budget given in SI units. Reference procedures are used to measure the analyte concentration in secondary reference materials, which typically have the same matrix as samples that are to be measured by routine procedures (e.g., human serum). Secondary reference materials are usually of high analytical quality, and certified secondary reference materials must be validated for commutability[1] with clinical samples if they are intended for use as trueness controls for routine methods. Otherwise, their use is restricted to those selected measurement procedures for which they are intended. T e certificate of analysis should state the methods for which the secondary reference materials have been validated to be commutable with clinical samples. When no information is given

[1]Several definitions have been developed for **commutability.** In this chapter, the following definition is used: "T e equivalence of the mathematical relationships between the results of different measurement procedures for a reference material and for representative samples from healthy and diseased individuals."

for commutability, it must be assumed that the reference material is not commutable with clinical samples, and the user has the responsibility to validate commutability for the methods of interest. Uncertainty of the measurement procedure results in increases from the top level to the bottom. ISO guidelines (15193 and 15194) address requirements for reference methods and reference materials.[9]

When cortisol is used as an example, the primary reference material is crystalline cortisol with a chemical analysis for impurities (NIST SRM 921, cortisol [hydrocortisone]). A primary calibrator is then a cortisol preparation with a stated mass fraction (purity) (e.g., 0.998 and a 95% CI of ±0.001). T e reference measurement procedure is an isotope dilution gas chromatography–mass spectrometry (IDMS) method that is calibrated with the primary calibrator. A panel of individual frozen serum samples that have values assigned by the primary reference measurement procedure is available from the Institute for Reference Materials and Measurements (IRMM) as secondary reference materials (ERM-DA451/IFCC). A manufacturer's selected measurement procedure is calibrated with the secondary reference materials and is used for measurement of the quantity in the manufacturer's product calibrator, which is the calibrator used for the routine method in clinical laboratories.

Only 25 to 30 of clinical chemistry analytes currently are traceable to SI units, such as electrolytes, some metabolites (glucose, creatinine, and uric acid), steroids, and some thyroid hormones). For plasma proteins, a human reference serum material is available from IRMM with certified mass concentrations of 12 serum proteins (ERM-DA470k/IFCC). With protein hormones, the existence of heterogeneity or microheterogeneity complicates the problem of traceability.[15]

The Uncertainty Concept

To assess in a systematic way errors associated with laboratory results, the uncertainty concept has been introduced into laboratory medicine.[6] According to the ISO "Guide to the Expression of Uncertainty in Measurement" (GUM), **uncertainty** is formally defined as "a parameter associated with the result of a measurement that characterizes the dispersion of the values that could reasonably be attributed to the measurand."[5] In practice, this means that the uncertainty is given as an interval around a reported laboratory result that specifies the location of the true value with a given probability (e.g., 95%). In general, the uncertainty of a result, which is traceable to a particular reference, is the uncertainty of that reference together with the overall uncertainty of the traceability chain.[6] Updated information on traceability aspects is available on the website of the Joint Committee on Traceability in Laboratory Medicine (www.bipm.org/en/committees/jc/jctlm/; accessed September 1, 2012).

The Standard Uncertainty (u_{st})

T e uncertainty concept is directed toward the end user (clinician) of the result, who is concerned about the total error possible and is not particularly interested in the question of whether the errors are systematic or random. In the outline of the uncertainty concept, it is assumed that any known systematic error components of a measurement method have been corrected, and the specified uncertainty includes uncertainty associated with correction of the systematic error(s).[6] Although this appears logical, one problem may be that some routine methods have systematic errors dependent on the patient category from which the sample originates. For example, kinetic Jaffe methods for creatinine are subject to positive interference by 2-Oxo compounds and to negative interference by bilirubin and its metabolites, which means that the direction of systematic error will be patient dependent and is not generally predictable.

In the theory on uncertainty, a distinction between type A and B uncertainties is made. Type A uncertainties are frequency-based estimates of SDs (e.g., an SD of the imprecision). Type B uncertainties are uncertainty components for which frequency-based SDs are not available. Instead, uncertainty is estimated by other approaches or by the opinion of experts. Finally, the total uncertainty is derived from a combination of all sources of uncertainty. In this context, it is practical to operate with standard uncertainties (u_{st}), which are equivalent to SDs. By multiplication of a standard uncertainty with a coverage *f*actor (k), the uncertainty corresponding to a specified probability level is derived. For example, multiplication with a coverage factor of 2 yields a probability level of ≈95%, given a Gaussian distribution. When the total uncertainty of an analytical result obtained by a routine method is considered, (1) preanalytical variation, (2) method imprecision, (3) sample-related random interferences, (4) uncertainty related to calibration and (5) bias corrections (traceability) should be taken into account. In expressing the uncertainty components as standard uncertainties, we have the following general relation:

$$u_{st} = \left[u^2_{P\,Ast} + u^2_{Ast} + u^2_{RB\,st} + u^2_{Trac\,st}\right]^{0.5}$$

where the individual components refer to preanalytical, analytical, and sample-related random bias and traceability uncertainty.

Uncertainty is assessed in various ways; often a combination of procedures is necessary. In principle, uncertainty is judged directly from measurement comparisons or indirectly from an analysis of individual error sources according to the law of error propagation ("error budget"). Measurement comparison may consist of a method comparison study with a reference method based on patient samples according to the principles outlined previously or by measurement of commutable certified matrix reference materials (CRMs).

Example of Direct Assessment of Uncertainty on the Basis of Measurements of a Commutable Certified Reference Material

Suppose a CRM is available that was validated to be commutable with patient samples for a given routine method with a specified value 10.0 mmol/L and a standard uncertainty of

0.2 mmol/L. Ten repeated measurements in independent runs give a mean value of 10.3 mmol/L with SD 0.5 mmol/L. The standard error of the mean is then $0.5/\sqrt{10} = 0.16$ mmol/L. The mean is not significantly different from the assigned value [$t = (10.3 - 10.0)/(0.2^2 + 0.16^2)^{0.5} = 1.17$]. The total standard uncertainty with regard to traceability is then $u_{Trac\,st} = (0.16^2 + 0.2^2)^{0.5} = 0.26$ mmol/L. If the bias had been significant, one might have considered making a correction to the method, and the standard uncertainty would then be the same at the given concentration. Thus measurements of the CRM provide an estimate of the uncertainty related to traceability, given the assumption of commutability with patient samples. The other components have to be estimated separately. Regarding method imprecision, long-term imprecision (e.g., observed from quality control measurements) should be used rather than the short-term SD observed for CRM material. Here we suppose that the long-term SD_A is 0.8 mmol/L. Data on preanalytical variation is obtained by sampling in duplicates from a series of patients or can be a matter of judgment (type B uncertainty) based on literature data or data on similar analytes. We here suppose that SD_{PA} equals half the analytical SD (i.e., 0.4 mmol/L). Finally, we lack data on a possible sample-related random bias component, which we may choose to ignore in the present example. The standard uncertainty of the results then becomes

$$u_{st} = \left[u_{P\,Ast}^2 + u_{Ast}^2 + u_{R\,B\,st}^2 + u_{Trac\,st}^2\right]^{0.5} = \left[0.4^2 + 0.8^2 + 0.26^2\right]^{0.5} = 0.93\ (\text{mmol/L})$$

In this case, the major uncertainty component is the long-term imprecision in the laboratory.

Indirect Evaluation of Uncertainty by Quantification of Individual Error Source Components

On the basis of a detailed quantitative model of the analytical procedure, the standard approach is to assess the standard uncertainties associated with the individual input parameters and combine them according to the law of propagation of uncertainties.[6] The relationship between the combined standard uncertainty $u_c(y)$ of a value y and the uncertainty of the independent parameters $x_1, x_2, \ldots x_n$, on which it depends, is

$$u_c\ [y(x1,x2,\ldots)] = \left[\sum c_i^2 u(x_i)^2\right]^{0.5}$$

where c_i is a sensitivity coefficient (the partial differential of y with respect to x_i). These sensitivity coefficients indicate how the value of y varies with changes in the input parameters x_i. If the variables are not independent, the relationship becomes

$$u_c\ [y(x_i,x_k,\ldots)] = \sum c_i^2 u(x_i)^2 + \left[\sum c_i c_k u(x_i,x_k)^2\right]^{0.5}$$

where $u(x_i, x_k)$ is the covariance between x_i and x_k, and c_i and c_k are the sensitivity coefficients. The covariance is related to the correlation coefficient ρ_{ik} by

$$u(x_i, x_k) = u(x_i)u(x_k)\,\rho_{ik}$$

TABLE 2-6 Relations Between Standard Deviation and Range for Various Types of Distributions

Gaussian Distribution	Rectangular Distribution	Triangular Distribution
SD = Half-width of 95% interval/$t_{0.975}(\nu) \approx$ Half-width of 95% interval/2	SD = Half-width/$\sqrt{3}$	SD = Half-width/$\sqrt{6}$

This is a complex relationship that usually will be difficult to evaluate in practice. In many situations, however, the contributing factors are independent, thus simplifying the picture. Below, some simple examples of combined expressions are shown. The rules are presented in the form of combining SDs or coefficients of variation (CVs) given independent input components.[6A]

$$q = x + y \quad SD(q) = \left[SD(x)^2 + SD(y)^2\right]^{0.5}$$

$$q = x - y \quad SD(q) = \left[SD(x)^2 + SD(y)^2\right]^{0.5}$$

$$q = ax \quad SD(q) = a\,SD(x) \text{ and } CV(q) = CV(x)$$

$$q = x^p \quad CV(q) = p\,CV(x)$$

$$q = xy \quad CV(q) = \left[CV(x)^2 + CV(y)^2\right]^{0.5}$$

$$q = x/y \quad CV(q) = \left[CV(x)^2 + CV(y)^2\right]^{0.5}$$

For example, the shown formulas may be used to calculate the combined uncertainty of a calibrator solution from the uncertainties of the reference compound, the weighting, and dilution steps.

Some relations between the SD and non-Gaussian distributions may also be of relevance for uncertainty calculations (Table 2-6). For example, if the uncertainty of a CRM value is given with some percentage, it may be understood as referring to a rectangular probability distribution. In relation to calibration of flasks, the triangular distribution is often assumed.

Software Packages

Statistical analyses today are usually carried out in spreadsheets or by statistical programs. Concerning the latter, large, general program packages or smaller programs more or less specialized toward the field of clinical chemistry may be applied. Various large, general packages are now on the market (e.g., SPSS, SAS, Stata, Systat). Among programs of an intermediate size, GraphPad (www.graphpad.com; accessed July 6, 2013) and SigmaStat should be mentioned. Excel (Microsoft) also contains various statistical routines. The general programs may lack procedures of interest to clinical chemists (e.g., the Deming and Passing-Bablok procedures). Among more or less specialized programs

for clinical chemistry, Analyze-it (www.analyze-it.com; accessed July 6, 2013), MedCalc (www.medcalc.be; accessed July 6, 2013), StatisPro (CLSI), and a program distributed by one of the authors (KL), CBstat (www.cbstat.com; accessed July 6, 2013), are available. The latter program includes automated routines for method validation (e.g., the Deming and Passing-Bablok procedures), reference interval estimation, and diagnostic test evaluation.

Review Questions

1. The type of error that occurs when an analytical method is nonspecific for an analyte and is actually considered to be a type of bias is:
   a. systematic error.
   b. nonsystematic error.
   c. random error.
   d. true error.
2. The statistical analysis commonly applied when the results of analytical method comparison that involves a plot of paired observations (one from the established method and the other from the new method) are assessed is:
   a. uncertainty analysis.
   b. traceability analysis.
   c. regression analysis.
   d. difference analysis.
3. In the selection of a new method, the first step in selecting a candidate method is the determination of:
   a. reliability.
   b. total allowable error.
   c. specifics of the assay including reagent stability.
   d. what is necessary clinically from a laboratory test.
4. To categorize whether a systematic error is either constant or proportional, one must assume and test for:
   a. randomness.
   b. linearity.
   c. precision.
   d. accuracy.
5. Which one of the following, when stated as an interval around a reported laboratory result, will specify the location of the true value with a given probability?
   a. Traceability
   b. Coefficient of variation
   c. Trueness
   d. Uncertainty
6. The closeness of agreement between independent results of measurements obtained under specific conditions is:
   a. linearity.
   b. precision.
   c. accuracy.
   d. specificity.
7. Analytical specificity is:
   a. the ability of an assay procedure to determine the concentration of a target analyte in the presence of interfering substances in the sample matrix.
   b. the detection limit of a method.
   c. the ability of an analytical method to assess small variations in the concentration of analyte.
   d. the analyte concentration range over which measurements are within the declared tolerances for imprecision and bias of the method.
8. In a regression analysis that compares results of two methods, the y-intercept is calculated to be 2.0 and the slope is 3. This is indicates a(n):
   a. calibration error.
   b. uncertainty.
   c. systematic difference.
   d. interference in one method.
9. A type of regression analysis that is used to estimate slope and intercept and that is acceptant to outlier values in the methods and does not require assumption of a Gaussian distribution is:
   a. weighted Deming regression analysis.
   b. ordinary least-squares regression analysis.
   c. linear regression analysis.
   d. nonparametric regression analysis.
10. In a method comparison analysis, the lowest value of an analyte that significantly exceeds the measurement of a blank sample is referred to as the
    a. limit of detection of a method.
    b. analytical sensitivity.
    c. analytical specificity.
    d. basic error of a method.

CHAPTER 3

Clinical Evaluation of Methods

Edward R. Ashwood, M.D., and David E. Bruns, M.D.

Objectives

1. Define the following terms:
   - Likelihood ratio
   - Odds ratio
   - Predictive value
   - Prevalence
   - Receiver operating characteristic plot
   - Sensitivity
   - Specificity
   - True/false positive
   - True/false negative
2. State the formulas for and calculate, given appropriate information, the following: sensitivity, specificity, predictive value for positive/negative tests, odds ratio, and positive/negative likelihood ratio.
3. State the relationship between high sensitivity and false negatives; state the relationship between high specificity and false positives.
4. Compare dichotomous and continuous tests; include definition, sensitivity/specificity, and a clinical example of each type of test.
5. State how the predictive value of a laboratory test is affected by prevalence.
6. Construct and interpret a receiver operating characteristic plot using data from a diagnostic test study.
7. Describe Bayes' theorem, its usefulness in the clinical laboratory, and its main limitation.
8. Write the formula for and calculate with Bayes' theorem the probability of disease given a positive test result.
9. Describe "combination testing" as it is used in the clinical laboratory; include examples, diagnostic usefulness, and associated problems.

Key Words and Definitions

Likelihood ratio The probability of occurrence of a specific test value given that the disease is present divided by the probability of the same test value if the disease was absent.

Odds ratio The probability of the presence of a specific disease divided by the probability of its absence.

Predictive value of a positive test The proportion of subjects with a positive test who have the disease.

Predictive value of a negative test The proportion of subjects with a negative test who do not have the disease.

Prevalence The frequency of disease in the population examined.

Receiver operating characteristic plot A graph of sensitivity versus 1 − specificity for all possible cutoff values of a diagnostic test; used to estimate sensitivity and specificity for various decision cutoffs.

Sensitivity The proportion of subjects with disease who have a positive laboratory test result.

Specificity The proportion of subjects without disease who have a negative laboratory test result.

Whenever a clinician or a healthcare professional uses a laboratory test, he or she needs to have a clear understanding of the clinical performance characteristics of that test. The extent of agreement of test results with accurate patient diagnosis is represented in several ways, including (1) sensitivity and specificity, (2) predictive values, (3) receiver operating characteristic (ROC) curves, and (4) likelihood ratios.

Sensitivity and Specificity

The **sensitivity** of a test reflects the fraction of those with a specified disease that the test correctly predicts. The **specificity** is the fraction of those without the disease that the test correctly predicts. Table 3-1 shows the classification of unaffected and diseased individuals by test result. True positives (TPs) are those diseased individuals who are correctly classified by the test. False positives (FPs) are nondiseased individuals misclassified by the test. False negatives (FNs) are those diseased patients misclassified by the test. True negatives (TNs) are nondiseased patients correctly classified by the test.

$$\text{Sensitivity} = \frac{TP}{TP + FN}$$

TABLE 3-1 Classifications of a Test Result Applied to Unaffected and Diseased Populations

	Number of Patients with Positive Test Result	Number of Patients with Negative Test Result
Number of patients with disease	TP	FN
Number of patients without disease	FP	TN

FN, False negative (number of diseased patients misclassified by the test); FP, false positive (number of nondiseased patients misclassified by the test); TN, true negative (number of nondiseased patients correctly classified by the test); TP, true positive (number of diseased patients correctly classified by the test).

$$\text{Specificity} = \frac{TN}{TN + FP}$$

Both high sensitivity (few FNs) and high specificity (few FPs) are desirable characteristics for a test, but one is typically preferred over the other, depending on the clinical situation.

By design, some tests have only positive or negative results and provide qualitative results. These tests, which are termed dichotomous, have a single sensitivity and specificity pair for a designated assay cutoff. If a cutoff value is selected to produce high sensitivity, the specificity often will be compromised. Likewise, cutoffs that maximize specificity lower sensitivity.

An example of a dichotomous test is the human immunodeficiency virus (HIV) screening test. This test detects HIV antibodies, producing results that may be nonreactive (negative) or reactive (positive). False positives occur owing to technical errors such as mislabeling or contamination and the presence of cross-reacting antibodies found in individuals such as multiparous women and multiply transfused patients.[10] False negatives occur because of technical problems such as pipetting errors and sampling determinants such as testing in early infection (3 to 4 weeks) before antibody production. Reported sensitivities and specificities for the HIV screening test vary widely,[9] but reasonable estimates are 96% and 99.8%, respectively. Thus, 4 of 100 HIV-infected subjects will test negative. Only 2 of 1000 noninfected subjects will test positive. The clinical usefulness of an HIV test result from an unknown subject will be explained later in the "Probabilistic Reasoning" section.

As opposed to dichotomous tests, continuous tests are those that produce quantitative results. Continuous tests have an infinite number of sensitivity and specificity pairs, as the cutoff varies from lowest to highest decision value.

Figure 3-1 is a dot plot of the performance of a continuous assay for prostatic-specific antigen (PSA) in patients with benign prostatic hyperplasia (BPH) and in those with established carcinoma of the prostate (stages A through D).[5] Often continuous tests are used in a dichotomous fashion by choosing one or more decision cutoffs. Note the two dashed lines crossing the graphs that represent two diagnostic cutoffs. Both tests A and B are PSA tests, but they have different decision cutoffs, namely, 4 μg/L and 10 μg/L. When test A is compared with test B, the decision cutoff of 4 μg/L for test A produces increased sensitivity but at the cost of a decrease in specificity. Thus increased true-positive detection has been traded for an increase in the number of false-positive results. This tradeoff occurs in every test performed in medicine.

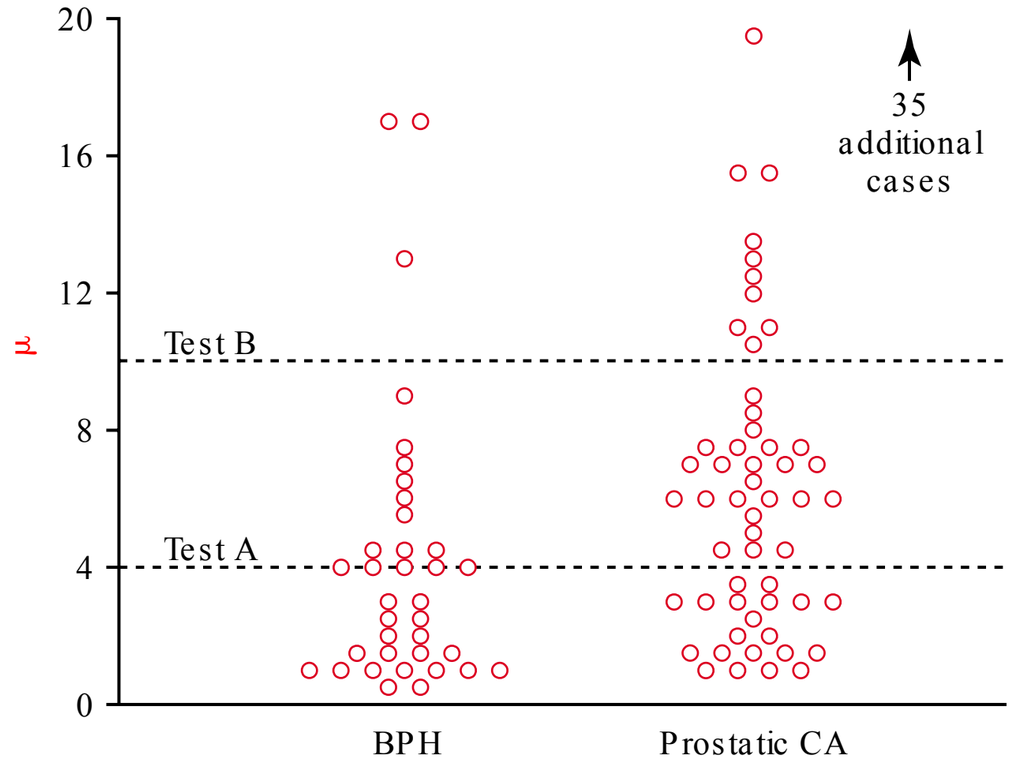

Figure 3-1 Prostate-specific antigen (PSA) concentrations for patients with benign prostatic hyperplasia (BPH) and known prostatic carcinoma (CA) are shown with two decision-level cutoffs.

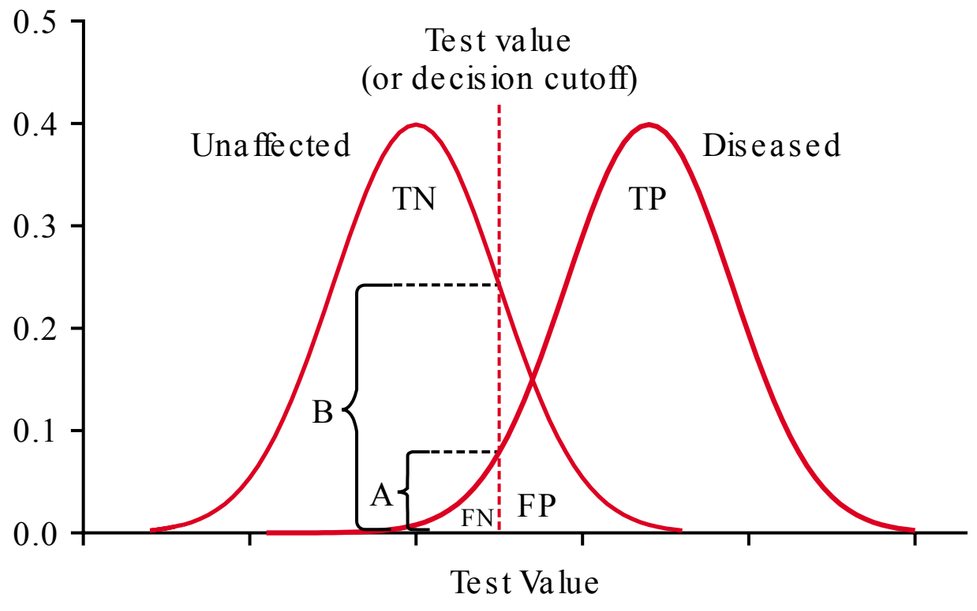

Figure 3-2 Simulated distributions of unaffected and diseased populations. Note that the ratio of diseased patients to healthy patients, A to B, is less than 1 and is very different at the point of decision (the likelihood ratio) from the ratio of TP to FP, which is much greater than 1. FN, False negative; FP, false positive; TN, true negative; TP, true positive.

Figure 3-2 illustrates a hypothetical test that shows higher results in patients who have a disease compared with those who are unaffected. As the decision cutoff is increased, FPs decrease and FNs increase. At extremely low and extremely high cutoffs, sensitivity and specificity are 100%.

Receiver Operating Characteristic Plots[7]

The dot plot (see Figure 3-1) displays quantitative performance in a limited fashion. For example, one cannot easily estimate sensitivity and specificity for various decision cutoffs using the dot plot. A graphical technique for displaying the same information is called a **receiver operating characteristic (ROC)**

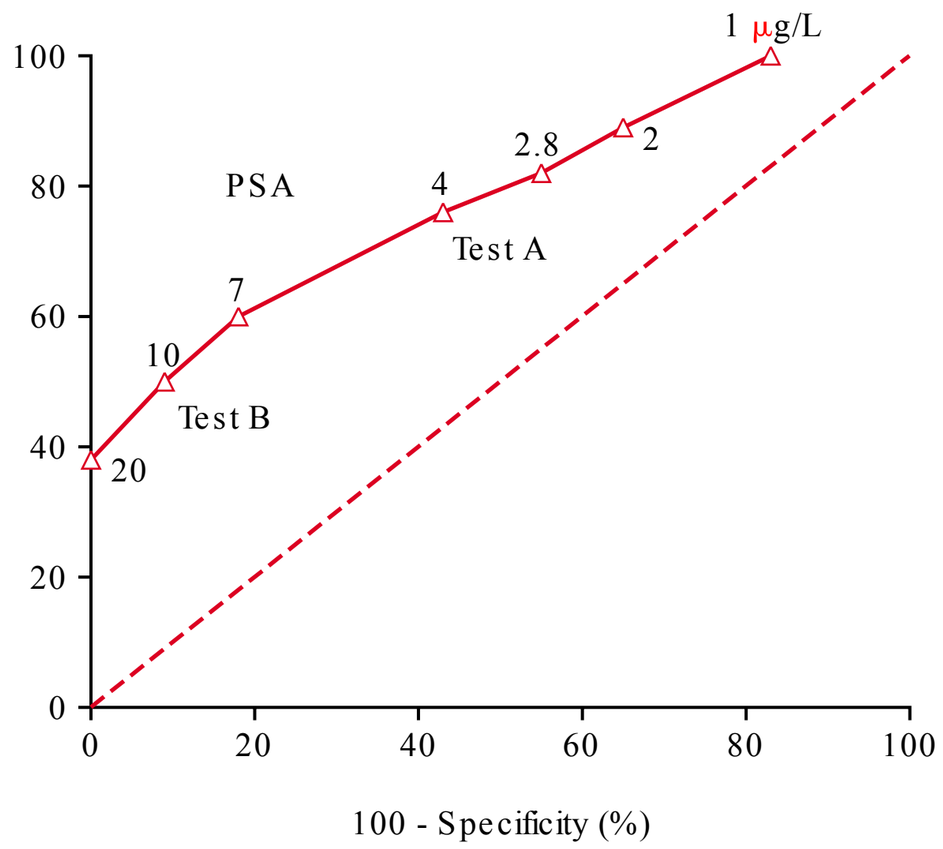

Figure 3-3 Receiver operating characteristic curve of prostate-specifc antigen (PSA). Each point on the curve represents a different decision level. The sensitivity and 1 − specifcity can be read for tests A and B, with 4 and 10 µg/L as decision thresholds, respectively.

plot. An ROC curve is generated by plotting sensitivity (y-axis) versus 1 − specificity (x-axis).[7]

Figure 3-3 shows the ROC curve for the data in Figure 3-1. The x-axis plots the fraction of nondiseased patients who were erroneously categorized as positive for a specific decision threshold. This is "false-positive rate" is mathematically the same as 1 − specificity. The y-axis plots the "true-positive rate" (the sensitivity). A "hidden" third axis is contained within the curve itself: The curve is drawn through points that represent different decision cutoff values. Those decision cutoffs are listed as labels on the curve. The entire curve is a graphical display of the performance of the test.

Tests A and B from Figure 3-3 are displayed as two decision points on the ROC curve. The dotted line extending from the lower left to the upper right represents a test with no discrimination and is designated the random guess line. A curve that is "above" the diagonal line describes performance that is better than random guessing. A curve that extends from the lower left to the upper left and then to the upper right is a perfect test. The area under the curve describes the test's overall performance. The strength of the ROC plot lies in its provision of a meaningful comparison of the diagnostic performance of different tests. In the medical literature, the use of 2 × 2 tables to present the sensitivity and specificity of a test has led to the common logical misconception that a quantitative test has a single sensitivity and specificity. When the initial publication of an assay recommends a cutoff for analysis purposes, the assay is often categorized as sensitive or specific on the basis of this cutoff. Yet, as seen in the ROC curve, every assay will be as sensitive as desired at some cutoff and as specific as desired at another. When two procedures are compared, confusion is avoided by using ROC curves instead of accepting statements such as, "Test A is more sensitive, but test B is more specific."

The area under the ROC curve is a relative measure of a test's performance. A Wilcoxon statistic statistically determines which ROC curve has more area. Area comparisons are particularly helpful when the curves do not intersect. When the ROC curves of two laboratory tests assessing for the same disease intersect, the tests may exhibit different diagnostic performances, even though the areas under the curve are identical. Test performance depends on the region of the curve (e.g., high sensitivity vs. high specificity) chosen.

Probabilistic Reasoning

Although the ROC curve improves our ability to judge a test's performance, a result should not be interpreted in isolation. The clinician must take into account the clinical setting before rendering an interpretation. For example, a positive HIV screening test has a different meaning for an adult as compared with a newborn. In the newborn, antibodies detected by an HIV test are maternal antibodies; thus the result is an indication of the HIV status of the newborn's mother.

Interpretation of almost all laboratory test results is affected by the probability of the disorder before testing. For example, an elevated PSA concentration in a 35-year-old is not interpreted in the same way as in a 70-year-old because the rate of occurrence of prostatic cancer in 35-year-olds is much lower than that in older men.[11] Interpretation must be tempered by knowledge of the prevalence of the disease.

Prevalence

Prevalence is defined as the frequency of disease in the population examined. Several useful techniques have been applied to combine the prevalence with information previously obtained in the results of testing.

Predictive Values

The results of dichotomous tests (and continuous tests used in a dichotomous manner) are interpreted using predictive values. The **predictive value of a positive test** (PV+) is the fraction of subjects with a positive test who have the disease. The **predictive value of a negative test** (PV−) is the fraction of subjects with a negative test who do not have the disease. The predictive value equations are as follows:

$$PV^{-} = \frac{TN}{TN + FN} \qquad PV^{+} = \frac{TP}{TP + FP}$$

Predictive values are a function of sensitivity, specificity, and prevalence. It is regrettable that clinicians often confuse sensitivity with PV+. For example, consider a situation where 1,000,000 U.S. residents were randomly chosen and tested for HIV infection using the HIV screening test. The Centers for Disease Control and Prevention estimates that the prevalence of HIV infection in the United States is 330.4 per 100,000 population.[4] On the basis of this prevalence, about 3304 infected individuals would be expected in a population of

1 million. Because the sensitivity of the HIV test is 96%, about 3172 infected individuals would have a positive test result (i.e., TP = 3172). Similarly, because the specificity of the HIV test is 99.8%, about 2 FPs per 1000 subjects would be expected. Thus about 1993 individuals would have false-positive results (i.e., FP = 1993). Therefore, the PV+ is 3172/(3172 + 1993), or 61%. Thus a random individual with a positive test result has a moderate chance of having a false-positive result. Additional testing is necessary to separate TP individuals from FP individuals. Most laboratories automatically test all specimens that have a positive HIV screening result with a confirmatory test such as the HIV Western blot.

In this example, the PV− is much higher than the PV+. Calculations reveal 132 false-negative results (3304 − 3172) and about 994,703 true negatives (99.8% × [1,000,000 − 3304]). Thus, the PV− is 99.987%. Note that many of the FNs could reflect these infected individuals with early HIV infection before antibody development. The limitation of FNs can be overcome by frequent testing of high-risk individuals.

Odds Ratio

The **odds ratio** (OR) is defined as the probability of the presence of a specific disease divided by the probability of its absence. The odds ratio reflects the prevalence of the disease in a population.

$$\text{Odds Ratio} = \frac{\text{Probability of event}}{1 - \text{Probability of event}}$$

Likelihood Ratio

The **likelihood ratio** (LR) is the probability of occurrence of a specific test value given that the disease is present divided by the probability of the same test value if the disease was absent. Choi[6] describes three different slopes of the ROC curve, which represent LR in different settings (as illustrated in Figure 3-4):

1. The tangent slope, which is equal to the LR of a continuous test at a given test value
2. The slope from the origin to a test value equal to a decision cutoff, the LR+ for a positive result of a dichotomous test; this slope has a companion slope (which is the slope from the cutoff value to the upper right corner of the ROC plot), which represents the LR− for a negative result of a dichotomous test.
3. A slope between any two test values (not illustrated in Figure 3-4), which is termed the interval LR and represents the LR of a result that lies between the values; the interval LR is useful for continuous tests that have results grouped into intervals.

For qualitative tests, the positive likelihood ratio (LR+) is equal to the sensitivity/(1 − specificity). Conversely, the negative likelihood ratio (LR−) is the probability of occurrence of a specific test value given that the disease is absent divided by the probability of the same test value if the disease were present. Thus for qualitative tests, the LR− is specificity/(1 − sensitivity).

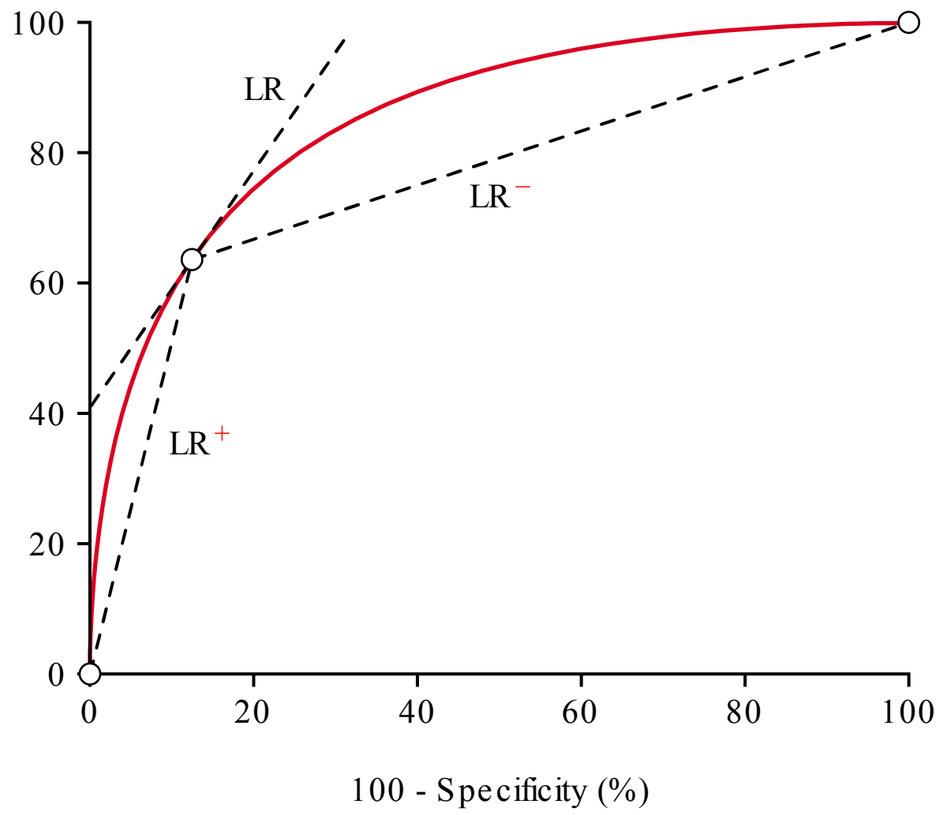

Figure 3-4 Receiver operating characteristic curve illustrating the slopes that define the likelihood ratio (LR) for a continuous test at a specific test result (the gray point) and the positive likelihood ratio (LR+) and the negative likelihood ratio (LR−) of a dichotomous test.[6]

For quantitative tests, the LR is the tangent slope of the ROC curve, which equals the ratio of the heights A and B of the two curves at the test value in Figure 3-2. Note that the areas under each curve in Figure 3-2 are the same. The likelihood ratio does not take disease prevalence or any other prior information into account. To arrive at a final probability, one must adjust for the best estimate of the probability of disease before obtaining the test result.

Bayes' Theorem

Bayes' theorem provides a method of calculating the probability of a disease after new information is added to previously obtained information. The basic theorem is usually written as follows:

$$P(D|R) = \frac{P(R|D) \times P(D)}{P(R)}$$

where D is disease and R is a positive result. Thus the above equation is "the probability of disease given a particular result is equal to the probability of that result given the disease (i.e., sensitivity) times the probability of disease (i.e., prevalence) divided by the overall probability of having that result." For a dichotomous test, the probability of a positive result is equal to the numerator of the equation plus P(R|not D) × P(not D), or (1 − specificity) × (1 − prevalence). Thus, Bayes' theorem can be rewritten to express the probability of disease given a positive test result as follows:

$$P(D|R) = \frac{\text{Sensitivity} \times \text{Prevalence}}{\text{Sensitivity} \times \text{Prevalence} + (1 - \text{Specificity}) \times (1 - \text{Prevalence})}$$

Bayes' theorem is also applied with the use of the likelihood ratio. The odds ratio of the occurrence of a disease is

calculated before the test result is known; this information is then combined with the LR. The final result is again in the form of an odds ratio, which can be converted into a probability, if desired.

$$\text{Odds ratio after testing} = \text{Odds ratio before testing} \times \text{Likelihood ratio of a given test result}$$

The calculation of the post-test probability has also been solved using a convenient nomogram.[3]

Limitations of Bayes' Theorem

Although Bayes' theorem is widely recommended as an aid to refine the probabilistic estimates of disease, it rests on the assumption of test independence, which often is not present. As an extreme example of the possible errors that occur when nonindependent tests are used, consider testing the PSA concentration of a BPH patient on three consecutive days. Each day, the PSA value is approximately 10 μg/L. The LR for this result is then estimated from the tangent of the slope at 10 μg/L in Figure 3-2. This slope is approximately 1.2. Using the likelihood form of Bayes' theorem, next multiply the prior odds ratio (assume 10 to 90) by the LR to obtain the odds ratio after 0.13, or a probability of 12% after the first test. The odds ratio is 1.2 × 0.13 = 0.16 after the second test, and finally 0.19 after the third test. This gives a 16% probability of disease. Very little new information has been provided by the second and third tests, yet the probability of disease has apparently increased from 10% to 16%.

Judging independence is difficult without collecting a large set of clinical data and examining them mathematically. A useful approach is to think about the incorrect results given by each test. If both tests tend to yield incorrect results for the same patients, then the tests are not independent, and thus Bayes' theorem cannot be applied to the combination of their results to correctly estimate the probability of disease. If the tests seem intuitively to be independent, then the errors made by assuming independence are likely to be small.

Combination Testing

Panels of tests are commonly used to increase sensitivity and specificity or are used sequentially to decrease costs. For the practicing laboratorian, the value of panels is limited by sparse literature on the performance of combinations of tests. The same issue of test independence addressed in the previous section makes it difficult to calculate the performance of panels of tests. In addition, the use of multiple tests can increase the probability of the occurrence of false-positive or false-negative results, depending on how the tests are combined. The often used maternal serum screening panel described in Chapter 44 uses four tests but combines the results using a log normal covariate distribution model, which adjusts for lack of independence among the tests.[13]

Because most reference intervals exclude a fraction of those patients without disease, there is an expected false-positive rate. As multiple tests are added to panels, the probability of false-positive results increases. Efforts have been made to establish multivariate reference intervals that correct for multiple tests and their interrelationships, but the concept has not found widespread acceptance. Although this concept is mathematically reasonable, those who have investigated the utility of multivariate reference intervals believe that more work is needed before they will prove useful.

TABLE 3-2 Combination Test Performance Maximizing Specificity*

	Sensitivity, %	Specificity, %	Cost
Test A	80	99	$100
Test B	99	80	$100
A followed by B	79.2	99.8	
Prevalence = 0.2			$117
Prevalence = 0.8			$164
B followed by A	79.2	99.8	
Prevalence = 0.2			$136
Prevalence = 0.8			$183

*Results of test A and test B must be positive for a positive diagnosis to be made.

The gain in test performance to be achieved by combining test results may be illusory. As demonstrated by the dot plot in Figure 3-1, and by the ROC curve in Figure 3-3, it is possible to increase sensitivity at the expense of decreased specificity. This is does not guarantee that the individual test, if the decision threshold were modified to improve sensitivity, would not have comparable performance.

A widely held belief[14] is that one should first test with a sensitive test and then follow up the occurrence of positive results with a specific test for best performance. The logic for this is that if the first test determines which patients are to undergo a second test, the first test should be the more sensitive of the two, to ensure that the disease has not been missed. It is surprising that even when the first test determines which patients will undergo a second test, the order in which the tests are performed does not affect the combination of sensitivity and specificity. However, it does affect the overall cost. In the following examples, two hypothetical tests that are independent are used sequentially. It is assumed that fixed decision limits are used for the two tests and that the two tests cost the same. Although these tests are hypothetical, the principles are generally applicable to other sequential testing situations.

Example 1. Often care is optimized if it is confirmed that a disease is not present. In this case, if screening test A yields a positive result, it will be followed by test B; otherwise, testing stops. If test B yields a positive result, then the overall interpretation is a positive result. Because tests A and B are necessary for the diagnosis, specificity is improved; however, sensitivity decreases compared with the use of test A alone. As shown in Table 3-2, the average cost of the combination varies with disease prevalence; however, note that performance of the more specific test first results in lower expected costs. This lower cost would be accentuated if the second test were to cost more than the first.

The net effect of the use of the test combination compared with the use of test A alone has been a fivefold decrease in the

TABLE 3-3 Combination Test Performance Maximizing Sensitivity*

	Sensitivity, %	Specificity, %	Cost
Test A	80	99	$100
Test B	99	80	$100
A followed by B	99.8	79.2	
Prevalence = 0.2			$183
Prevalence = 0.8			$136
B followed by A	99.8	79.2	
Prevalence = 0.2			$164
Prevalence = 0.8			$117

*Results of test A or test B must be positive for a positive diagnosis to be made.

false-positive rate with a decrease of 0.8% in the true-positive rate. Whether this tradeoff is desirable depends on the implications of missing a diagnosis versus generating false-positive results.

Example 2. Diagnosing a curable disease that has a low-cost therapy often increases the relative value of sensitivity over specificity. If the first test result is negative, the second test might still be performed to maximize sensitivity. When either of two tests yields a positive result, this would be interpreted as a positive finding overall. This is more typically seen when tests are done simultaneously, but it also occurs in sequential testing. In Table 3-3, a negative result on the first test is followed by performance of the second test; otherwise, testing ceases. If the result of the second test is negative, the overall interpretation is negative. The cost of performing tests sequentially with this rule varies with prevalence, as can be seen in Table 3-3. When this rule is used, the combination sensitivity increases as the specificity decreases. Note that the strategy of first using the test with lower specificity results in lower average cost.

According to the strategy outlined in Table 3-2, the first test's specificity determines the cost of sequential testing. When the strategy is to confirm all negative results of the first test (see Table 3-3), the first test should be the more sensitive, so as to minimize costs. As demonstrated in the two examples presented earlier, the decision rule used preferentially trades off sensitivity at the expense of specificity, or vice versa. Although independent tests have been used in these examples, the conclusions are the same for dependent tests. It should be remembered that it is the interpretive rule and the two tests that determine the overall panel performance and costs; the order of testing does not affect performance but can dramatically affect costs.

Methods of Assessing Diagnostic Accuracy

Most studies of diagnostic accuracy are cross-sectional as opposed to longitudinal, attempting to determine the utility of a test at a single point in time. The results of a new test (often referred to as the index test, the test of interest) are compared with those from a "gold standard test" using the same subjects, which is more formally called a reference standard (the best current practice for establishing the presence of a disorder). The reference standard often includes many methods of establishing a subject's health status, such as (1) additional laboratory tests, (2) imaging tests, (3) medical history, (4) physical examination, and (5) clinical changes over time.

Around 1980, some investigators realized that most diagnostic accuracy studies contained serious flaws, introducing biases into reported performance characteristics. The work of advocates for improved study design and reporting led to the development of many important assessment tools.[8] Of note are QUADAS (Quality Assessment of Diagnostic Accuracy Studies)[15] and STARD (Standards for Reporting of Diagnostic Accuracy).[1,2] Both QUADAS and STARD are described in greater detail in Chapter 4.

Well-designed studies minimize several sources of bias and variation, including those that affect the selection of study subjects (both patients and controls), verification using the reference standard, observer/technician bias, missing or incomplete patient data, and analysis techniques that affect estimates of diagnostic accuracy. A 2006 meta-analysis concluded that most reported studies have shortcomings that variably affect estimates of diagnostic accuracy.[12] Often, an incomplete study description prevents full assessment of potential sources of bias and variation. Chapter 3 of Tietz Textbook of *Clinical Chemistry and Molecular Diagnostics*, 5th edition, describes how to design a study to assess diagnostic accuracy.

Review Questions

1. A dichotomous laboratory test is one that produces _____ results.
   a. semi-quantitative
   b. quantitative
   c. qualitative
   d. semi-qualitative
2. When a receiver operating characteristic plot is plotted, the x-axis plots the:
   a. false-positive rate.
   b. true-positive rate.
   c. false-negative rate.
   d. true-negative rate.
3. The frequency of a disease in a particular population is referred to as its:
   a. predictive value.
   b. likelihood.
   c. probability.
   d. prevalence.
4. The probability of the presence of a specific disease divided by the probability of its absence is the:
   a. likelihood ratio.
   b. odds ratio.
   c. prevalence.
   d. predictive value.
5. True positives /(true positives + false positives) is the formula used to determine the:
   a. predictive value of a positive test.
   b. predictive value of a negative test.
   c. prevalence.
   d. odds ratio.

6. A graphical plot for quantitative analyses that is generated using sensitivity and 1 − specificity and is used to estimate sensitivity and specificity at various decision cutoff values is a:
   a. Bayes' theorem plot.
   b. Levey-Jennings chart.
   c. receiver operating characteristic plot.
   d. dot plot.
7. An important limitation of using Bayes' theorem for determining probabilities of having a particular disease given a specific result is that the theorem assumes:
   a. test dependence.
   b. result independence.
   c. an odds ratio of 50%.
   d. test independence

CHAPTER

4 Evidence-Based Laboratory Medicine

Christopher P. Price, Ph.D., Patrick M.M. Bossuyt, Ph.D., and David E. Bruns, M.D.

Objectives

1. Define the following terms or acronyms:
   - Bias
   - Evidence-based medicine
   - Evidence-based laboratory medicine
   - External validity
   - Index test
   - Internal validity
   - Meta-analysis
   - QALY
   - Quality
   - Randomized controlled trial
   - STARD
2. State the justification for practicing an evidence-based approach to medicine and evidence-based laboratory medicine; list and describe the five major needs in evidence-based laboratory medicine studies.
3. State the four diagnostic questions addressed by the decision-making process in laboratory medicine.
4. Compare and contrast internal and external validity in relation to a diagnostic accuracy study.
5. Discuss the STARD initiative, including its uses, its components, and its application in the clinical laboratory.
6. Explain the need for and describe the different types of outcome studies in medical practice; compare outcome studies with prognostic value studies.
7. Design a mock randomized controlled trial, including subjects, treatments or interventions, and measurable outcomes.
8. List and describe the key steps of a systematic review of a diagnostic test.
9. List and describe five methods of evaluating the economic impact of a diagnostic test; state how economic evaluations are perceived by patients, laboratory practitioners, clinicians, insurance companies, and society.
10. State the need for clinical practice guidelines and clinical audits; list the steps involved in preparing clinical practice guidelines and problems that might be involved in these steps; list and describe the four components of a clinical audit.

Key Words and Definitions

Bias Systematic error that occurs when there is constant overestimation or underestimation of a measured value as opposed to random error, which is unpredictable.

Clinical audit A review of case histories of patients against the benchmark of current best practice; used as a tool to improve clinical practice.

Clinical practice guidelines Systematically developed statements to assist practitioner and patient decisions about appropriate healthcare for specific clinical circumstances; in the laboratory, goals for accuracy, precision, and turnaround times of tests are included.

Clinical reference standard The best available method for establishing the presence or absence of the target condition; also, the suspected condition or disease for which the target is to be applied.

Diagnostic accuracy The closeness of agreement between values obtained from a diagnostic test (index test) and those of reference standard (gold standard) for a specific disease or condition; these results are expressed in a number of ways, including sensitivity and specificity, predictive values, likelihood ratios, diagnostic odds ratios, and areas under receiver operating characteristic (ROC) curves.

Evidence-based medicine The conscientious, judicious, and explicit use of best evidence in making decisions about the care of individual patients.

Evidence-based laboratory medicine The application of principles and techniques of evidence-based medicine to laboratory medicine; the conscientious, judicious, and explicit use of best evidence in laboratory medicine investigations to assist decision making about the care of individual patients.

Index test In diagnostic accuracy studies, the "new" test or the test of interest.

Outcomes Results related to the quality or quantity of life of patients; examples include mortality, functional status, quality of life, and well-being.

Outcomes studies Studies performed to determine whether a medical intervention (such as a specific laboratory test) will improve patient outcomes.

Key Words and Definitions—cont'd

Randomized controlled trial An experimental study in which study participants are randomly allocated to an intervention (treatment) group or an alternative treatment (control) group.

STARD Standards for Reporting of Diagnostic Accuracy; a project designed to improve the quality of reporting of the results of diagnostic accuracy studies.

Systematic review A methodical and comprehensive review of all published and unpublished information about a specific topic to answer a precisely defined clinical question.

In this chapter, we review the new influences on clinical chemistry and laboratory medicine from the fields of clinical epidemiology and evidence-based medicine (EBM). Key chapter topics include the following:

- How to assess the diagnostic accuracy of tests
- How to use clinical outcomes studies.
- Ways to evaluate the economic value of medical tests.
- How to conduct systematic reviews of diagnostic tests.
- How to use clinical practice guidelines.
- When and how to conduct a clinical audit.

These principles provide a foundation for the rational and appropriate use of diagnostic tests.

Clinical chemists/laboratorians must know (1) how to select tests based on their analytical performance, (2) how well tests perform as diagnostic or prognostic tests, and (3) how use of tests affects the care of patients. Clinical epidemiologists have developed study designs to quantify the diagnostic (and prognostic) accuracy of the tests employed in laboratory medicine. They have also developed study methods that can be used to evaluate the value of laboratory testing and its effect on patient outcomes and, more broadly, on healthcare. Practitioners of Evidence Based Medicine (EBM) focus on using the best available evidence from such well-designed studies in the care of individual patients. In practice, EBM does the following:

- Rephrases problems as structured clinical questions in the clinical care of patients.
- Looks for (or develops) available evidence.
- Evaluates the quality of that evidence (clinical studies).
- Evaluates the clinical implications of the results (including the impact of changes in practice).
- Provides tools to help clinicians use those results, both effectively and efficiently, in the care of individual patients.

Today, these principles are applied in decisions about whether or not to introduce new tests, as well as in the audit of utilization of tests (see later in chapter).

Evidence-Based Medicine—What Is It?

Since the term **evidence-based medicine** was introduced in 1991, EBM has had an important influence on medicine.

Definition and Goals of Evidence-Based Medicine

In this chapter, EBM is defined as "the conscientious, judicious, and explicit use of the best evidence in making decisions about the care of individual patients."[11] The word judicious implies the use of skills of experienced clinicians to put evidence in context and to recognize patient individuality and preferences. A goal of EBM is "to incorporate the best evidence from clinical research into clinical decisions."[5] The word best implies the necessity for critical appraisal. The words making decisions indicate why the principles of EBM must be applied in laboratory medicine, as laboratory medicine is one of the fundamental tools used in making decisions in the practice of medicine.

Justifications for an evidence-based approach to medicine are founded in the following: (1) constant requirement for information; (2) constant addition of new information; (3) recognition of poor quality of access to good information; (4) decline in up-to-date knowledge and/or expertise with advancing years of an individual clinician's practice; (5) limited time available to read the literature; and (6) variability in the values and preferences of individual patients. To this one might add, specifically in relation to laboratory medicine, (1) limited number and poor quality of studies linking test results to patient benefits, (2) poor appreciation of the value of diagnostic tests, (3) relatively limited integration of laboratory medicine services into the care pathway, as witnessed by poor adherence to clinical practice guidelines, (4) ever-increasing demand for tests, and (5) disconnected approach to resource allocation (reimbursement) in laboratory medicine—"silo budgeting," which addresses only laboratory costs without consideration of benefit outside the laboratory. Silo budgeting forces healthcare staff to make decisions that save expense in the laboratory but provide insufficient attention to the needs of patients, caregivers, and payers. Silo budgeting also stifles innovation and inhibits change. EBM is a rational counterforce.

The Practice of Evidence-Based Medicine

Guyatt and colleagues[5] summarized the practice of EBM as follows: "An evidence-based practitioner must (1) understand the patient's circumstances or predicament; (2) identify knowledge gaps and frame questions to fill those gaps; (3) conduct an efficient literature search; (4) critically appraise the research evidence; and (5) apply that evidence to patient care." Glasziou and colleagues described a key objective of EBM as "…trying to improve the quality of the information on which decisions are based," and pointed out that EBM was "…not about mechanisms, but about outcomes…"[4]

Efficient practice of EBM requires the following:

- Knowledge of the clinical process and conversion of a clinical need into an answerable question.

- A facility that can generate and critically appraise information to generate knowledge.
- A critically appraised knowledge resource.
- Ability to use that knowledge resource.
- Means of accessing and delivering the knowledge resource.
- Means of assessing application of the knowledge.
- A framework of clinical and economic accountability.
- A framework of quality management.

Evidence-Based Medicine and Laboratory Medicine

The services of laboratory medicine are important tools at the disposal of clinicians for answering diagnostic questions and making decisions.

The tools provided by laboratory medicine are called diagnostic tests, but these tests are used for much more than making a diagnosis. As mentioned previously and discussed later, diagnostic tests are also used in (1) making a prognosis, (2) excluding a diagnosis, (3) selecting, (4) guiding, and (5) monitoring a treatment or disease process, and (6) screening for disease. Thus the word diagnostic is used in a much broader sense. An alternative phrase would be a medical test.

What Is Evidence-Based Laboratory Medicine?

Evidence-based laboratory medicine is the application to laboratory medicine of the principles and techniques of EBM and clinical epidemiology. A clinician or healthcare provider who requests an investigation has a question and must make a decision. These providers hope that the test result will help them answer the question and will assist them in making decisions. Thus a definition of evidence-based laboratory medicine could be "the conscientious, judicious, and explicit use of best evidence from laboratory medicine investigations in decision making about the care of individual patients." It might also be expressed more directly in terms of health outcomes as "ensuring that the best evidence obtained on testing is made available and the clinician is assisted in using the best evidence to ensure that the best decisions are made about the care of individual patients, leading to an increased probability of improved health outcomes." Clearly, this discussion makes the assumption that appropriate action is taken once the decision is made. As is discussed later, outcomes may be (1) clinical, (2) operational, and/or (3) economic.

Types of Diagnostic Questions Addressed in Laboratory Medicine

The decision-making process involves one of four scenarios (Figure 4-1), typified by questions such as these:

- What is the diagnosis?
- Can another diagnosis be ruled out?
- What is this patient's prognosis and disease severity?
- What is the most appropriate treatment intervention?
- How is the patient doing?

In the first scenario, a diagnosis is being sought. Diagnostic conclusions lead to a decision and to some form of action, which often involves an intervention designed to improve outcomes. Thus, when a test for acetaminophen reveals a dangerously high concentration of the drug, administration of N-acetyl cysteine will reduce the risk of a fatal outcome. The measurement of acetaminophen in this scenario is referred to as a "rule-in test."

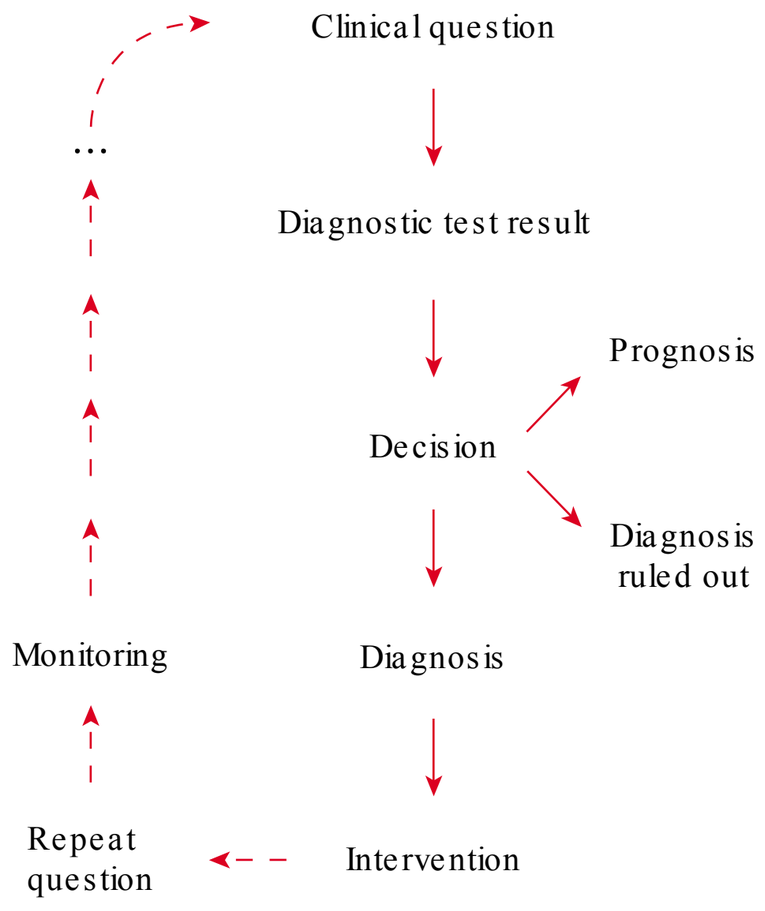

Figure 4-1 Schematic representation of four common decision-making steps in which the result of an investigation is involved.

In the second scenario, the test result excludes a diagnosis; this is referred to as a "rule-out test." For example, when a patient is admitted with chest pain and acute myocardial infarction is suspected, a finding that cardiac troponin is undetectable in plasma may be used to rule out acute myocardial necrosis.

The third use of an investigation is for prognosis, which may be considered as the assessment of risk and complements the diagnostic application. For example, measurement of the concentration of human immunodeficiency virus (HIV) RNA in plasma after the initial diagnosis of HIV infection has been used to predict the time interval before immune collapse if the condition is not treated. The test result is used in a similar way to stratify the patient according to disease severity, which may influence the treatment strategy. For example, a patient with diabetes and a hemoglobin A_{1c} (HbA_{1c}) result of 69 mmol/mol (8.5%) may be treated differently than a patient with HbA_{1c} of 55 mmol/mol (7.2%).The fourth and fifth uses of a test result are concerned with patient management, which consists of treatment selection and optimization, and then treatment monitoring. For example, in a patient with breast cancer, a tissue test for Her-2/neu is required to determine candidacy for use of the drug Herceptin. In the case of a patient with a chronic disease, the test result may be used to assist in optimizing and assessing the effectiveness of an intervention, which will also include assessing patient compliance. For example, in a person with diabetes, HbA_{1c} measurements are used to assess glycemic control and thus the effectiveness of therapy. If HbA_{1c} is high, changing treatment should be considered. If HbA_{1c} is not elevated, the current treatment should be

maintained. Tests employed in this way are often referred to as "companion diagnostics"; they help to provide "personalized medicine".

In each of these examples, three components are present: (1) a question, (2) a decision, and (3) an action. Identifying these three components proves to be critical in designing studies of outcomes of testing (see later in this chapter). These components are also important in auditing (see later) the use of investigations from the viewpoints of both clinical and financial governance. Recognition of this triad has led to the definition of an appropriate test request as one in which there is a clear clinical question for which the result will provide an answer, enabling the clinician to make a decision and to initiate some form of action, leading to a health benefit for the patient. This benefit is extended to the healthcare provider and to society as a whole to encompass more completely the potential for operational and economic benefit.

Examples of questions that specify the amount of detail required to accurately qualify the use of a test result are given in Table 4-1. Criteria for introducing a screening test have been identified for many years but with some degree of variation; one of the key criteria is that valid treatment must be available; furthermore, the combination of test and treatment should do more good than harm.

Using the Test Result

The key criterion for a useful diagnostic test is that the result leads to a change in the probability of the presence of the target condition. The change in probability does not, in itself, make the decision. The clinician must use this information along with other findings and clinical judgment to make decisions or recommendations about care.

Test Results Alone Do Not Produce Clinical Outcomes

In most cases, testing must be followed by an appropriate intervention to produce a desired outcome. A test result alone may provide reassurance or an understanding of the origin of one's complaint, but even this may require explanation and further reassurance from a physician or healthcare provider. The value of a test is assessed only by looking at its impact on the patient's health.[3] Because of the difficulty involved in documenting that testing improves patient outcomes, most research in laboratory medicine addresses only the analytical characteristics and diagnostic performance of tests, not the effects of tests on patients' lives. This restricted research leads to a poor understanding and appreciation of the contribution that the test result makes to improved outcomes. For example, a randomized study of a rapid chest pain evaluation protocol that shows that normal results for cardiac markers ruled out myocardial infarction does not address the question of whether testing leads to fewer admissions to the coronary care unit with decreased morbidity and mortality. The consequence of this argument is that the impact of a test on an outcome should be evaluated as a "test-and-act," or "test-and-treat," intervention.

Information Needs in Evidence-Based Laboratory Medicine

Studies in the field of evidence-based laboratory medicine are of five major types:

1. Characterization of the diagnostic accuracy of tests by studying groups of patients.
2. Determination of the value of testing for people who are tested (outcomes).
3. Systematic review of studies of diagnostic accuracy or outcomes of tests to answer a specific clinical question.
4. Economic evaluation of tests to assess the economic value of using the test.
5. Audit of performance of tests during use to answer questions about their use.

Increasingly, researchers in laboratory medicine are beginning to use computer-based modeling techniques to assess

TABLE 4-1 Examples of Clinical Questions for Which a Laboratory Assessment May Be of Value, and the Associated Action and Potential Outcome (Benefit)

Test	Question	Result	Possible Action	Potential Outcome
Rule In				
TSH	Does this child have hypothyroidism?	12.2 mU/L	Treat with thyroxine	Decreased morbidity and mortality
Rule Out				
BNP	Is this breathless patient suffering from heart failure?	56 ng/L	Seek alternative diagnosis	Avoid incorrect diagnosis and treatment with their potential for harm
Monitoring				
HbA_{1c}	Is patient complying with treatment protocol?	92 mmol/mol (10.6%) (no change in a year)	Consider changing treatment, closer monitoring of compliance, clinic visits and consultations with diabetes nurse	Persistently high HbA_{1c} carries increased risk of complications; intervention necessary to decrease risk
Prognosis				
cTnI	What is this patient's risk of a further cardiac event?	0.9 µg/L	Consider intervention	Increased risk without intervention

BNP, B-type natriuretic peptide; cTnI, cardiac troponin I; HbA_{1c}, hemoglobin A_{1c}; TSH, thyroid-stimulating hormone.

the cost-effectiveness of tests, as well as to assess the impact of process changes on resource utilization. The following sections of this chapter provide brief introductions to the principles of how to gain these critical types of information, which are needed for patient care.

Characterization of Diagnostic Accuracy of Tests

When a new test is developed or an old test is applied to a new clinical question, users need information about the extent of agreement of the test's results with the correct diagnoses of patients. We refer to such studies as **diagnostic accuracy** studies.

Study Design

In studies of diagnostic accuracy, the results of one test (of en referred to as the **index test,** the test of interest) are compared with those from the clinical reference standard—the best current practice to arrive at a diagnosis. A reference standard is any method that is used to obtain additional information on a patient's health status. Methods include (1) laboratory tests, (2) imaging tests, (3) function tests, (4) data from the history and physical examination, and (5) genetic data.

The **clinical reference standard** is the best available method of establishing the presence or absence of the target condition—the suspected condition or disease for which the test is to be applied. The reference standard can be a single test or can consist of a combination of methods and techniques, including clinical follow-up of tested patients. In some cases, it is the independent opinion of two experts in the field, as in the case of the diagnosis of heart failure.

There are several potential threats to the internal and external validity of a study of diagnostic accuracy, of which only the major ones will be addressed in this section. Poor internal validity (problems in the design of the study) will produce **bias,** or systematic error, because the estimates of diagnostic accuracy differ from those one would have obtained using an optimal design for the study. Poor external validity limits the "extent" to which clinical research studies apply to broader populations. A research study has external validity if its results can be generalized to the larger population (Agency for Health Research and Quality Effective Health Care Program; http://effectivehealthcare.ahrq.gov/index.cfm/glossary-of-terms/?pageaction=showterm&termid=26; accessed July 5, 2013).

The ideal diagnostic accuracy study examines a consecutive series of patients by enrolling all consenting patients suspected of the target condition within a specific period. All patients undergo the index test and are evaluated by the reference standard. The term consecutive refers to the total absence of any form of selection beyond the definition (determined at the start of the study) of the criteria for inclusion in the study (and exclusion); explicit efforts are required to identify and enroll all patients who qualify for inclusion.

Alternative designs are possible. Some studies first select patients known to have the target condition and then contrast the study results of these patients with those of patients from a control group. This approach has been used to characterize the performance of tests in settings in which the condition of interest is uncommon, as in maternal serum screening tests for detection of Down syndrome in the fetus. It is also used in preliminary studies to assess the potential of a test before prospective studies of a series of patients are begun. With this design, the selection of the control group is critical. If the control group consists of healthy individuals only, the diagnostic accuracy of the test will tend to be overestimated. The control group should include patients in whom the disease is suspected but has been ruled out.

In the ideal study, the results of all patients in whom the test under evaluation has been performed are contrasted with the results of a single reference standard. If the reference standard is not applied to all patients, partial verification is the result. In a typical case, some patients with negative test results (test-negatives) are not verified by an expensive or invasive reference standard, and those patients are excluded from the analysis. This may result in an underestimation of the number of false-negative results.

A different form of verification bias happens if more than one reference standard is used, and the two reference standards correspond to different manifestations of disease. This study design can produce *differential verification* bias. Suppose the diagnoses in test-positive patients are verified through further testing, but the diagnoses in test-negative patients are verified by clinical follow-up. An example is the verification of suspected appendicitis, with histopathology of the appendix versus follow-up as the two forms of the reference standard. A patient is classified as having a false-positive test result if the additional test does not confirm the presence of disease after a positive index test result. Alternatively, a patient is classified as false-negative if an event compatible with appendicitis is observed during follow-up after a negative test result. Yet these are different definitions of disease because not all patients who have positive test results by the reference standard would have experienced an event during follow-up if they had been left untreated. The use of two reference standards, one pathological and the other based on follow-up, can affect the assessment of diagnostic accuracy and usually leads to inflated estimates of accuracy.[6] This approach also leads to variability among studies when studies differ in the proportions of patients verified by each of the two standards.

Should clinical information be provided to those performing or reading the index test for the study of its diagnostic accuracy? For example, should the radiologist reading the new type of x-ray image know the results of prior tests on the patient? Withholding this information is known as blinding or masking. Some clinical information is often routinely known by the reader of the test, as when a pathologist is told the site from which a biopsy is obtained. To try to withhold such information in the context of a study of diagnostic accuracy may create an artificial scenario that has no counterpart in routine patient care. For most study questions, however, masking is preferable because knowledge of the results will tend to increase agreement of the results of the studied (index) test with those of the reference standard (test).

Severity of disease in studied patients with the target condition and the range of other conditions in other patients (controls) can affect the apparent diagnostic accuracy of a test. For example, if a test that is designed to detect early cancer is evaluated in patients with clinically apparent cancer, the test is likely to perform better than when used for persons who do not yet show signs of the condition. T is problem has been called spectrum bias. Similarly, if a test is developed to distinguish patients with the target condition from patients with a similar condition, it may be misleading to use healthy subjects as controls, rather than patients with similar symptoms, when the diagnostic accuracy of the test is evaluated.

Reporting of Studies of Diagnostic Accuracy and the Role of the STARD Initiative

Complete and accurate reporting of studies of diagnostic accuracy should allow the reader to detect the potential for bias in the study and to assess the ability to generalize the results and their applicability to an individual patient or group. In fact, most studies of diagnostic accuracy published in leading general medical journals either showed poor adherence to standards of clinical epidemiologic research or failed to provide information about adherence to those standards. T is deficiency led to efforts at the journal Clinical Chemistry in 1997 to produce a checklist for reporting of studies of diagnostic accuracy. Af er this checklist was introduced, the quality of reporting improved in that journal but not in another journal that did not use the checklist.

In 1999, Lijmer et al[6] showed that poor study design and poor reporting are associated with overestimates of the diagnostic accuracy of evaluated tests. T is report reinforced the necessity to improve the reporting of studies of diagnostic accuracy for all types of tests, not only those in clinical chemistry. T is led to the **STARD** initiative on Standards for Reporting of Diagnostic Accuracy.

Key components of the STARD document[1] include a checklist of items to be included in reports of studies of diagnostic accuracy and a diagram to document the flow of participants in the study. T e checklist contains 25 items that are worth reading and understanding (Figure 4-2). T e flow diagram (Figure 4-3) communicates vital information about the design of a study—including the method of recruitment and the order of test execution—and about the f ow of participants.

T e STARD document has been endorsed by numerous journals, including all the major journals of clinical chemistry and general medicine. A separate document, referenced in STARD, explains the meaning and rationale of each item and briefly summarizes the available evidence. Most if not all of the content of STARD also applies to studies of tests used for prognosis, monitoring, or screening.

Outcomes Studies

Medical and public health interventions are intended to improve the health of (1) patients, (2) the population at large, or (3) population segments. In terms of therapeutic interventions, patients are interested not only in whether a drug decreases serum cholesterol or blood pressure (risk factors) but, more important, whether it decreases the risk of (1) heart attack, (2) stroke, and (3) cardiovascular death. On the diagnostic side of medicine, most patients have little interest in knowing their serum cholesterol concentration unless that knowledge will lead to actions that improve their quality and/or quantity of life. People want improved outcomes, and healthcare providers and policymakers are increasingly demanding evidence of improved outcomes.

What Are Outcomes Studies?

Outcomes may be defined as results of medical interventions in terms of health or cost; they are of en described in terms of (1) clinical, (2) operational, and (3) economic outcomes. "Patient outcomes" are outcomes that are associated with the patient's condition and experience. Examples of outcomes include (1) mortality, (2) morbidity, (3) complication rates, (4) length of stay in the hospital, (5) waiting times at a clinic, (6) cost of care, and (7) patient satisfaction with care. An improved test will improve outcomes when the outcomes depend on making the correct diagnosis. Improved outcomes may be difficult to establish, however, if no effective treatment is available for the diagnosed condition, or if the condition and the conditions with which it is confused are treated in the same way.

Some tests are used as surrogate outcome markers in intervention studies when a strong relationship has been documented between the test result and morbidity or mortality. Examples include the use of HbA_{1c} and the urine albumin-to-creatinine ratio in studies on the management of diabetes mellitus.

Operational and economic outcomes are results of interest to patient care providers, purchasers, and policy makers. A correct diagnosis of en saves money. Much recent interest has been focused on rates of re-admission to the hospital for patients with heart failure. Some patients diagnosed with heart failure are suffering from lung disease and vice versa; failure to diagnose and treat the condition that the patient actually has leads to costly re-admissions. Proper use of diagnostically accurate tests reduces these costs. Proper testing also reduces the length of hospital stay, and thus cost, by facilitating early diagnosis and treatment. Point-of-care testing (POCT) in doctors' offices may save patients money by avoiding the need to travel to a laboratory facility.

Outcomes studies must be distinguished from studies of prognosis. Studies of the prognostic value of a test ask the question, "Can the test be used to predict an outcome?" By contrast, outcomes studies ask questions such as, "Does use of the test improve outcomes?" For example, a study of the prognostic ability of a test might ask the question, "Does the concentration of a cardiac troponin I in serum correlate with the mortality rate af er myocardial infarction?" An outcomes study might ask, "Is the mortality rate of patients with suspected myocardial infarction decreased when physicians use troponin testing to guide decisions?"

Many test attributes are amenable to studies of outcomes. Such studies address not only the effect of making a test

Section and Topic	Item #		On page #
TITLE/ABSTRACT/ KEYWORDS	1	Identify the article as a study of diagnostic accuracy (recommend MeSH heading sensitivity and specificity).	
INTRODUCTION	2	State the research questions or study aims, such as estimating diagnostic accuracy or comparing accuracy between tests or across participant groups.	
METHODS		Describe	
Participants	3	The study population: The inclusion and exclusion criteria, setting, and locations where the data were collected.	
	4	Participant recruitment: Was recruitment based on presenting symptoms, results from previous tests, or the fact that the participants had received the index tests or the reference standard?	
	5	Participant sampling: Was the study population a consecutive series of participants defined by the selection criteria in items 3 and 4? If not, specify how participants were further selected.	
	6	Data collection: Was data collection planned before the index test and reference standard were performed (prospective study) or after (retrospective study)?	
Test methods	7	The reference standard and its rationale.	
	8	Technical specifications of material and methods involved, including how and when measurements were taken, and/or cite references for index tests and reference standard.	
	9	Definition of and rationale for the units, cutoffs, and/or categories of the results of the index tests and the reference standard.	
	10	The number, training, and expertise of the persons executing and reading the index tests and the reference standard.	
	11	Whether or not the readers of the index tests and reference standard were blind (masked) to the results of the other test and describe any other clinical information available to the readers.	
Statistical methods	12	Methods for calculating or comparing measures of diagnostic accuracy, and the statistical methods used to quantify uncertainty (e.g., 95% confidence intervals).	
	13	Methods for calculating test reproducibility, if done.	
RESULTS		Report	
Participants	14	When study was done, including beginning and ending dates of recruitment.	
	15	Clinical and demographic characteristics of the study population (e.g., age, sex, spectrum of presenting symptoms, comorbidity, current treatments, recruitment centers).	
	16	The number of participants satisfying the criteria for inclusion that did or did not undergo the index tests and/or the reference standard; describe why participants failed to receive either test (a flow diagram is strongly recommended).	
Test results	17	Time interval from the index tests to the reference standard, and any treatment administered between.	
	18	Distribution of severity of disease (define criteria) in those with the target condition; other diagnoses in participants without the target condition.	
	19	A cross tabulation of the results of the index tests (including indeterminate and missing results) by the results of the reference standard; for continuous results, the distribution of the test results by the results of the reference standard.	
	20	Any adverse events from performing the index tests or the reference standard.	
Estimates	21	Estimates of diagnostic accuracy and measures of statistical uncertainty (e.g., 95% confidence intervals).	
	22	How indeterminate results, missing responses, and outliers of the index tests were handled.	
	23	Estimates of variability of diagnostic accuracy between subgroups of participants, readers, or centers, if done.	
	24	Estimates of test reproducibility, if done.	
DISCUSSION	25	Discuss the clinical applicability of the study findings.

available but also such attributes of tests as (1) the method used to obtain a measurement, (2) the analytical quality of the test performance, (3) turnaround time (as for POCT in the emergency department), (4) the method of reporting test results (e.g., rapid reporting of life-threatening results), and (5) reporting of results with or without extensive interpretation.

Why Outcomes Studies?

Outcomes studies have taken on considerable importance in medicine. On the therapeutic side of medicine, few drugs are approved by modern government agencies (or paid for by healthcare organizations or health insurers) without strong evidence of their safety and effectiveness. Increasingly, diagnostic testing is entering a similar environment, in which individuals or institutions such as (1) physicians, (2) healthcare providers, (3) governments, (4) commercial health insurers, and (5) patients demand evidence of effectiveness of diagnostic procedures. To appreciate this, one need only recall the enormous interest in controversies about the value of mammography and the effectiveness of measuring serum prostate-specific antigen (PSA) in population programs. T ese issues (and many others) hinge on studies of outcomes.

In the United States, the Joint Commission has defined quality as increased probability of desired outcomes and decreased probability of undesired outcomes. If a healthcare organization, or a unit of it, such as the clinical laboratory, wishes to propose that its quality is high, or that it contributes to the quality of the institution, the message is clear: Demonstrate improved outcomes.

Design of Studies of Medical Outcomes

T e **randomized controlled trial (RCT)** is the de facto standard for studies of the health effects of medical interventions. In these studies, patients are randomly assigned to receive either the intervention to be tested (such as a new drug or a

new test) or an alternative (typically either a placebo or a conventional drug or test), and an outcome is measured. RCTs have been used to evaluate (1) therapeutic interventions, including drugs, (2) radiation therapy, (3) surgical interventions, and (4) others. Measured outcomes vary from (1) hard measures, such as mortality and morbidity, to (2) softer measures, such as patient-reported satisfaction, or (3) surrogate measures, typified by markers of disease activity (e.g., HbA_{1c}, serum creatinine, urine albumin-to-creatinine ratio).

The high impact of RCTs of therapeutic interventions has led to scrutiny of how they are conducted and reported. An interdisciplinary group (largely editors of medical journals and clinical epidemiologists) developed a guideline known as CONSORT (Consolidated Standards for Reporting Trials)[13] for the conduct of these studies. Although initially designed for trials of therapies, CONSORT provides useful reminders for those designing or appraising outcomes studies of tests in clinical chemistry. As for STARD, the key features of the CONSORT guidelines include a checklist of items to include in the report and a flow diagram of patients in the study.

The optimal design for an RCT of a diagnostic test is not always obvious. A classic design is to randomly assign patients to receive a test or not receive it, and then to take clinical action (from conventional therapy to a different therapy) based on the test result in the tested patients. However, this approach leads to problems in interpretation.[7] For example, if the new therapy is always effective, the tested group will always fare better, even if the test is a coin-toss, because only the tested group had access to the new therapy. The conclusion that the testing was valuable would thus be wrong. By contrast, if the new therapy is always worse than the conventional treatment, patients in the tested group will do worse, and the test will be judged worse than useless, no matter how diagnostically accurate it is. Similarly, if the two treatments are equally effective, the outcomes will be the same with or without testing; this scenario, too, will lead to the conclusion that the test is not good, no matter how diagnostically accurate it is. When a truly better therapy becomes available, the test may prove to be valuable, so it is important to not discount the test's potential based on a study with a new therapy that offers no advantage over the old therapy.

If the treatment choice remains the same in the two arms of a study, these problems do not arise, for example, when a test done in a clinic is compared with a similar (or identical) test done in a laboratory, the treatment choices would not be expected to change. In all cases, however, it is crucial to evaluate the combination of test and treatment as a single intervention.

Alternative designs have been described to address the question of test use in an RCT.[7] In one design, all patients undergo the new test, but the results are hidden during the trial. Patients are randomly assigned to receive or not receive the new therapy. In this design, the new test should be adopted only if a benefit is associated with switching to the new therapy in a subgroup of test results. The test should not be adopted if all patients tested benefit sufficiently, or if none of those tested in the trial benefits sufficiently.

Unfortunately an RCT is not always feasible, and an alternative is used. These studies include those that use historical or contemporaneous control patients in whom the intervention was not undertaken. Uncertainty about the comparability of controls and patients with such designs is a threat to the validity of these studies. Another approach is to use the "before-and-after" approach, that is, to compare clearly identified outcome measures using the existing diagnostic approach with outcome measures after introduction of the new diagnostic (test) approach. Again, problems have been associated with this approach, one of which involves ensuring that the spectrum of patients is similar in both phases of the study. Handling confounders is a challenge, and statistical techniques to improve comparability, such as the use of propensity scores, are considered.

In making decision about whether the results of an **outcome study** are relevant to one's own situation or hospital, it is essential to evaluate if one's situation is comparable with that of the setting where the study was done. Results of outcomes studies performed at a referral hospital may not apply in a community hospital (different spectrum of disease); results of outcomes studies that were done exclusively in men may not apply in women; etc.

Systematic Reviews of Diagnostic Tests

Systematic reviews, in contrast to traditional narrative reviews, aim to answer an exactly defined clinical question and to do so in a way that is transparent and designed to minimize bias. Some of the defining features of systematic reviews are (1) a clear definition of the clinical question to be addressed; (2) an extensive and explicit strategy to find all studies (published or unpublished) that may be eligible for inclusion in the review; (3) explicit criteria by which studies are included and excluded; (4) a mechanism to assess the risk of bias in each study; and, in some cases, (5) synthesis of results with the use of statistical techniques of meta-analysis. By contrast, traditional reviews (1) are subjective, (2) are rarely well focused on a clinical question, (3) lack explicit criteria for selection of studies to be reviewed, (4) do not indicate criteria to assess the quality of included studies, and (5) rarely are amenable to meta-analysis.

The explicit method required for systematic reviews suggests that persons skilled in the art of systematic reviewing should be able to reproduce the data of a systematic review, just as researchers in chemistry or biochemistry expect to be able to reproduce published primary studies in their fields. This concept strengthens the credibility of systematic reviews, and workers in the field of EBM generally consider well-conducted systematic reviews of high-quality primary studies to constitute the highest level of evidence on a medical question.

Why Systematic Reviews?

The medical literature is so vast that no one is able to read, much less digest, all relevant work. This serves as an impetus for systematic reviews. Other motivations include (1) the

massive amount of new technology, (2) the poor quality of narrative reviews—especially in relation to guiding practice, and (3) the need to provide an accurate digest for practicing clinicians. Systematic reviews are at the core of health technology assessment (HTA).

In practice, systematic reviews are designed to achieve multiple objectives. For example, they are able to (1) identify the number, scope, and quality of primary studies and (2) provide a summary of available evidence on the diagnostic accuracy of a test. They are also capable of exploring sources of heterogeneity in test results by comparing the diagnostic accuracy of tests across settings or subgroups, or by examining associations between study results and study design features. In this way, they also are able to identify areas that require further research and to recognize questions that are well answered and for which additional studies may not be necessary. In addition, some systematic reviews, by analyzing data on many patients from multiple similar studies, include a sufficient number of patients to achieve the statistical "power" requirements for a reliable assessment of statistical significance of results and for sufficiently precise estimates of diagnostic accuracy; this often is not possible in the individual studies.

Conducting a Systematic Review

Systematic reviewing is time-consuming and requires multiple skills. Usually a team is required, including at least one person experienced in the science and art of systematic reviewing. The team must agree on the clinical problem to be tackled and on the scope of the review.

An early step in preparation for performing a systematic review is to identify whether a similar review has been undertaken recently. Among other things, such a search helps to focus the review. The Cochrane Collaboration provides an excellent resource of reviews, with an increasing number covering diagnostic tests. The Database of Abstracts of Reviews of Effectiveness (DARE), which is run by the Centre for Reviews and Dissemination at the University of York, in the United Kingdom, contains reviews of some diagnostic tests. Other resources include electronic databases, such as PubMed and EMBASE, and recent clinical practice guidelines, which are likely to cite systematic reviews that were available at the time of the guideline's development (see section on guidelines later in this chapter).

The review team must develop a protocol for the project. A protocol should include:

- A title
- Background information
- Composition of the review group
- A timetable
- The clinical question(s) to be addressed in the review
- Search strategy
- Inclusion and exclusion criteria for selection of studies
- Methodology of data extraction and data extraction forms
- Methodology of and checklists for critical appraisal of studies
- Methodology of study synthesis and summary measures to be used.

Description of all of the details is beyond the scope of this chapter, and only some highlights will be discussed. Review of the references cited here, and of references therein,[10,15] is recommended before one embarks on a systematic review.

The Clinical Question and Criteria for Selection of Studies

The most important of the steps (Box 4-1) in conducting a systematic review is the formulation of the clinical question for which the test results are expected to give an answer. This question forms the basis of the review. Two types of questions are addressed in a systematic review in diagnostic medicine: One type is related to the diagnostic accuracy of a test, and the other is related to the value (to patients or to others) of using the test. The questions that arise are similar in structure but require different approaches.

Examples:

Type 1 question regarding diagnostic accuracy of a test: In patients coming to the emergency department with shortness of breath, how well does B-type natriuretic peptide (BNP) or N-terminal pro-BNP (NT-proBNP) predict (identify the presence of) heart failure, as assessed by the independent opinions of two experienced cardiologists?

Type 2 question regarding the value of a test in improving patient outcomes:

In patients admitted to the hospital for treatment of heart failure, how well does use of BNP or NT-proBNP as a guide to therapy reduce the need for subsequent readmission?

Note that each question identifies (1) the patient's problem (shortness of breath or heart failure in a clinical setting [emergency department or hospital]), (2) the test being used (BNP or NT-proBNP), (3) the reference standard for the diagnosis (the independent opinions of two experienced cardiologists) or for the clinical outcome (rate of subsequent re-admission), and (4) the studied attribute of the test (diagnostic accuracy, the ability to detect the presence of heart failure vs. process outcome).

More complex questions often arise. For example, a type 1 question may involve comparing the diagnostic accuracy of two or more tests, or it may address the improvement in diagnostic accuracy that results from adding the results of a new test to those of an existing test or tests. In all cases, however, it

BOX 4-1 Selected Key Steps in a Systematic Review of a Diagnostic Test

Identify the clinical question.
Define inclusion and exclusion criteria.
Search the literature.
Identify relevant studies.
Select studies against explicit quality criteria.
Extract data and assess quality.
Analyze and interpret data.
Present and summarize findings.

is recommended that the clinical question be specific, and that it focuses on defined clinical scenarios and clinical settings. This could be considered part of the application of EBM in comparative effectiveness, where the performance of the new test is compared with current practice.

The clinical question leads to inclusion and exclusion criteria for studies to be included in the review. These criteria include the setting in which the test is to be used, as well as the measures to be considered. The setting and the nature of the question affect the diagnostic performance of a test, because they identify a unique population of patients.

Until recently, individuals interested in systematic reviews have focused on studies of the effects of interventions, especially drugs, on patient outcomes. Their work is generally applicable to systematic reviews of diagnostic tests that start with a question of the second type above. Although this discussion is focused on systematic reviews of the diagnostic accuracy of tests, it is important to recognize the increasing literature on reviews of the use of diagnostic tests as part of a "test-and-treat" intervention and their impact on health outcomes.

When the questions to be addressed are defined, the review group must agree on the scope of the review. The review group may do the following:

- Restrict the review to studies of high quality directly applicable to the problem of immediate interest, or
- Explore the effects of variability in study quality and other characteristics (setting, type of population, disease spectrum, etc.) on estimates of accuracy, using subgroup analysis or meta-regression.

The second approach is more complex but allows estimates of such things as the applicability of estimates of diagnostic accuracy to different settings and the effects of study design and inherent patient characteristics (such as age, sex, and symptoms) on estimates of a test's diagnostic accuracy.

Search Strategy

Searching of the primary literature is usually carried out in three ways: (1) an electronic search of literature databases, (2) hand searching of key journals, and (3) review of the references of key review articles. It is usual to search both MEDLINE and EMBASE because the overlap between the two has been as low as 35%. Searching of databases is a detailed exercise, and the help of a librarian or information scientist is recommended. Guidance that is tailored to searching for studies of diagnostic accuracy in the published literature is available in the Cochrane Handbook *for* Diagnostic Test Accuracy Reviews (http://srdta.cochrane.org/handbook-dta-reviews; accessed July 5, 2013). The Agency for Health Research and Quality has also published a comprehensive guide to searching the literature on medical tests for systematic reviews (http://effectivehealthcare.ahrq.gov/index.cfm/search-for-guides-reviews-and-reports/?pageaction=displayproduct&productid=1091; accessed July 5, 2013).

Additional studies may be found in the "grey" literature, such as (1) theses, (2) conference proceedings, (3) technical reports, and (4) monographs. Consultation with individuals active in the field may uncover studies in these sources and studies that are being prepared for publication.

Data Extraction and Critical Appraisal of Studies

Identified papers should be read independently by two persons and data extracted according to a template. A checklist of items to extract from primary studies in preparing a systematic review on test accuracy is available in the Cochrane Handbook *for* Diagnostic Test Accuracy Reviews. The STARD checklist[1] has been used as an additional guide in designing the template.

The quality of studies must be assessed as part of the systematic review. The study design is an important consideration. For many questions related to outcomes, an RCT will be the design of highest quality. For studies of diagnostic accuracy, studies of consecutive series of patients will rank above studies using historical controls. In practice, a study may use a good design but suffer from serious drawbacks in other dimensions, for example, many patients may have been lost to follow-up, or the studied test may have performed poorly during the study, as indicated by high day-to-day imprecision. Thus, adequate grading of the quality of studies must go beyond the categorization of study design. Tools for assessment of studies of diagnostic accuracy include QUADAS (Quality Assessment of Diagnostic Accuracy).[15]

Summarizing the Data

Characteristics and data from critically appraised studies should be presented in tables. Data from studies of diagnostic accuracy should include (1) sensitivities, (2) specificities, and (3) likelihood ratios wherever possible. These are summarized in plots that provide an indication of the variation among studies. The summary should also include an assessment of the quality of each study, using an explicit scoring system such as QUADAS. A review should also present critical analysis of the data highlighted in the review.

Meta-Analysis

A meta-analysis is a statistical way of analyzing data from multiple studies. It may be possible to undertake a meta-analysis if data are available from sufficiently similar studies. Meta-analyses (1) explore sources of variability in the results of clinical studies, (2) increase confidence in the data and conclusions, and (3) signal when no further studies are necessary. The conduct of meta-analyses, however, is beyond the scope of this chapter. Meta-analysis of test accuracy studies is more challenging than for RCTs because tests of accuracy usually produce two statistics (such as sensitivity and specificity)—not one, and these two statistics are correlated over studies. For guidelines on the conduct of meta-analyses of RCTs, see the Cochrane Handbook *for* Diagnostic Test Accuracy Reviews (http://srdta.cochrane.org/handbook-dta-reviews; accessed July 5, 2013) or the overview paper by Reitsma et al.[10]

Economic Evaluations of Diagnostic Testing

Healthcare costs worldwide have surged in recent decades. For example, the United States spent $2.3 trillion, or 17.3% of its gross domestic product, on healthcare in 2010. Although

direct laboratory costs are small in comparison, these tests have a profound influence on medical decisions and therefore on total costs.

A Hierarchy of Evidence

A hierarchy of evidence regarding medical tests begins with assessment of the test's technical performance and proceeds through study of the test's clinical performance to clinical effectiveness (an identification of the benefits) and an economic evaluation. T is hierarchy of evidence also is seen in the context of the data required to make decisions about the implementation of a test. It therefore lies at the heart of the processes of policy making and service management. Economic evaluation provides a means of evaluating the comparative costs and comparative health effects of alternative care strategies. T e use of economic modeling to assess cost-effectiveness af er meta-analysis of clinical effectiveness data is increasing.[12]

Methodologies for Economic Evaluations

Health economics is concerned with the costs and consequences of decisions made in the care of patients. It therefore involves (1) identifying, (2) measuring, and (3) appraising the value of both costs and consequences. T e process is complex and is an "inexact science." Approaches to economic evaluation include (1) cost minimization, (2) cost benefit, (3) cost-effectiveness, and (4) cost utility analysis (Table 4-2).

Cost-minimization analysis compares the costs of alternative approaches that produce the same outcome. It is considered the simplest type of economic evaluation. In the area of diagnostic testing, it is applicable to the costs of alternative suppliers of the same (1) test, (2) device, or (3) instrument. It is therefore a technique that is limited to the procurement process, whereby the specifications of the service are already established and the outcomes clearly defined. It might be considered as providing the "cost per test," an often quoted indicator that is not, however, a true economic evaluation because it does not identify an outcome except the provision of a test result.

Cost-benefit analysis determines whether the value of the benefit exceeds the cost of the intervention and therefore whether the intervention is worthwhile. T e benefit is assessed in monetary terms, and so is the cost; this is often challenging because it may require the analyst to equate a year of life to a monetary amount. Several methods may be used, including the "human capital approach," which assesses the individual's productivity (in terms of earnings), and the "willingness to pay approach," which assesses how much money individuals are prepared to pay for a specific benefit.

A variant of cost-benefit analysis is cost-consequences analysis, which measures benefit in different ways and not necessarily in monetary or natural units (see next paragraph). T is enables different types of decision makers to make assessments in the context of their own areas of responsibility.

Cost-effectiveness analysis looks at the most efficient way of spending a fixed budget to achieve a certain goal. T is goal is expressed in natural units, such as years of life or number of strokes prevented. Surrogate measures with clear relationships to morbidity and mortality have also been used (e.g., change in blood pressure). When an intervention is assessed, the number of cases of disease prevented may be used as a measure of benefit. T e analysis evaluates differences in effectiveness between alternative approaches relative to corresponding differences in costs.

Cost-utility analysis focuses on the quality and the quantity of the health outcome. T e cost of the intervention is assessed in monetary terms, but the outcomes are expressed in utilities, that is, quantitative expressions of their relative value. An often used metric is quality-adjusted life-years (QALYs). T e analysis evaluates differences in expected utility between alternative approaches relative to corresponding differences in costs. Cost-utility analysis has been used to evaluate and compare screening programs.

New technology often increases both cost and benefit. When tests increase both the cost and the benefit, decisions about their use will depend on factors such as willingness to pay and other political and individual pressures. A figure of $50,000 per QALY has been used in the United States as a reference point. T is reflects a decision by the U.S. Congress to approve dialysis treatment for end-stage renal failure—a treatment with approximately this cost per QALY.

Four possible findings may result from cost-effectiveness or cost-utility analyses and corresponding possible decisions; they are often summarized in an incremental cost-effectiveness plane (Figure 4-4):

- Test is more costly but provides greater benefit—possibly introduce test, depending on overall gain (A).
- Test is more costly but provides less benefit—do not introduce test (B).
- Test is less costly but provides greater benefit—introduce test (C).

TABLE 4-2 Approaches to Economic Evaluation

Type of Evaluation	Test Evaluated	Effect or Outcome	Decision Criteria
Cost minimization	Alternative tests or delivery options	Identical outcomes	Least expensive alternative
Cost benefit	Alternative tests or delivery options	Improved effect or outcome	Effect evaluated purely in monetary terms
Cost effectiveness	Alternative tests or delivery options	Common unit of effect but differential effect	Cost per unit of effect (e.g., dollars per life-year gained)
Cost utility	Alternative tests or delivery options	Improved effect or outcome	Outcome expressed in terms of survival and quality of life

- Test is less costly but provides less benefit—possibly introduce test, depending on the size of the loss in benefit and the magnitude of savings (D).

Note: This cost may be able to produce a demonstrably greater benefit if spent on a different intervention or test.

Perspectives of Economic Evaluations

The perspective from which an economic evaluation is performed affects the (1) design, (2) conduct, and (3) results of the evaluation, which may prompt the use of cost-consequences analysis. The perspective may, for example, be that of (1) a patient, (2) a provider, (3) a payer (government health agency or health insurance company), or (4) society. The perspective for evaluating cost and benefit may be long term or short term. The questions below illustrate the importance of perspective:

- What is the cost of the test result produced on analyzer A compared with analyzer B?
- What is the cost of the test result produced by laboratory A compared with laboratory B?
- What is the cost of the test result produced by POCT compared with the laboratory?
- Will provision of rapid blood testing for the emergency department reduce the length of patient stays in the department, thus decreasing costs for the hospital?
- Will rapid HbA_{1c} testing in a clinic (rather than in a distant laboratory) save time for patients by providing results at the time of the clinic visit?
- Will it save money for patients' employers by reducing employees' time away from work to go to repeated physician appointments?
- Will it save time for the physician and thus money for the clinic? Will it improve care of diabetes for the patient as indicated by independent measures of glycemic control (perhaps by facilitating counseling at the time of the clinic visit)?
- Will it save money for the healthcare system by improving glycemic control and thus decreasing hospitalizations related to poor glycemic control?
- Will it provide benefit for society by decreasing society's healthcare costs (for hospitalizations) and increasing patients' functioning and contributions to society?

The first scenario describes the type of evaluation made for equipment-purchasing decisions and is a simple procurement exercise. The outcome is the same—the provision of a given test result to a given standard of accuracy and precision within a given time (the specification). The second question might appear to be the same, but it is not, and it will undoubtedly have to take into account other issues such as the logistical issues associated with sample transport or the level of communication support provided by the laboratories. To make a relevant evaluation in the third scenario concerning the value of POCT, it is important to take into account the implications outside of the laboratory that may result from a delay in sending the sample to the laboratory. The implications of the remaining questions are similar. Note that the clinical complications of poor glycemic control are largely long term and may extend beyond the time frame of the financial interests of those performing an economic analysis. Indeed, rigorous long-term economic evaluations of the use of tests are rare, except in the particular scenario of national screening programs, such as for neonatal hypothyroidism and breast cancer, where they form part of a "test-and-treat" intervention.

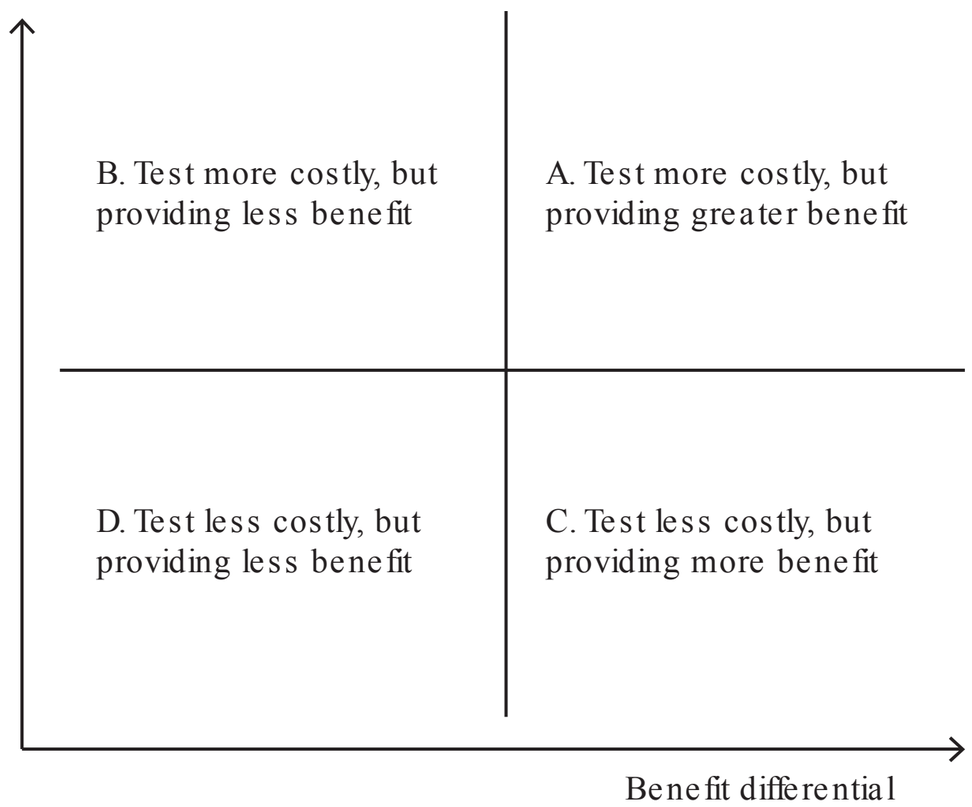

Figure 4-4 A summary of the incremental cost-effectiveness plane.

Quality of Economic Evaluations

Criteria for evaluating an economic study of a diagnostic test include the following:

- Clear definition of the economic question, including perspective of the evaluation (e.g., perspective of [1] a patient, [2] society, [3] an employer, [4] a health insurance company, or [5] a hospital administrator; long-term versus short-term perspective).
- Description of competing alternatives.
- Evidence of effectiveness of intervention.
- Clear identification and quantification of costs and consequences, including incremental analysis.
- Appropriate consideration of effects of differential timing of costs and benefits.
- Performance of sensitivity analysis (How sensitive are results and conclusions to plausible changes in assumptions or in input [e.g., changes in cost of drugs or benefit in life-years]?).
- Inclusion of summary measure of efficiency, ensuring that all issues are addressed.

Use of Economic Evaluations in Decision Making

The stream of new tests in laboratory medicine requires frequent decisions about whether or not to implement them. Economic evaluations help in making these decisions. The finite resources for healthcare require use of an objective means of determining how resources are allocated and how the efficiency and effectiveness of service delivery are improved.

Economic evaluations are important for laboratories. First, the laboratory budget is usually "controlled" independently of the other costs of healthcare. This is often referred to as "silo budgeting." The budget for testing is established independently

of the budgets for services that might achieve benefit if a new diagnostic test is introduced. Second, achievement of a favorable outcome (e.g., a reduction in length of stay, a decrease in admissions to the coronary care unit) is of use from a management standpoint only if that outcome is turned into real money. Third, the introduction of a new test or testing modality (e.g., POCT) will produce benefits only if a corresponding change in practice is implemented. For example, the d-dimer test has been used to exclude diagnoses of thromboembolic disease and thus avoid the need for expensive radiologic procedures. This approach works only if clinicians actually consider the d-dimer results and stop ordering the expensive imaging tests when the d-dimer result and the clinical findings indicate that they are not needed. Finally, even if the desired cost savings are achieved, silo budgeting ensures that the savings are seen in a budget different from that of the laboratory, and the laboratory budget shows only an increased expenditure. Fortunately, the drawbacks of silo budgeting are being recognized, and a broader view of health economics seems to be developing in some healthcare settings. Thus the Office of Health Economics in the UK is asking whether a value-based pricing approach should be taken to molecular diagnostics, the arguments for which could equally be applied to all types of diagnostic tests (http://www.ohe.org/publications/article-/value-based-pricing-and-molecular-diagnostics-117.cfm; accessed July 5, 2013).

Clinical Practice Guidelines

The patient-centered goals of evidenced-based laboratory medicine are not reached by primary studies and systematic reviews alone. The results of these investigations must be turned into action. Increasingly, health systems and professional groups in medicine have turned to the use of clinical practice guidelines. Guidelines are a tool that are used to facilitate implementation of lessons from primary studies and systematic reviews. Important motivations for development of guidelines have been to decrease variability in practice (and improve the use of best practices) and to shorten the (often prolonged) time required for new information to be used for the benefit of patients or for prevention of disease.

The development of practice guidelines for the clinical laboratory is a challenging new area. A limited amount of advice is available on preparing such guidelines,[8] but the applicability of the AGREE (Appraisal of Guidelines for Research and Evaluation) tool has recently been described in preparation of the National Clinical Biochemistry Practice Guidelines.[2]

What Is a Clinical Practice Guideline?

According to the Institute of Medicine, "**Clinical practice guidelines** are systematically developed statements to assist practitioner and patient decisions about appropriate healthcare for specific clinical circumstances". Guidelines of various sorts have long addressed issues of concern to laboratorians, such as requirements or goals for (1) accuracy, (2) precision, and (3) turnaround time of tests and considerations about the frequency of repeat tests in the monitoring of patients. The focus of modern clinical practice guidelines, such as recent ones on laboratory testing in diabetes and liver disease, is the patient in the "specific clinical circumstances" referred to in the definition of clinical practice guidelines. The tools of EBM and clinical epidemiology allow guidelines to be developed in a more transparent way from thoroughly conducted studies and systematic reviews.

Use of Transparency in the Development of Guidelines

In the absence of a transparent process for the development of a guideline, the credibility of the product is compromised and should be questioned. When guidelines are developed by a professional group (such as specialist physicians or laboratory-based practitioners), the recommendations (e.g., to perform a diagnostic procedure in a given setting) may be suspected of promoting the welfare of that professional group. In contrast, when guidelines are prepared under the auspices of healthcare payers (governments and insurance companies), the recommendations may be suspected of being influenced by cost-control measures, which sometimes may harm patients. In the latter setting, a key danger is that the absence of evidence of benefit from a medical intervention may be interpreted as proof of absence of benefit.

Steps in the Development of Guidelines

The development of guidelines is best undertaken according to a step-by-step plan. One such scheme is shown in Figure 4-5; only selected issues of this will be discussed here. For a more detailed discussion, see Oosterhuis et al[8] or Watine et al.[14]

Selection and Refinement of a Topic

The critical importance of this first step is analogous to the importance of the corresponding step in the development of a systematic review. For example, (1) the scope must not exceed the capabilities in time, funding, and expertise of the group, (2) the topic must not be without evidence (or the guideline will lack credibility), and (3) the area must be one that requires attention (or the guideline will have little value).

Typically such guidelines will address (1) clinical conditions—such as diabetes and liver disease, (2) symptoms—chest pain, (3) signs—abnormal bleeding, or (4) interventions—whether therapeutic (coronary angioplasty and aspirin) or diagnostic (cardiac markers). To decide whether developing a guideline should be considered, the following questions are of help:

- Is there variation in practice that suggests uncertainty?
- Is the issue a matter of public health importance, such as the increasing problems of diabetes and obesity? and
- Is there a perceived necessity for cost reduction?

Refinement of the topic ideally involves a multidisciplinary group that includes (1) clinicians, (2) healthcare providers, (3) laboratory experts, (4) patients, and (5) likely users of the guidelines. The scope will be affected by the support staff (if any) and the financial support available to the guideline group.

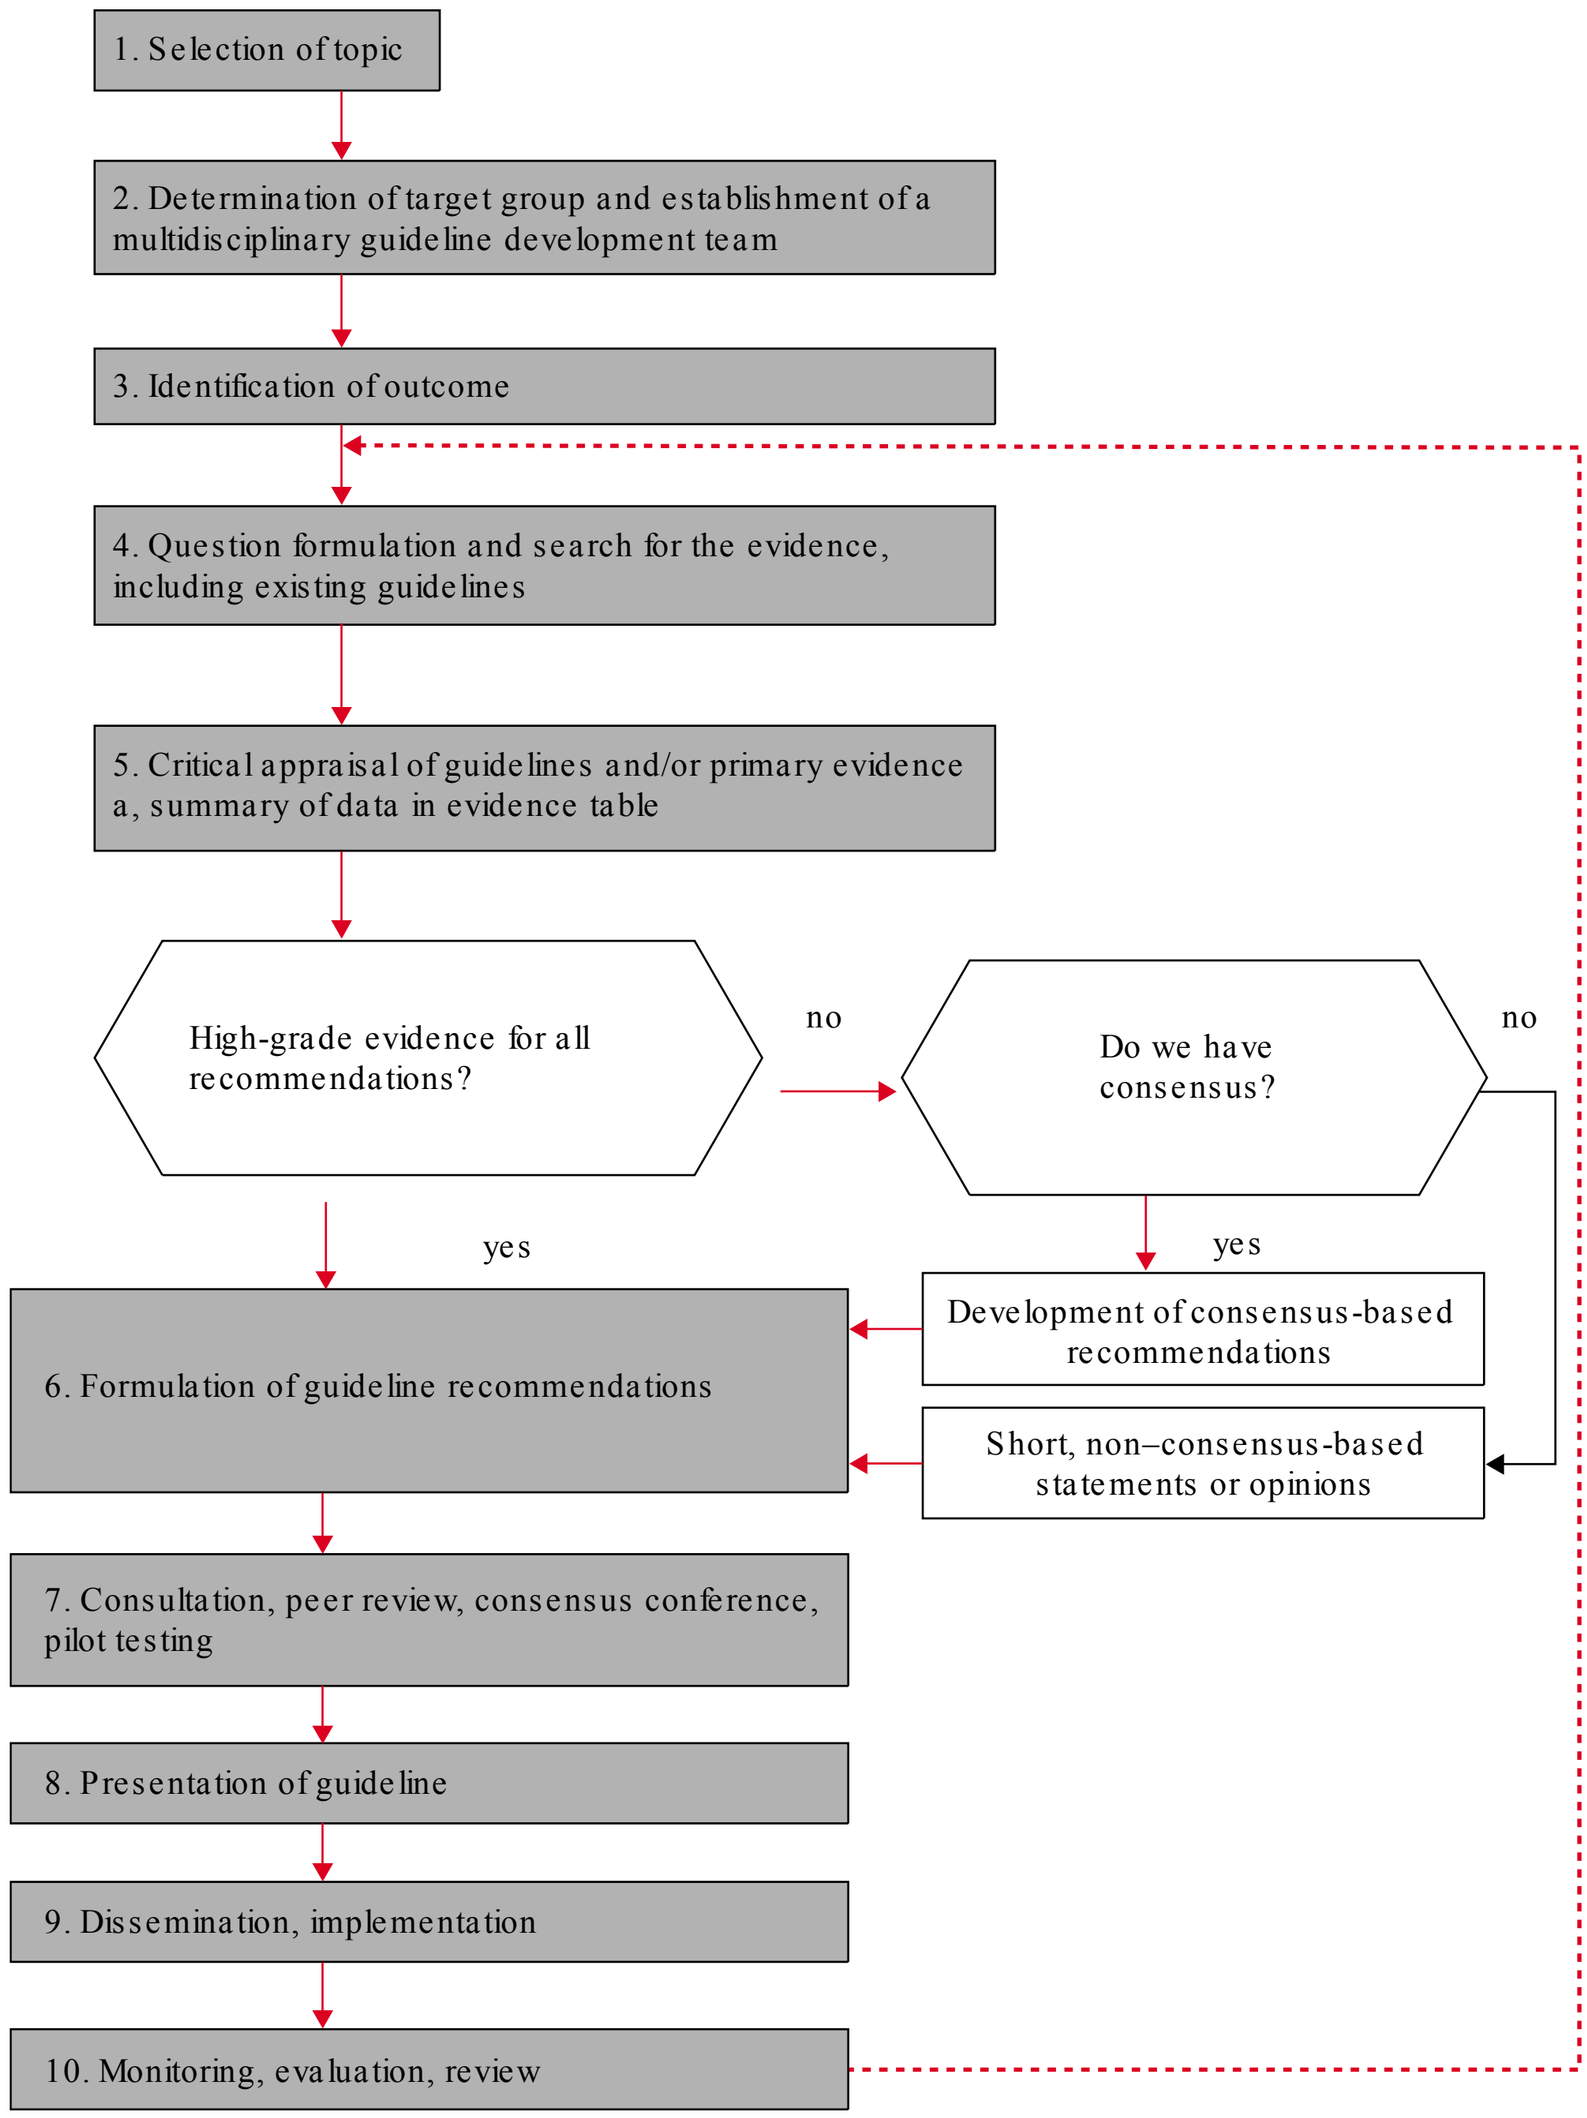

Figure 4-5 Steps in the development of a clinical practice guideline. (Modifed from Oosterhuis WP, Bruns DE, Watine J, Sandberg S, Horvath AR. Evidence-based guidelines in laboratory medicine: principles and methods, Clin Chem 2004;50:806-818.)

Determination of Target Group and Establishment of a Multidisciplinary Guideline Development Team

The intended audience must be identified. For example, is it (1) nurses, (2) general practice physicians, (3) clinical specialty physicians, (4) healthcare providers, (5) laboratory specialists, or (6) patients?

The guideline development team should include representatives from all key groups involved in management of the target condition. For the development of guidelines in laboratory medicine, teams ideally include (1) relevant medical specialists, (2) laboratory experts, (3) methodologists (for expertise in statistics, literature search, critical appraisal, and guideline development), and (4) those who deliver services (e.g., nurse practitioners and patients, for guidelines on home monitoring of glucose; laboratory technologists and managers, for a guideline that addresses turnaround times for cardiac markers).

Potential conflicts of interest of all members must be noted. The role, if any, of sponsors (commercial or nonprofit) in the guideline development process must be agreed upon and reported. Ideally, staff support members are available to (1) help arrange meetings and conference calls, (2) retrieve published work, and (3) assist with publication and other forms of dissemination (e.g., audio conferences).

A minimum group size of six has been recommended. Groups consisting of more than 12 to 15 persons will inhibit the airing of each person's views. A recommended tool is the

use of subgroups to focus on specific questions, with a steering committee responsible for coordination and production of the final guideline.

Identifying and Assessing the Evidence

When available, well-performed systematic reviews form the most important part of the evidence base for guidelines. Systematic reviews are necessary when variation between studies is expected. When no systematic reviews exist, the group effectively must undertake to produce one. The level of evidence supporting each conclusion in the review will affect the recommendations made in the guidelines.

Translating Evidence Into a Guideline and Grading the Strength of Recommendations

The processes required for preparing recommendations within an expert group are poorly understood; this challenge has been addressed by the Grading of Recommendations Assessment, Development, and Evaluation (GRADE) Working Group (http://www.gradeworkinggroup.org; accessed July 5, 2013). The GRADE process begins when an explicit question is asked, including specification of all important outcomes. After evidence has been collected and summarized, GRADE provides explicit criteria for rating the quality of evidence, including (1) study design, (2) risk of bias, (3) imprecision, (4) inconsistency, (5) indirectness, and (6) magnitude of effect. Recommendations are then characterized as strong or weak according to the quality of the supporting evidence and the balance between desirable and undesirable consequences of the alternative management options.

Developing recommendations for clinical practice guidelines may involve balancing of costs and benefits after values are assigned and the quality of evidence has been determined. Conclusive evidence for recommendations is not always available. However, authors of guidelines have an ethical responsibility to make very clear the level of evidence that supports each recommendation.

Several schemes are available for rating the evidence. For example, the National Academy of Clinical Biochemistry (NACB) is working with the Professional Practice Committee of the American Diabetes Association to revise the NACB diabetes guidelines. Their goal is to develope a new system that offers a means of both rating the overall quality of evidence and grading the strength of recommendations. This approach is summarized in Table 4-3. The level or rating of evidence does not always predict the strength of a recommendation because recommendations involve assessing changes in outcome and may require extrapolation from study results. For example, multiple studies supporting use of a drug may have been done well and a competent systematic review may be available, so the evidence may be graded as high. However, if the studies were done in adults and the guideline is for children, the strength of the recommendation may be low.

The highest level of evidence is rare in guidelines on the use of diagnostic tests. With many such guidelines, most of the recommendations are based on expert opinion. As more studies are published on the diagnostic accuracy of tests and on the relationships of tests to outcomes, the dependence of guidelines on "opinion" should decrease.

For analytical goal setting or "quality specifications" for analytical methods in guidelines, randomized controlled clinical trials (outcomes studies) are not appropriate. In such situations, a different hierarchy of evidence (Table 4-4) may be useful for grading of such laboratory-related recommendations. The

TABLE 4-3 A Scheme for Rating the Quality of Evidence in Grading the Strength of Recommendations in Clinical Guidelines

Level	Characteristics
	Rating scale for quality of evidence
High	Further research is unlikely to change the confidence in the results. Body of evidence from individual studies sufficiently powered provides precise, consistent, and directly applicable results in a relevant population.
Moderate	Further research is likely to have an important impact on confidence in the estimate of effect and may change the estimate and the recommendation. Body of evidence comes from high/moderate-level individual studies sufficient to determine effects, but strength of evidence may be limited by number, quality or consistency of included studies, generalizability to routine practice, or the indirect nature of the evidence.
Low	Further research is very likely to have an important impact on confidence in the estimate of effect and may change the estimate and the recommendation. Body of evidence is of low level with serious design flaws, or evidence is indirect.
Very low	Any estimate of effect is very uncertain. Evidence is insufficient for assessment of effects on health outcomes because of the limited number or power of studies, important flaws in their design or conduct, gaps in the chain of evidence, or lack of information.
	Grading strength of recommendation
	Grading based on rating of evidence and expert agreement on impact on health outcomes and substantial benefit over harm
A	Strongly recommend for or against adoption
B	Recommend for or against adoption
C	Insufficient evidence to make a recommendation because of poor quality or lack of evidence
GPP	Good practice point based on expert consensus and mainly applicable to technical matters

For full information, consult Sacks DB, Arnold M, Bakris GL, Bruns DE, Horvath AR, Kirkman MS, et al. Executive summary: guidelines and recommendations for laboratory analysis in the diagnosis and management of diabetes mellitus, Clin Chem 2011;57:793-798.

highest level of evidence is evidence related to medical needs. It is conceivable that even statistical modeling of specific clinical decisions could be considered as a subtype of evidence related to medical needs. For example, simulation modeling of the diagnostic process has been employed to study the impact of rapid turnaround of results for troponin measurements on triage times in the emergency room for patients presenting with chest pain. Monte Carlo simulation has been used to quantify the effects of errors in glucose measurements (imprecision and bias) on the ability of insulin-dosing protocols to control glucose concentrations in patients.

Level 1B in Table 4-4 refers primarily to the concepts of within-individual and among-individual biological variation. Levels of (1) optimum, (2) desirable, and (3) minimum performance for both imprecision and bias have been defined on the basis of these concepts. Meeting these performance goals ensures that the analytical imprecision is small compared with the normal day-to-day variations that occur within an individual. Similarly, the goal for bias is to minimize variation within an individual compared with variation among individuals. Thus, reference intervals for a test in a given reference group will be unaffected by the small amount of analytical error or bias. Use of this type of quality specification for imprecision and bias appears appropriate in guidelines. In practice, failure to use this approach is difficult to justify because data on within-individual and among-individual biological variation are available for virtually all commonly used tests.

Obtaining External Review and Updating the Guidelines

Three types of outside examiners have been used to evaluate guidelines:

- Experts in the clinical content area—to assess completeness of the literature review and the reasonableness of recommendations.
- Experts on systematic reviewing and guideline development—to review the process of guideline development.
- Potential users of the guidelines.

In addition, (1) journals, (2) sponsoring organizations, and (3) other potential endorsers of the guidelines may undertake formal reviews. Each of these reviews adds value.

As part of the guideline development process, a plan for updating should be developed. The importance of this step is underscored by the finding that one of the most common reasons for nonadherence to guidelines is that the guidelines are outdated. About half of published guidelines are outdated in 5 to 7 years, and no more than 90% of conclusions are still valid after 3 to 5 years. These findings suggest that the time interval between completion and review of a guideline should be short.

TABLE 4-4 Hierarchy of Criteria for Quality Specifications

Level	Basis
1A	Medical decision making: use of test in specific clinical situations
1B	Medical decision making: use of test in medicine generally
2	Guidelines—"experts"
3	Regulators or organizers of external quality assurance schemes
4	Published data on state of the art

From Fraser CG, Petersen PH. Analytical performance characteristics should be judged against objective quality specifications, Clin Chem 1999;45:321-323.

Clinical Audit

In healthcare, the term audit refers to the review of case histories of patients against the benchmark of current best practice. In practice, the **clinical audit** improves clinical practice. However, the effects are typically modest. A more general role for audit, however, is that it is used as part of the wider management exercise of benchmarking of performance with the use of relevant performance indicators against the performance of peers. This is sometimes referred to as performance management.

Audits also are used to (1) solve problems, (2) monitor workload in the context of controlling demand, (3) monitor the introduction of a new test and/or change in practice, and (4) monitor the variation between providers and adherence with best practices (e.g., with guidelines).

The components of the audit cycle are depicted in Figure 4-6. All of the audit activities are found in the practice of evidence-based laboratory medicine. There is a clinical question for which the test result should provide an answer, and the answer will lead to a decision being made and an action taken, resulting in an improved health outcome.

Audit to Help Solve Problems

All audits involve the collection of observational data and comparison against a standard or specification. Thus, an audit

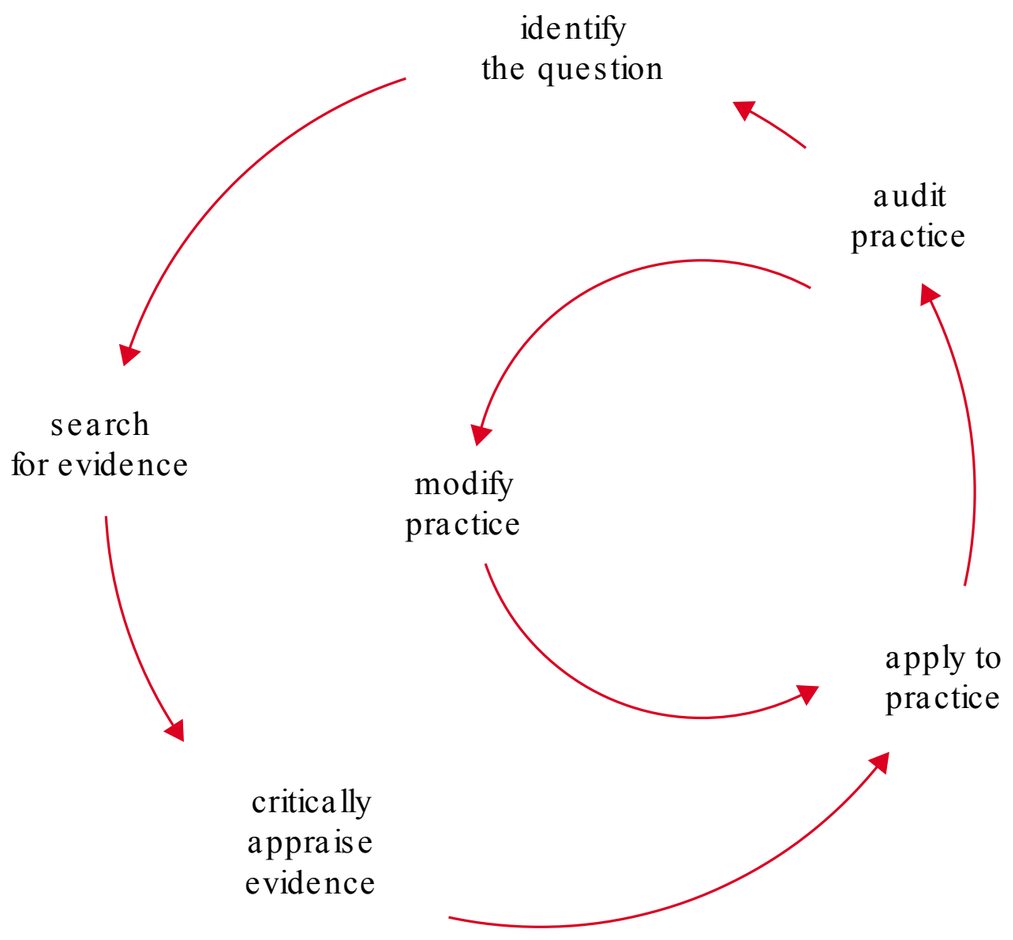

Figure 4-6 The audit cycle. (From Price CP. Evidence-based laboratory medicine: supporting decision-making, Clin Chem 2000;46:1041-1050.)

may determine the proportion of test results that are returned within a specified time or standard (such as 45 minutes from receipt). In many cases a standard does not exist, and maybe not even a specification. In such cases, the first step of an auditing process is to establish a specification.

Solving a problem related to a process may first involve collecting data on aspects of the process that are considered to have an influence on the outcome. For example, a study of test result turnaround times might collect data on (1) phlebotomy waiting time, (2) quality of patient identification, (3) transport time, (4) sample registration time, (5) quality of sample identification, (6) sample preparation time, (7) analysis time, (8) test result validation time, and (9) result delivery time.

Audit to Monitor Workload and Demand

The true demand for a test will depend on the number of patients and the spectrum of disease in the group for which the test is appropriate. When an audit of workload for a test is conducted, it is possible to ask a number of questions that address the appropriateness of the test requests. These questions, which typically are asked by questionnaire, include the following:

- What clinical question is being asked?
- What decision will be aided by the results of the test?
- What action will be taken after the decision is made?
- What risks are associated with not receiving the result?
- What are the expected outcomes?
- Is there evidence to support the use of the test in this setting?
- And, for tests ordered urgently, why was this test result required urgently?

This approach is likely to identify (1) unnecessary use of tests, (2) misunderstandings about the use of tests, and (3) instances of use of the wrong test. With the advent of electronic requesting and the electronic patient record, it is possible to build this approach into routine practice.

Actions that may follow from the answers to these questions include (1) feedback of results to users, (2) re-education of users, (3) identification of unmet needs and research to satisfy, for example, a need for advice on an alternative test, (4) creation of an algorithm or guideline on use of the test, and (5) re-audit in 6 months to review for changes in practice. An algorithm may be embedded in the electronic requesting package to provide an automatic bar to inappropriate requesting (e.g., liver function tests being requested every day on a patient).

Audit to Monitor the Introduction of a New Test

An audit is used to ensure (1) that the change in practice that should accompany the introduction of a new test has occurred, and (2) that the outcomes originally predicted are being delivered. The development of any new test should lead to evidence that identifies the way in which the test is going to be used, including:

- Identification of the clinical question(s), the patient cohort, and the clinical setting.
- Identification of preanalytical and analytical requirements for the test.
- Identification of any algorithm into which the test might have to be inserted (e.g., use in conjunction with other tests, signs, or symptoms).
- Identification of the decision(s) likely to be made on receipt of the result.
- Identification of the action(s) likely to be taken on receipt of the result.
- Identification of the likely outcome(s).
- Identification of any risks associated with introduction of a new test.
- The evidence (and the quality of that evidence) that supports the use of the test and the outcomes to be expected.
- Identification of any changes in practice (e.g., deletion of another test from the repertoire, move to POCT, reduction in laboratory workload).

This is summary of use and portfolio of evidence forms the basis of the standard operating procedure for (1) the clinical use of the test, (2) the core of the educational material for users of the service, and (3) the basis for conducting the audit.

Before the introduction of a new test is audited, it is obviously important to have ensured that a full program of education of users has been completed, and that any other changes in practice have been accommodated in the clinic and/or ward routines.

Audit to Monitor Variation Between Providers and Adherence to Best Practice

This is the scenario that probably best reflects the way in which the clinical audit was first conceived and practiced. Typically the clinical audit takes two forms: (1) auditing the log of requests for a specific test from users of a service (e.g., HbA_{1c} testing ordered by primary care physicians' practices or hospital clinical departments); (2) auditing randomly selected cases from a clinical team, with the review undertaken by an independent clinician. Both approaches are likely to identify when a test has not been performed and to identify unnecessary testing; the former is possibly of greater interest to the payer. The audit is best performed against some form of benchmark, which may be a local, regional, or national guideline; a guideline will have used the best evidence and thus removed differences of opinion that may exist between clinical teams.

Applying the Principles of Evidence-Based Laboratory Medicine in Routine Practice

The principles of evidence-based laboratory medicine support the manner in which laboratory medicine is practiced, from the discovery of a new diagnostic test through to its application in routine patient care. These principles provide the logic on which all of the elements of practice are founded. The tools of evidence-based laboratory medicine provide the means of delivering the highest quality of service in meeting the needs of patients and the healthcare professionals

who serve them, extending from purchase of the service to performance management of the practice.[9] In practice, the application of evidence-based practice is far more complex for laboratory medicine than for therapeutic interventions, but it is critical for success.

Review Questions

1. Meta-analysis:
   a. is a statistical technique that compares results from various studies.
   b. is an extensive and explicit strategy that is used to find all studies (published or unpublished) pertaining to a single assay.
   c. includes the quality and the quantity of the health outcome.
   d. is a tool used to facilitate implementation of lessons from primary studies and systematic reviews.
2. Systematic error produces bias and typically results from a flawed design of a study of diagnostic accuracy. This is caused by poor:
   a. reliability.
   b. external validity.
   c. internal validity.
   d. standardization.
3. In an economic evaluation of a medical test, the determination of whether or not the value of the benefit of performing the test exceeds the cost of the intervention is referred to as:
   a. minimal cost analysis.
   b. cost-effectiveness analysis.
   c. cost-utility analysis.
   d. cost-benefit analysis.
4. The first step in designing clinical practice guidelines that focus on a patient is:
   a. establishing a multidisciplinary guideline development team.
   b. selecting and refining a topic for which to develop guidelines.
   c. translating evidence into a guideline.
   d. obtaining external reviewers to evaluate guidelines.
5. The overall aim of a systematic review is to:
   a. review all literature on a particular subject.
   b. reach a recommendation by an expert group.
   c. answer an exactly defined clinical question with transparency and minimal bias.
   d. develop a recommendation that involves a balance of cost and benefit.
6. Which one of the following IS NOT a component of a clinical audit?
   a. Solving problems associated with a process or outcome
   b. Monitoring workload in the context of controlling demand
   c. Evaluating the costs of alternative approaches that produce the same outcome
   d. Monitoring the introduction of a new test and/or changes in practice
7. A systematically developed statement to assist practitioner and patient decisions about appropriate healthcare for specific clinical circumstances defines:
   a. clinical practice guidelines.
   b. systematic review.
   c. STARD.
   d. evidence-based laboratory medicine.
8. The acronym QALY stands for:
   a. quality of all life-years.
   b. quality assessment of living youth.
   c. quantifiable analysis of life's yields.
   d. quality-adjusted life-year.
9. The de facto standard for research studies of the health effects and outcomes of medical interventions is the:
   a. epidemiologic study.
   b. randomized controlled trial.
   c. open-ended survey.
   d. before-and-after design study.
10. In relation to healthcare, the word quality is defined as:
    a. the most expensive care that can be provided to a patient.
    b. the use of the best analyzers and equipment available for diagnostics to improve outcomes.
    c. the increased probability of desired outcomes and the decreased probability of undesired outcomes.
    d. an improved outcome.

CHAPTER

5 Establishment and Use of Reference Values*

Gary L. Horowitz, M.D.

Objectives

1. Define the following terms:
   - Clinical sensitivity
   - Clinical specificity
   - Exclusion criteria
   - Interpercentile interval
   - Outlier
   - Partitioning; partitioning criteria
   - Population-based reference value
   - Predictive value
   - Prevalence
   - Random sample
   - Range
   - Reference individual
   - Reference interval
   - Reference limits
   - Reference population
   - Reference value
   - Selection criteria
   - Subject-based reference value
   - Transferability or transference
2. List three conditions that are essential when a valid comparison of individual laboratory results with reference values is performed; state the need for establishing reference intervals.
3. Give three examples of exclusion criteria used in the production of health-associated reference values; give three examples of partitioning criteria used to subgroup a reference group.
4. State why standardization of specimen collection is important when reference values are established.
5. Compare the terms reference value and reference interval; list three categories of reference intervals.
6. Briefy state the parametric and nonparametric statistical methods of determining an interpercentile interval; state the important assumption that must be made when parametric statistics are used.
7. State the limitation of using population-based reference intervals instead of subject-based reference intervals, and state a solution to this limitation.
8. Discuss the issue of transferability of reference values with regard to prerequisites and solutions to the issue.
9. State the formulas used in calculating clinical sensitivity, clinical specificity, and predictive value of a laboratory test; given appropriate values, calculate clinical sensitivity, clinical specificity, and predictive value for a laboratory test.
10. State how the predictive value of a laboratory test is affected by prevalence.

Key Words and Definitions

Clinical sensitivity The proportion of subjects with disease who have positive test results.

Clinical specif city The proportion of subjects without disease who have negative test results.

Nonparametric analysis Astatistical approach to reference value analysis that requires no assumptions about the nature of the distribution; thus, it can be applied to distributions that are Gaussian or non-Gaussian.

Parametric analysis A statistical approach to reference value analysis that requires specific distributional assumptions. For example, it usually requires that the distribution of values be Gaussian (or that the values be mathematically manipulated so that they become Gaussian).

Partitioning The use of specific criteria in the subclassification of reference groups to reduce the biological variation in each group; the most commonly used criteria are age and sex.

Predictive value The predictive value of a positive laboratory test is the number of true positive results divided by the total number of positive results (true positives plus false positives); the negative predictive value is the number of true negative results divided by the total number of negative results (true negatives plus false negatives).

Prevalence The proportion of subjects in a specified population who have a specified disease or condition.

Reference individual An individual selected as the basis for comparison with individuals under clinical investigation through the use of defined criteria.

Reference interval (population-based) A set of values usually defined by an upper reference limit and a lower reference limit, representing a specified proportion of the reference population; this is frequently the central 95% of values from the reference population.

*T e author gratefully acknowledges the original contribution by Helge Eric Solberg on which major portions of this chapter are based.

Key Words and Definitions—cont'd

Reference interval (subject-based) A set of values usually defined by an upper reference limit and a lower reference limit, representing a specified proportion of the values from a reference individual; this is frequently the central 95% of values from the reference individual.

Reference population An undefined number of individuals that represent the demographic for which the reference intervals will be used. Reference individuals are chosen, preferably at random, from this larger population to provide reference samples for the establishment of a reference interval.

Reference value A value obtained by observation or measurement of a particular type of quantity on a reference individual; results of a certain type of quantity obtained from a single individual or group of individuals corresponding to a stated description.

Selection criteria A set of criteria that define the desired characteristics of a reference individual. The specific criteria chosen will depend of the purpose of the reference interval and the specific population the RI is intended to represent.

Transferibility or Transference The adoption by a laboratory of previously established reference intervals established elsewhere. Procedures for validation of reference intervals must be completed by the adopting laboratory prior to the use of the transferred RI to ensure that they are appropriate to the laboratory's patient population and laboratory methods.

In practice, data collected during (1) medical interviews, (2) clinical examinations, and (3) supplementary investigations are interpreted by comparison with reference data. If the condition of the patient resembles that typical of a particular disease, the clinician or healthcare provider may base the diagnosis on the observation (positive diagnosis). This diagnosis is made more likely if observed symptoms and signs do not fit the patterns that characterize a set of alternative diseases (diagnosis by exclusion).

Interpretation of medical laboratory data is an example of decision making by comparison. We therefore need reference values for all tests performed in the clinical laboratory, not only from healthy individuals but from patients with relevant diseases.[8,9,14] Ideally, observed values should be related to several collections of reference values, such as values from (1) healthy people, (2) undifferentiated hospital population, (3) people with typical diseases, or (4) ambulatory individuals, and to previous values from the same subjects.[9] A patient's laboratory result is simply not medically useful if appropriate data for comparison are lacking. Establishment and use of such reference values are the topics of this chapter.

Establishment of Reference Values

Certain conditions are mandatory for ensuring that the comparison of a patient's laboratory results with reference values is valid:

1. All groups of reference individuals should be clearly defined.
2. The patient examined should resemble sufficiently the reference individuals (in all groups selected for comparison) in all respects other than those under investigation.
3. The conditions under which the samples were obtained and processed for analysis should be known.
4. All quantities compared should be of the same type.
5. All laboratory results should be produced with the use of adequately standardized methods under sufficient analytical quality control (see Chapter 7).
6. The clinical sensitivity, clinical specificity, and prevalence in the populations tested should be known so that laboratory tests can be interpreted intelligently (see Chapter 3).

Background

The term normal values has been used frequently in the past. Confusion arose because the word normal has several very different connotations. Consequently, this term is now considered obsolete and **should not be used!** Instead, the International Federation of Clinical Chemistry and Laboratory Medicine (IFCC)[9] recommends use of the term *reference* values and related terms, such as *reference* individual, *reference* limit, *reference* interval, and observed values. **Reference values** are results of a certain type of quantity obtained from a single individual or group of individuals corresponding to a stated description, which must be spelled out and made available for use by others.

A short description of qualifiers associated with the term *reference* values, such as health-associated *reference* values (close to what was understood by the obsolete term normal values), is convenient. Other examples of such qualifying words are (1) diabetic patient, (2) hospitalized diabetic patient, and (3) ambulatory diabetic patient. These short descriptions prevent the common misunderstanding that reference values are associated only with health.

A further distinction is made between subject-based and population-based reference values. Subject-based *reference* values are previous values from the same individual, obtained when the individual was in a defined state of health. Population-based *reference* values are those obtained from a group of systematically defined reference individuals and are usually the values referred to when the term *reference* values is used with no qualifying words.

Selection of Reference Individuals

A set of explicit criteria should be used to determine which individuals should be included in the group of **reference individuals**. Such criteria include (1) statements describing the source population, (2) specifications of criteria for health, and (3) the disease of interest.[9,14] The selection of reference individuals is based essentially on the application of these defined criteria to the entire group of examined candidates. The required characteristics of the reference values determine which criteria should be used in the selection process.

BOX 5-1 Examples of Exclusion Criteria for Health-Associated Reference Values*

Diseases
Risk Factors
Obesity
Hypertension
Risks from occupation or environment
Genetically determined risks
Intake of Pharmacologically Active Agents
Drug treatment for disease or suffering
Oral contraceptives
Drug abuse
Alcohol
Tobacco
Specific Physiological States
Pregnancy
Stress
Excessive exercise

*This box lists only some major classes of criteria. It should be supplemented with other relevant criteria based on known sources of biological variation.

BOX 5-2 Examples of Partitioning Criteria for Possible Subgrouping of the Reference Group

Age (not necessarily categorized by equal intervals)
Gender
Genetic Factors
Ethnic origin
Blood groups (ABO)
Histocompatibility antigens (HLA)
Genes
Physiological Factors
Stage in menstrual cycle
Stage in pregnancy
Physical condition
Other Factors
Socioeconomic
Environmental
Chronobiological

HLA, Human leukocyte antigen.

As examples, Box 5-1 provides some criteria that should be considered when excluding individuals in the production of health-associated reference values.

Ideally the group of reference individuals should be a random sample of all individuals in the parent population who meet the selection criteria. However, a strictly random sampling scheme is impossible to obtain in most situations for a variety of practical reasons. For example, it would imply the examination and application of selection criteria to the entire population (thousands or millions of individuals) and the random selection of a subset of individuals among those accepted. Therefore, using the best reference sample obtained after all practical considerations have been taken into account is necessary. Data then should be used and interpreted with due caution because of the possible bias introduced by the nonrandomness of the sample selection process.

Often, separate reference values for sex, age group, and other criteria are necessary. Thus, it is important to define the partitioning criteria for the subclassification of the set of selected reference individuals. Some examples are provided in Box 5-2.[2,3] In practice, each partition could require as many as 120 samples; therefore the number of partitions should usually be kept as small as possible to obtain sufficient sample sizes for the derivation of valid statistical estimates.

Age and sex are the most frequently used criteria for partitioning because several analytes vary significantly among different age and gender groups. Age may be categorized by equal intervals (e.g., by decades) or by intervals that are narrower in the periods of life where greater variation is observed. In addition, the use of qualitative age groups (e.g., [1] postnatal, [2] infancy, [3] childhood, [4] prepubertal, [5] pubertal, [6] adult, [7] premenopausal, [8] menopausal, and [9] geriatric)] often may be appropriate. Height and weight also have been used as criteria for the categorization of children.

Specimen Collection

Preanalytical standardization of (1) preparation of individuals before sample collection, (2) the sample collection itself, and (3) handling of the sample before analysis may eliminate or minimize bias or variation from these factors. These steps may reduce biological "noise" that otherwise may conceal important biological "signals" of (1) disease, (2) risk, or (3) treatment effect.

The magnitudes of preanalytical sources of variation clearly are not equal for different analytes. Therefore one may argue that one should consider only those factors that cause unwanted variation in the biological quantity for which reference value production is intended. Body posture during sample collection is, for instance, highly relevant for the establishment of reference values for nondiffusible analytes, such as albumin in serum, but is irrelevant for diffusible ones, such as serum sodium.

However, performing separate studies to allow for different preanalytical conditions for each constituent is impractical. In addition, several constituents are typically analyzed in the same clinical specimens. For these reasons, standardized procedures are recommended for sample collection, taking into account the requirements that will enable all the constituents under study to be measured accurately.

A special problem is caused by drug ingestion before sample collection. A distinction may be made between indispensable and dispensable medications. The latter category of drugs always should be avoided for at least 2 days before specimen collection. The use of indispensable drugs, such as contraceptive pills or essential medication, may be a criterion for exclusion or partition.

Analytical Procedures and Quality Control

Essential components of the required definition of a set of reference values are specifications concerning (1) analysis method, including information on (a) equipment, (b) reagents, (c) calibrators, (d) types of raw data, and (e) calculation method; (2) quality control (see Chapter 7); and (3) reliability

criteria (see Chapter 2). Specifications should be carefully described so that another investigator will be able to reproduce the study and evaluate comparability of the reference values with values obtained by the methods used for production of the patient's values in a routine laboratory. To ensure comparability between reference and observed values, the same analytical method should be used. Alternatively (or in addition), one establishes comparability of methods and populations by analyzing 20 samples from reference individuals and ensuring that no more than two values fall outside the proposed limits.[1]

Statistical Treatment of Reference Values

After the analysis of the reference specimens is performed, the reference values are subjected to a statistical treatment, which includes (1) partitioning of the reference values into appropriate groups, (2) inspection of the distribution of each group, (3) identification of outliers, and (4) determination of reference limits.

Partitioning of Reference Values

The subset of reference individuals and the corresponding reference values may be partitioned according to sex, age, and other characteristics (see Box 5-2). **Partitioning** is also known as (1) stratification, (2) categorization, or (3) subgrouping, and its results are called (1) partitions, (2) strata, (3) categories, (4) classes, or (5) subgroups. Such partitioning gives rise to narrower and potentially more appropriate reference intervals. For example, testosterone reference intervals for adult males and adult females do not overlap; combining them into a single interval would obscure those differences. Various statistical criteria for partitioning have been suggested,[6] and all feature the need to collect sufficient data to allow evaluation of the partitions separately and then, if appropriate, to combine them. One may, for example, test for differences in means or in standard deviations of the separate distributions. Note, though, that differences in means or differences in variability may be statistically significant and still too small clinically to justify replacing a single overall reference interval with several class-specific intervals. Harris and Boyd[6] and Lahti and coworkers[11] have developed other criteria for partitioning and statistical methods for this purpose.

In the following sections, a homogeneous reference distribution is assumed to exist—either the complete sample distribution (if partitioning is unnecessary) or a subclass distribution after partitioning.

Inspection of Distribution

It is advisable to display the reference distribution graphically and subsequently to inspect it. A histogram, as shown in Figure 5-1, is prepared manually or by a computer program. Examination of the histogram serves as a safeguard against the misapplication or misinterpretation of statistical methods, and it may provide valuable information about the data. The following characteristics should be sought in an examination of the distribution:

1. Highly deviating values (outliers) may represent erroneous values.
2. Bimodal or polymodal distributions have more than one peak and may indicate that the distribution is nonhomogeneous because of the mixing of two or more distributions. If nonhomogeneity is the case, the criteria used to select reference individuals should be reevaluated or partitioning of the values according to age, sex, or other relevant factors attempted.
3. The shape of the distribution may be asymmetrical (skewed) or more or less peaked than the symmetrical and bell-shaped Gaussian distribution (non-Gaussian kurtosis).[8,14]
4. Visual inspection may provide initial estimates of the location of reference limits that are useful as checks on the validity of computations.

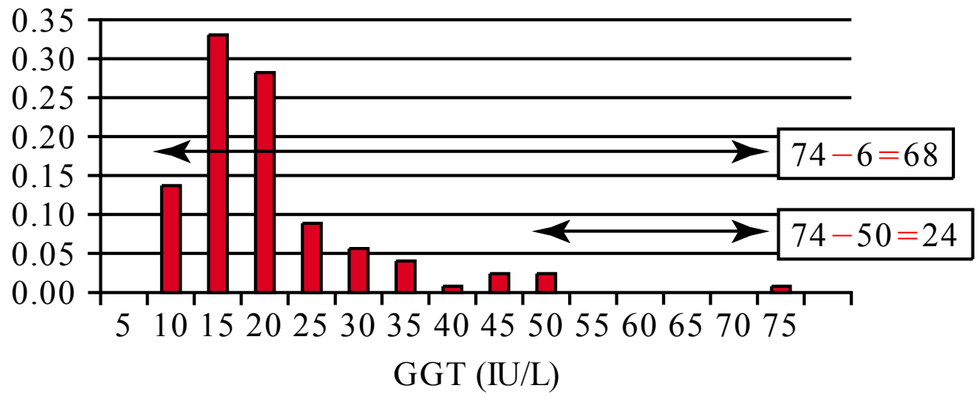

Figure 5-1 Observed distribution of 124 γ-glutamyltransferase (GGT) values in serum (IU/L). This distribution is clearly not Gaussian; it appears skewed to the right. The upper arrow indicates the range of observed values (highest − lowest, or 74 − 6 = 68); the lower arrow indicates the difference between the highest value and the next highest value (74 − 50 = 24). Because the quotient (24/68 = 0.35) exceeds 0.33, Dixon's range test indicates that the highest value is an outlier and therefore is omitted from all further analyses.

Identification and Handling of Outliers

An outlier is an erroneous value that deviates significantly from the proper reference values.[15] Visual inspection of a histogram is a reliable method for identification of possible outliers. However, the inspector must keep in mind that values near the farthest point on the long tail of a skewed distribution may easily be misinterpreted as outliers. If the distribution is positively skewed, inspection of a histogram displaying the logarithms of the values may aid in the identification of outliers. Some outliers may be identified by statistical tests,[7,9,14] but no single method will detect outliers in every situation that may occur. Two main problems are often encountered:

1. Many tests assume that the type of the true distribution is known before the tests are used. Some tests specifically require that the distribution be Gaussian. However, biological distributions are very often non-Gaussian, and their types seldom are known in advance. The Dixon-Reed range test, described in IFCC's recommendation,[9] is relatively robust and involves identification of the extreme value as an outlier if the difference between the two highest (or lowest) values in the distribution exceeds one-third of the range of all values (see Figure 5-1).
2. Several tests for outliers assume that the data contain only a single outlier. Thus the range test may fail in the presence of several outliers.

A method published in 2005[12] may provide a solution to both of these problems. The algorithm involves mathematically transforming the data so as to approximate a Gaussian

distribution, calculating the range of the central 50% of the resulting distribution, and then subtracting 150% of this value from the 25th percentile and adding 150% of this value to the 75th percentile. Any values beyond these limits are considered outliers.

Deviating values identified as possible outliers should not be discarded automatically. Values should be included or excluded on a rational basis. The records of the suspect values should be checked and any errors corrected. In some cases, deviating values should be rejected because uncorrectable causes have been found, such as previously unrecognized conditions that qualify individuals for exclusion from the group of reference individuals.

Determination of Reference Limits

In clinical practice, an observed patient's value usually is compared with the corresponding **reference interval,** which is bounded by a pair of reference limits. This interval, which may be defined in different ways, is a useful condensation of the information carried by the total set of reference values.

The terms reference limits and clinical decision limits should not be confused. Reference limits describe the reference distribution and provide information about the observed variation of values in the selected set of reference individuals. Thus comparison of new values with these limits only conveys information about similarity to the given set of reference values. In contrast, clinical decision limits provide optimal separation among clinical categories. Such limits usually are based on analysis of reference values from several groups of individuals (e.g., healthy individuals, patients with relevant diseases) and thus are used for the purpose of differential diagnosis. Alternatively, such values are established scientifically on the basis of outcome studies and are used as clinical guidelines for treatment. The National Cholesterol Education Program guidelines for cholesterol is an example of decision limits currently in widespread use.[2]

As discussed earlier, the term reference range has been used for the term reference interval, but this use should be discouraged because the statistical term range denotes the difference (a single value!) between maximum and minimum values in a distribution.

Categories of reference intervals include (1) tolerance interval, (2) prediction interval, and (3) interpercentile interval.[9] The choice from among these three may be important for certain systematically defined statistical problems, but, in practice, their numerical differences are negligible when based on at least 100 reference values.

The interpercentile interval is (1) simple to estimate, (2) more commonly used, and (3) recommended by the IFCC.[9] It is defined as an interval bounded by two percentiles of the reference distribution. A percentile denotes a value that divides the reference distribution such that a specified percentage of its values has magnitudes less than or equal to the limiting value. For example, if 47 IU/L is the 97.5 percentile of serum γ-glutamyltransferase (GGT) values, then 97.5% of the values are equal to or below this value.

The definition of the reference interval as the central 95% interval bounded by the 2.5 and 97.5 percentiles is an arbitrary but common convention as 2.5% of the values are cut off in both tails of the reference distribution.[9] Another size or an asymmetrical location of the reference interval may be more appropriate in particular cases.

Of importance is the degree of uncertainty associated with a given percentile as an estimate of a population value; the magnitude of this uncertainty depends on the size of the number of samples, which increases when the number of observations is low. If the assumption of random sampling is fulfilled, determination of the confidence interval of the percentile (i.e., the limits within which the true percentile is located with a specified degree of confidence) is possible. The 0.90 confidence interval of the 97.5 percentile (upper reference limit) for serum GGT may, for example, be 39 to 50 IU/L. The true percentile would be expected in this interval with a confidence limit of 0.90 if all serum GGT concentrations in the total reference population were measured. The theoretical minimum sample size required for estimation of the 2.5 and 97.5 percentiles is 40 values, but usually at least 120 reference values are required to obtain reliable estimates.

The interpercentile interval has been determined by both parametric and nonparametric statistical techniques. The **parametric** method for the determination of percentiles and their confidence intervals assumes a certain type of distribution, and it is based on estimates of population parameters, such as the mean and standard deviation (SD). For example, a parametric method is used if the true distribution is believed to be Gaussian and reference limits (percentiles) are determined as the values located 2 SDs below and above the mean. Most parametric methods in fact are based on the Gaussian distribution. If the reference distribution has another shape, mathematical functions that transform data to approximately Gaussian shape may be used. In contrast, the **nonparametric** method makes no assumptions concerning the type of distribution and does not use estimates of distribution parameters. The percentiles are determined simply by cutting off the required percentage of values in each tail of the subset reference distribution.

When the results obtained by these two methods are compared, the estimates of the percentiles usually are very similar. In general, the simple and reliable nonparametric method is preferable to the parametric method.

Nonparametric Method

Several nonparametric methods are available,[14] but those based on ranked data are simple and reliable and allow nonparametric estimation of the confidence intervals of the percentiles.[6,9,13,14]

The steps in a nonparametric procedure are as follows:

1. Sort the n reference values in ascending order of magnitude, and rank the values. The minimum value has rank number 1, the next value number 2, and so on, until the maximum value, rank n, is reached. Consecutive rank numbers should be given to two or more values that are equal ("ties"). Spreadsheet software such as EXCEL is often used to sort and rank this type of data.
2. Compute the rank numbers of the 2.5 and 97.5 percentiles as 0.025(n + 1) and 0.975(n + 1), respectively.

3. Determine the percentiles by finding the original reference values that correspond to the computed rank numbers, provided that the rank numbers are integers. Otherwise, interpolation between the two limiting values is necessary.
4. Finally, determine the confidence interval of each percentile by using the binomial distribution. Table 5-1 facilitates this step for the 0.90 confidence interval of 2.5 and 97.5 percentiles. The bounding rank numbers for each percentile may be located in the table.

Table 5-2, A and B shows an example of the nonparametric determination of percentiles using the serum GGT values shown in Figure 5-1.

Parametric Method

The parametric method[6,8,9,14] is more complicated than the nonparametric method and usually requires the use of a computer statistics program when large data sets are processed.[13] The parametric method assumes that the true distribution is Gaussian. It is absolutely critical, therefore, to test the goodness-of-fit level of the reference distribution to a hypothetical Gaussian distribution. A simple test is examination of the cumulative frequency plotted on Gaussian probability paper (Figure 5-2, B); the plot should be close to a straight line if the distribution is Gaussian. In addition, many statistical computer programs have goodness-of-fit tests (e.g., tests based on coefficients of skewness and kurtosis, the Kolmogorov-Smirnov test, the Anderson-Darling test).[9,13,14]

TABLE 5-1 Nonparametric Confidence Intervals of Reference Limits*

	Rank Numbers	
Sample Size	Lower	Upper
119-132	1	7

469-470	6	19
471-500	7	19

*The table shows the rank numbers of the 0.90 confidence interval of the 2.5 percentile for samples with 119 to 500 values. To obtain the corresponding rank numbers of the 97.5 percentile, subtract the rank numbers in the table from (n = 1), where n is the sample size.
From IFCC.[9]

If the reference distribution does not differ significantly from the Gaussian distribution, the 2.5 and 97.5 percentiles are estimated by values approximately 2 SDs on each side of the mean, or, more precisely:

$$2.5 \text{ percentile} = \bar{x} - 1.96 \times SD$$

$$97.5 \text{ percentile} = \bar{x} + 1.96 \times SD$$

The 0.90 confidence interval of each percentile is estimated by the following two limits:

$$\text{Lower confidence limit} = \text{percentile limit} - 2.81 \times \frac{SD}{\sqrt{n}}$$

$$\text{Upper confidence limit} = \text{percentile limit} + 2.81 \times \frac{SD}{\sqrt{n}}$$

If the reference distribution is non-Gaussian, mathematical transformation of data may adjust the shape to approximate

TABLE 5-2, A γ-Glutamyltransferase (GGT) Values Used in the Nonparametric Determination of Reference Intervals

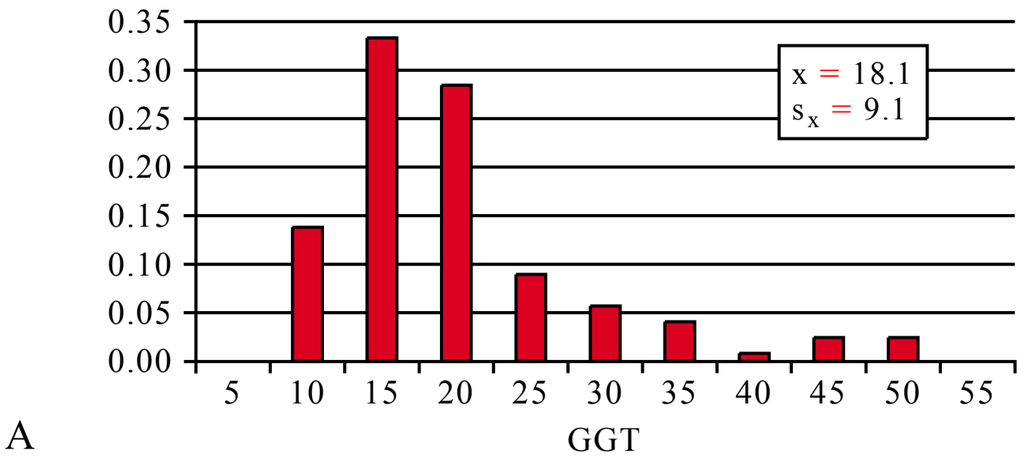
TABLE 5-2, B Nonparametric Determination of Reference Interval*

Calculation of Rank Numbers of Percentiles	
Lower	0.025 (123 + 1) = 3.1 (i.e., Rank #3)
Upper	0.975 (123 + 1) = 120.9 (i.e., Rank #121)
Original Values Corresponding to These Rank Numbers	
Lower limit (2.5 percentile)	7 IU/L
Upper limit (97.5 percentile)	47 IU/L
Rank Numbers and Values of the 0.90 Confidence Limits	
Lower Reference Limits	
Rank numbers (see Table 5-1)	#1 and #7
Values	#6 and #8 IU/L
Upper Reference Limits	
Rank numbers (see Table 5-1)	(123 + 1) − 7 = 117 and (123 + 1) − 1 = 123
Values	39 and 50 IU/L
Summary	
Lower reference limit	7 (6 to 8) IU/L
Upper reference limit	47 (39 to 50) IU/L

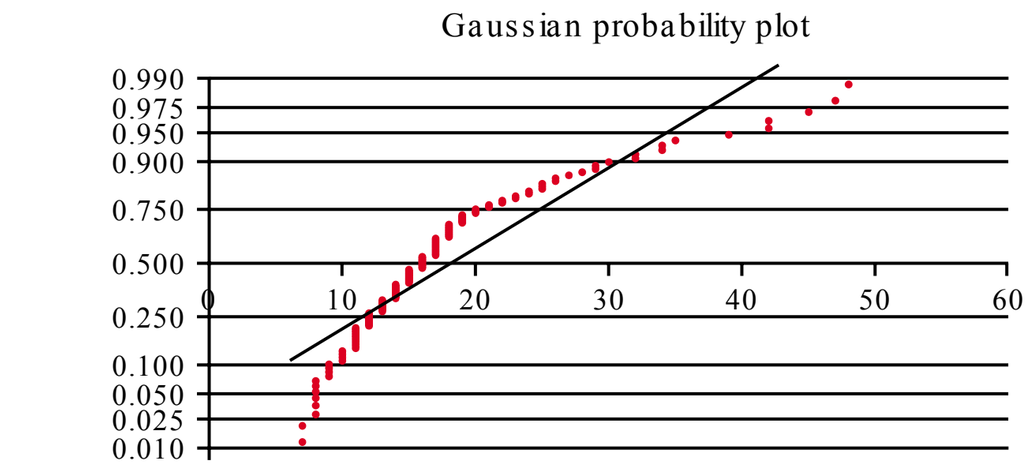
*The table shows an example using the γ-glutamyltransferase (GGT) results listed in Table 5-2, A

the Gaussian distribution. One frequent observation of interest is that logarithmically transformed values of a distribution with a long right tail (positively skewed) fit the Gaussian distribution rather closely (Figure 5-2, D). In other cases, square roots of the values better approximate the Gaussian distribution. T is information provides the basis for the common use of logarithmic and square root transformations when reference limits are estimated, as described in the following section. If these two functions fail to transform data to fit a Gaussian distribution, more general transformations can be used. Such functions are described in other relevant literature.[6,8,9,14]



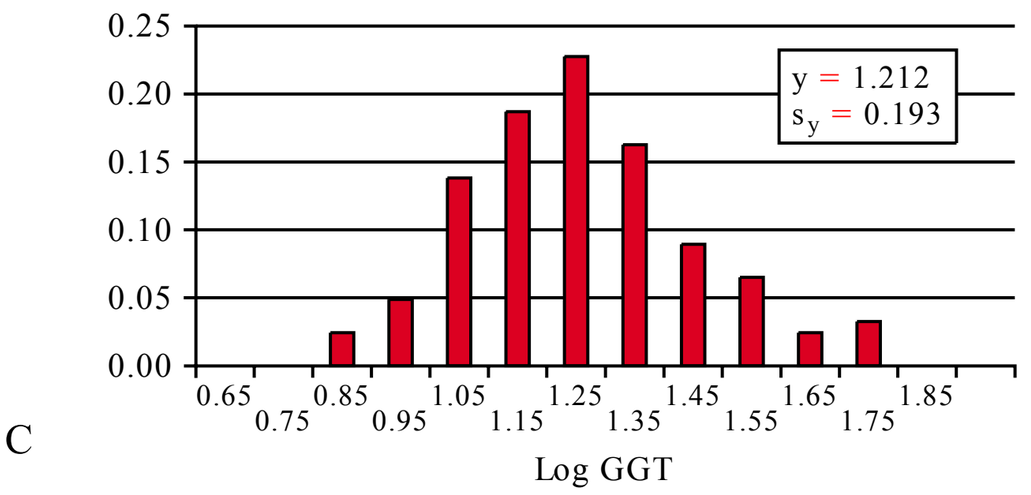
To apply the parametric procedure to transformed data, the process is very similar, as shown in the following steps:

1. Transform data with the logarithmic function $y = \log_{10}(x)$ (or $y = \ln[x]$) or by using square roots: $y = \sqrt{x}$. T en test the fit to the Gaussian distribution by using the methods described previously. If both transformations fail, then more general functions, which usually are more complicated, or the simple nonparametric method previously described should be used.
2. T en compute the mean ($\bar{y}$) and the standard deviation (SD_y) of the transformed data.
3. Next, estimate the percentiles and their confidence intervals in the transformed scale by using the formulas presented above, substituting $\bar{y}$ for $\bar{x}$ and SD_y for SD.
4. Finally, reconvert the percentiles and their confidence intervals to the original data scale by using inverse functions—antilogarithms or squares, respectively.

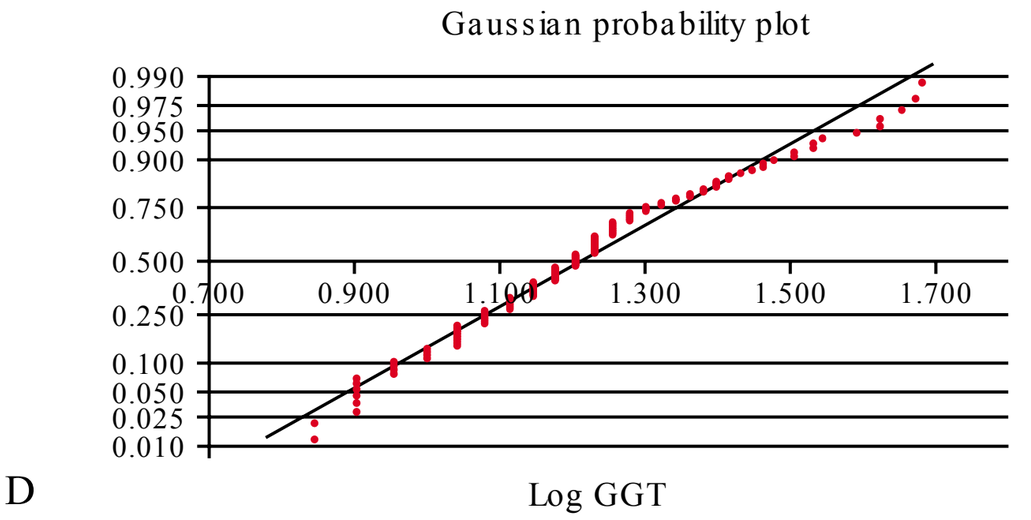


As shown in Figure 5-2, D, the mean and the SD of the serum GGT values in Figure 5-1 after logarithmic ($\log_{10}$) transformation are $\bar{y} = 1.212$ and $SD_y = 0.193$. T e 2.5 percentile is:

$$1.212 - 1.96 \times 0.193 = 0.835$$



$$2.5 \text{ percentile} = 10^{0.835} = 6.84$$



A

B

C

D

Figure 5-2 Distribution of 123 remaining γ-glutamyltransferase (GGT) values from reference subjects. A, A histogram of the original, untransformed data. B, The cumulative frequency of the data from A, plotted on Gaussian probability paper. C, A histogram of the logarithmic transformed data. D, The cumulative frequency of the data from C, plotted on Gaussian probability paper.

T e lower reference limit of serum GGT thus is 7 IU/L. T e 0.90 confidence interval of this percentile is:

$$1.212 - 2.81 \times (0.193/\sqrt{123}) = 0.786$$

$$\text{Lower confidence limit} = 10^{0.786} = 6.1$$

$$1.212 + 2.81 \times (0.193/\sqrt{123}) = 0.884$$

$$\text{Upper confidence limit} = 10^{0.884} = 7.7$$

TABLE 5-3 Summary of GGT Reference Interval Determination by Three Methods

Method	Lower Limit (Confidence Interval)	Upper Limit (Confidence Interval)	Values Below Lower Limit	Values Above Upper Limit
Nonparametric	7 (6 to 8)	47 (39 to 50)	1	2
Parametric—untransformed data	0 (−2 to 2)	36 (34 to 38)	0	7
Parametric—transformed data	7 (6 to 8)	40 (35 to 44)	1	6

The table summarizes the 95% reference intervals and associated 90% confidence limits generated by each of three methods for the same data set. The numbers of observed values deemed lower and higher than the corresponding interval for each method are given in the last two columns. Because the original data are positively skewed, note that the parametric techniques generate intervals that are biased low. Note too that the parametric technique on untransformed data has a lower confidence interval, which is actually less than 0.

that is, 6 to 8 IU/L. The 97.5 percentile (and its 0.90 confidence interval) is by the same method found to be 40 IU/L (35 to 44 IU/L).

Table 5-3 demonstrates that the nonparametric method and the parametric method (using the transformed data) result in very similar estimates of reference limits (percentiles).

Other Methods for Calculating Reference Limits

Other methods have been recommended for calculating reference limits, including the so-called bootstrap and robust methods. Neither of these methods makes assumptions about the underlying distribution; it need not be Gaussian. Both require the use of computer software because they involve numerous iterations and somewhat complicated calculations. A brief discussion of these two methods is available elsewhere.[8]

Use of Reference Values

In practice, interpreting medical laboratory data requires comparison of the patient's values with reference values.

Presentation of an Observed Value in Relation to Reference Values

An observed value (patient's value) may be compared with reference values. This comparison is often similar to hypothesis testing, but it is seldom statistical testing in the strict sense. Thus it is advisable to consider the reference values as the yardstick for a less formal assessment than hypothesis testing.

The clinician or healthcare provider should be supplied with as much information about the reference values as necessary for the interpretation.[9] Reference intervals for all laboratory tests may be presented to clinicians or healthcare providers in a booklet, together with information about the analysis methods and their imprecision, along with descriptions of the reference values. A convenient presentation of the observed value and the reference interval on the same report sheet may be helpful for the busy clinician or healthcare provider. For example, the reference intervals may be preprinted on report forms, or the computer system may select the appropriate age- and sex-specific reference interval from the database and print it next to the test result or in graphical form.

An observed value may be classified as low, usual, or high, depending on its location in relation to the reference interval. On reports, a convenient practice is to flag unusual results (e.g., through use of the letters L and H for low and high, respectively).

Another popular method of classification is expressing the observed value by a mathematical distance measure. For example, the well-known SD unit, or normal equivalent deviation, is such a measure. It is calculated as the difference between the observed value and the mean of the reference values divided by their SD.[2] This measure, however, is unreliable if the distribution of values is skewed. Values beyond ≈2 SD imply that the value is beyond the central 95% of the reference interval. Indeed, by using the SD unit deviation value, one determines the percentile of the observed value (e.g., values greater than 3.0 SD occur in only less than 0.15% of people in the reference distribution).

Subject-Based Reference Values

Figure 5-3 illustrates the inherent problem associated with population-based reference values. The figure shows two hypothetical reference distributions. One represents the common reference distribution based on single samples obtained from a group of several different reference individuals. It has a true (hypothetical) mean μ and an SD of σ. The other distribution is based on several samples collected over time in a single individual, the ith individual. Its hypothetical mean is μ_i and the SD, σ_i.

If an observed value is located outside the subject's 2.5 and 97.5 percentiles, the personal or **subject-based reference interval**, the cause may be a change in biochemical status, suggesting the presence of disease. Figure 5-3 demonstrates that such an observed value still may be within the population-based reference interval.[5] The sensitivity of the latter interval to changes in a subject's biochemical status depends accordingly on the location of the individual's mean μ_i relative to the common mean μ and to the relative magnitudes of the corresponding SDs, σ_i and σ. A mean μ_i close to μ and a small σ_i relative to σ may conceal the individual's changes entirely within the population-based reference interval.

Two specific examples may help to clarify this concept. Figure 5-4 depicts immunoglobulin M (IgM) values from several healthy individuals over the course of several days.[16] As illustrated, intraindividual differences are small as compared with interindividual differences. Even though the population-based reference interval might extend from 200 to 1600 mg/dL, in practice it would be unusual (abnormal) for any patient's IgM

value to change by more than 200 mg/dL, even if the value remained within the population-based reference interval. Similarly, it is well known that any given patient's serum creatinine value is reasonably constant,[4] and this is related both to glomerular filtration rate (GFR) and to lean muscle mass. If the latter is constant, then changes in GFR are inversely proportional to the serum creatinine (see Chapters 21 and 35), that is, even though a typical (population-based) reference interval for serum creatinine might extend from 62 to 106 μmol/L (0.7 to 1.2 mg/dL), a change from 65 to 105 μmol/L in a given patient would be distinctly abnormal, representing loss of almost half of the GFR.

At least one solution is known for the problem of the limitations of population-based reference intervals for certain tests. With this solution, the subject's previous values, obtained in a well-defined state of health, are used as the reference for any future value.[6,14] Application of subject-based reference values becomes more feasible as "health-screening" by laboratory tests and computer storage of results become available to large sections of the general population.

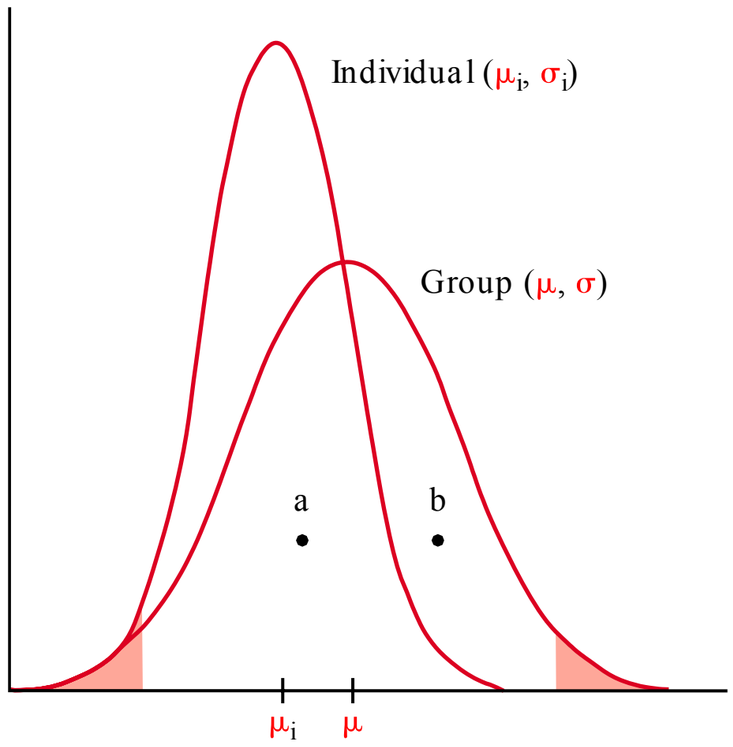


Figure 5-3 The relationship between population-based and subject-based reference distributions and reference intervals. The example is hypothetical, and the two distributions are, for simplicity, Gaussian. Hypothetical means and standard deviations are μ and σ (for the population) and μ_i and σ_i (individual i); x, analysis result. (Modifed *from* Harris EK. E*ff*ects o*f* intra- and interindividual variation on the appropriate use o*f* normal ranges, Clin Chem 1974;20:1536.)

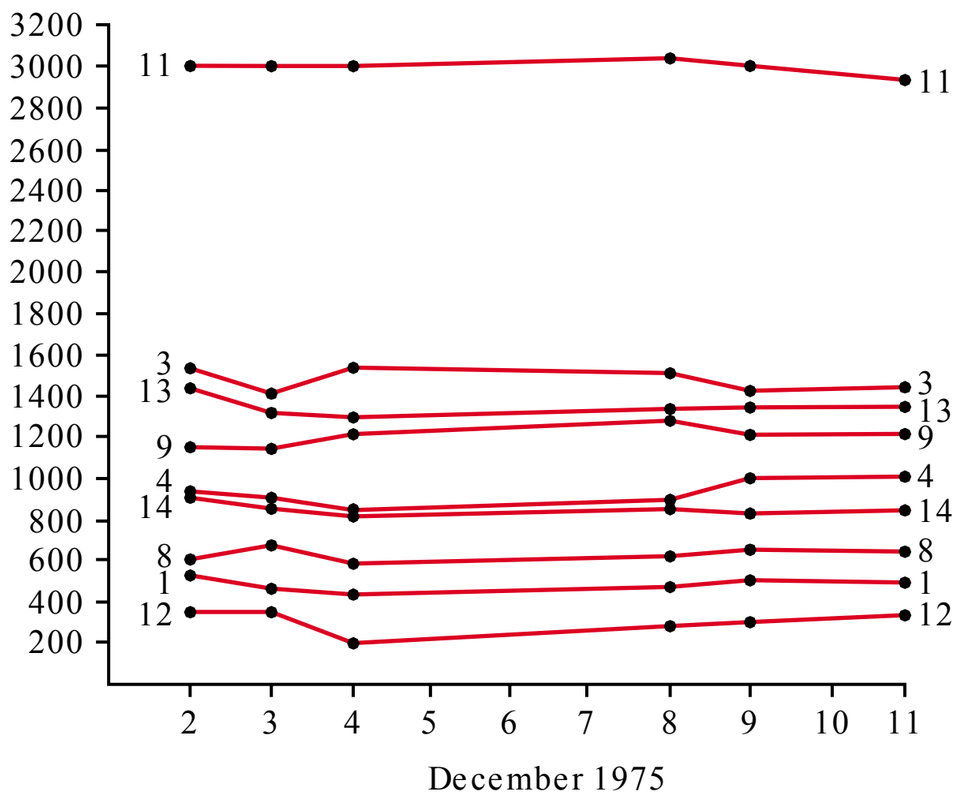

Figure 5-4 Serial immunoglobulin M (IgM) values over several days from reference individuals. Note that intraindividual variability is very small compared with interindividual variability. (From Statland BE, Winkel P, Killingsworth LM. Factors contributing to intra-individual variation o*f* serum constituents: 6. Physiological day-to-day variation in concentrations o*f* 10 specifc proteins in sera, Clin Chem 1976;22:1635-6.)

Transferability (Transference) of Reference Values

Determining reliable reference values for each test in the laboratory's repertoire is a major task that is often far beyond the capabilities of the individual laboratory. T erefore, it would be convenient if reference values generated in another laboratory could be used. T is is especially important when ethical considerations limit the number of available individuals (e.g., when pediatric reference values are produced). T en, cooperative establishment of reference values may be necessary.

A major prerequisite for transfer of reference values is that the populations must be comparable, and no major ethnic, social, or environmental differences must be noted between them. If they are not comparable, a separate reference interval study must be done.

Other factors that should not be overlooked include adherence to explicit, standardized protocols for (1) qualifying reference individuals, (2) preparing those individuals for specimen collection, and (3) performing specimen collection.

Analytical Issues

In practice, even if the populations are comparable and preanalytical standards are met, the problem of analytical transferability remains. T e optimal, but usually very unrealistic, situation assumes that analytical methods, including their calibration and quality assurance, are identical in the laboratories. A more pragmatic approach involves (1) standardization of analytical protocols, (2) common calibration, (3) design of a sufficiently efficient external quality control scheme, and (4) the use of mathematical transfer functions if results still are not directly comparable.

Multicenter Trials

Another way to assist individual laboratories in generating reference values is to pool data from multiple sites to obtain the requisite minimum 120 samples (per partition). Multicenter production o*f* reference values is gaining acceptance, both as a theoretical concept and as a practical approach. A Spanish study[3] introduced a cooperative model by simulating a virtual laboratory for 15 biochemical quantities. A project in the Nordic countries (NORIP) has produced common reference intervals for 25 analytes.[12]

Verifcation of Transfer

Whether a laboratory adopts reference values from (1) a package insert, (2) another laboratory, or (3) a multicenter trial, it

is important that the laboratory verify the appropriateness of those values for its own use.[6] T is verification serves as the final check that the laboratory has implemented the analytical method correctly and that the laboratory's own population is comparable with that used for the original reference value study.

Comparison of a locally produced, small subset of values with the large set produced elsewhere using traditional statistical tests often is not appropriate because the underlying statistical assumptions are not fulfilled and the sample sizes are unbalanced. A reasonably practical alternative has been

A

Formulas

	Patients with positive test result	Patients with negative test result	
Patients with disease	True Positives (TP)	False Negatives (FN)	Clinical sensitivity = $\frac{TP}{TP+FN}$
Patients without disease	False Positives (FP)	True Negatives (TN)	Clinical specificity = $\frac{TN}{FP+TN}$
	Total Positives = TP + FP	Total Negatives = FN + TN	
	PV (positive test) = $\frac{TP}{TP+FP}$	PV (negative test) = $\frac{TN}{(FN+TN)}$	

B

Test X: Disease prevalence = 50%

	Patients with positive test result	Patients with negative test result	
100	95	5	Sensitivity = 95/(95 + 5) = 95%
100	10	90	Specificity = 90/(90 + 10) = 90%
	Positives = 95 + 10 = 105	Negatives = 5 + 90 = 95	
	PV (positive) = 95/(95 + 10) = 90%	PV (negative) = 90/(90 + 5) = 95%	

C

Test X: Disease prevalence = 5%

	Patients with positive test result	Patients with negative test result	
500	475	25	Sensitivity = 95%
9500	950	8550	Specificity = 90%
	Positives = 475 + 950 = 1425	Negatives = 25 + 8550 = 8575	
	PV (positive) = 475/1425 = 5%	PV (negative) = 8550/8575 = 100%	

Figure 5-5 A, A basic 2 × 2 table (bold lines) facilitates understanding of the concepts of sensitivity, specificity, and predictive value. In the left-hand column, all patients with positive test results are tabulated; in the right-hand column, all patients with negative test results are tabulated. In the top row, patients with the disease under study are divided by their test results; likewise, the bottom row (show shading symbol) divides people without the disease by their test results. The top left-hand corner, then, represents patients with disease who have positive results, TRUE POSITIVES. The other three boxes are as labeled. As shown, the clinical sensitivity is calculated using the top row; the clinical specificity is calculated using the bottom row. The predictive value of a positive test is calculated using the data in the left-hand column; the predictive value of a negative test, using the right-hand column. B, The calculations described in A are done on test X, whose sensitivity and specificity are 95% and 90%, respectively. For this example, the prevalence of the population tested is 50%, refected in the fact that 100 people with disease and 100 people without disease are tested. Of note, this is frequently the prevalence used when tests are first described in the literature. As shown, the predictive value of a positive test is 90%. C, The same calculations are done on the same test X, but the prevalence used is a more realistic, but still quite high, 5%, refected in the fact that 500 people have the disease and 9500 do not. Although the sensitivity and specificity remain unchanged (95% and 90%, respectively), the predictive value of a positive test is now just 5%, that is, the likelihood that a patient with a positive test result in this population actually has the disease is 5%, or, in other words, 67% of the positive results are FALSE POSITIVES.

recommended by the Clinical Laboratory and Standards Institute (CLSI)[1]: With a sample size of 20 reference values, one verifies the appropriateness of a proposed reference interval so long as no more than two values are outside the proposed limits.

Clinical Sensitivity and Specificity and Predictive Value

When a clinician or a healthcare provider uses a laboratory test to help establish a diagnosis (as opposed to following a trend or evaluating the effectiveness of treatment), knowing the test's sensitivity and specificity can assist with proper interpretation (see Chapter 3). The **clinical sensitivity** of an assay is the fraction of those subjects with a specific disease that the assay correctly predicts. The **clinical specificity** is the fraction of those individuals without the disease that the assay correctly predicts. Figure 5-5, A, illustrates pertinent definitions and formulas.

Changing the decision limit of an assay affects both clinical sensitivity and specificity. Consider the case when the disease group has higher assay values than the nondisease group (Figure 5-6). Values above the decision limit are classified as positive; those at or below are negative. Moving the upper decision limit to a lower value increases the clinical sensitivity—but at the cost of a decrease in the clinical specificity. Thus increased true positive detection is traded for an increase in the number of false positive results. This trade-off occurs in most tests performed in medicine.

A separate, perhaps more important and more practical, issue that faces clinicians is this: Given a positive result, what is the likelihood that a patient actually has the disease? The **predictive value** of a positive test answers this question. The predictive value of a test combines disease prevalence with the test's sensitivity and specificity. **Prevalence** is the proportion of the population (or of those being tested) with the disease. The predictive value of a positive test is the number of true positive results divided by the total number of positive results (true positive and false positive results combined). As reflected in Figure 5-5, B-C, the proportion of true-positive and false-positive results is a function of the prevalence in the population and of the sensitivity and specificity of the test in question.

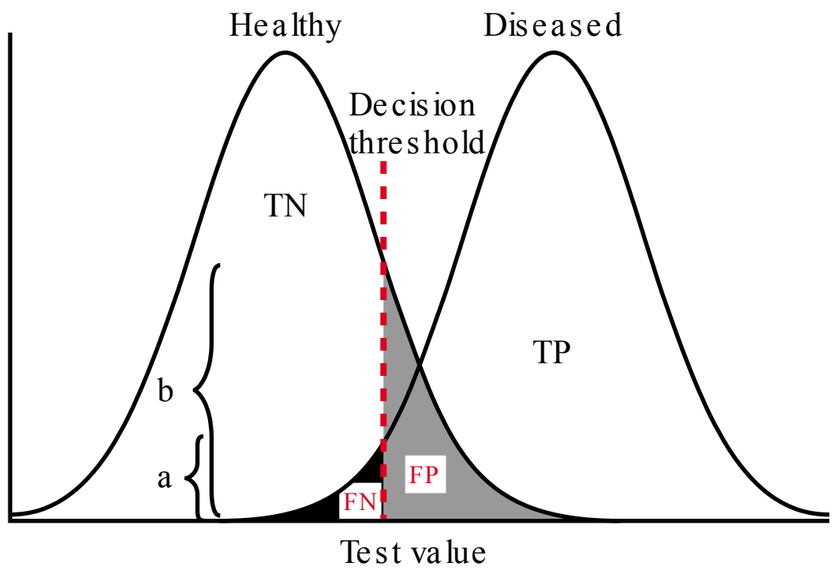

Figure 5-6 Simulated distributions of healthy and diseased populations. Note that at the shown decision threshold, the probability of a subject with disease (a) is much less than the probability of a healthy subject (b). TN, true negatives; TP, true positives; FN, false negatives; FP, false positives.

As shown in Figure 5-5, A, the predictive value of a negative test follows in a similar way. It answers the question, "Given a negative result, how likely is it that a patient does not actually have the disease?" It has been used very effectively in many situations, for example, to reliably exclude, in the appropriate clinical context, deep venous thrombosis and/or pulmonary embolism.[10]

Review Questions

1. A "subject-based" reference value is:
   a. obtained from a group of systematically defined reference individuals.
   b. the type of value referred to when the term reference value is used with no qualifying words.
   c. based on several samples collected over time in a single individual.
   d. a random sample of all individuals in the parent population who fulfill the selection criteria.
2. True negatives ÷ (false positives + true negatives) × 100 is the formula for determining:
   a. clinical sensitivity.
   b. clinical specificity.
   c. predictive value.
   d. reference value.
3. The proportion of a population that has the particular disease being studied for establishment of reference values is referred to as the:
   a. prevalence.
   b. predictive value.
   c. positive value.
   d. clinical sensitivity.
4. When reference values are established, the criteria used to determine which individuals should be included in the group of reference individuals are referred to as:
   a. exclusion criteria.
   b. inclusion criteria.
   c. partition criteria.
   d. selection criteria.
5. Calculate the predictive value of a test in which 220 tested individuals with positive test results actually have the disease and 45 tested individuals with positive test results do not have the disease.
   a. 16.9%
   b. 66%
   c. 83%
   d. 120%
6. An example of an exclusion criterion would be a(n):
   a. individual's age.
   b. risk factor such as obesity.
   c. individual's ethnic origin.
   d. individual's sex.
7. In the selection of reference individuals, subclassifying a set of these individuals into homogeneous groups is referred to as:
   a. partitioning.
   b. excluding.
   c. transferring.
   d. including.

8. The number of true positive results divided by the sum of true positive results plus false positive results is referred to as:
   a. clinical sensitivity of a positive result.
   b. clinical specificity of a positive result.
   c. prevalence of the disease.
   d. predictive value of a positive result.
9. When reference limits are determined, the statistical method that assumes that the true distribution of reference values is a Gaussian (normal) distribution is the:
   a. nonparametric method.
   b. parametric method.
   c. interpercentile interval method.
   d. predictive value.

CHAPTER

6 Specimen Collection, Processing, and Other Preanalytical Variables*

Doris M. Haverstick, Ph.D., D.A.B.C.C., and Amy R. Groszbach, M.E.D., M.L.T., M.B.(A.S.C.P.)C.M

Objectives

1. Define the following terms:
   - Anticoagulant
   - Controllable preanalytical variable
   - Hemolysis
   - Order of draw
   - Phlebotomy
   - Plasma
   - Preanalytical variable
   - Preanalytical error
   - Serum
   - Uncontrollable preanalytical variable
   - Venipuncture
2. Give two examples of a preanalytical error and two examples of an uncontrollable preanalytical variable.
3. List the types of biological specimens that are analyzed in a clinical laboratory.
4. Summarize the steps that are performed by a phlebotomist in obtaining a blood sample by venipuncture; state the preferred site of venous blood collection, including the practice used when an intravenous line is present.
5. List the general effects on analytes caused by the following:
   - Pumping a fist before venipuncture
   - Stress
   - Collection order (first tube, second tube, etc.)
   - Time of collection related to diurnal variation
   - Prolonged venous occlusion with a tourniquet
   - Not filling collection tube completely
6. Discuss order of draw for multiple blood specimens, including the order required for collecting multiple tubes of blood, color of stopper and associated additive, need for tube filling and inversion, and reason for filling tubes in a specific order.
7. Describe the skin puncture collection technique, including methods of stimulating blood fow; state the reasons for collecting a specimen using skin puncture; and describe the collection procedure for obtaining a blood spot for molecular genetic testing.
8. Explain the difference between serum and plasma.
9. Compare the difference in composition, if any, between serum and plasma specimens of the following analytes:
   - Calcium
   - Cholesterol
   - Albumin
   - Creatinine
   - Total protein
   - Glucose
   - Potassium
10. State how the following anticoagulants prevent blood from coagulating:
    - Heparin
    - EDTA
    - Citrate
    - Oxalate
    - Iodoacetate
11. State the appropriate analytical situations for using evacuated tubes containing various additives; state reasons why blood collected in the same anticoagulants cannot be used for certain analyses.
12. Describe the hemoglobin concentration at which hemolysis is observable in plasma; describe how hemolysis affects measurement of certain analytes and use of certain analytical procedures.
13. List three types of urine specimens and their use in clinical analysis; list two methods of urine preservation and discuss the use of each.
14. Outline the procedure for collecting a timed urine specimen.
15. List the clinical chemistry analyses performed on the following specimen types and the collection procedure name, if any:
    - Feces
    - Cerebrospinal fuid (CSF)
    - Synovial fuid
    - Amniotic fuid
    - Chorionic villus
    - Pleural, pericardial, and ascitic fuids
    - Saliva
    - Buccal cells
    - Hair and nails
16. Summarize each of the four aspects of specimen handling; discuss these in relation to specimen identification on various containers, centrifugation of blood samples, sample storage on ice/at −20 °C/at 4 °C, protection from light, and transport guidelines.

*T e authors gratefully acknowledge the original contributions by Drs. Donald S. Young and Edward W. Bermes, on which portions of this chapter are based.

Key Words and Definitions

Additives Compounds added to biological specimens to prevent them from clotting or to preserve the constituents of a specimen.

Anticoagulant Any substance that prevents blood from clotting.

Chorionic villus sampling A prenatal test to detect birth defects that is performed at an early stage of pregnancy and involves retrieval and examination of tissue from the chorionic villi. Also called chorionic villus biopsy.

Coagulation (clotting) The sequential process by which the multiple coagulation factors of blood interact in the coagulation cascade, resulting in formation of an insoluble fibrin clot.

Diurnal variation Variation that occurs in the amount of a substance during a 24-hour period.

Hemolysis Disruption of the red cell membrane causing release of hemoglobin and other components of red blood cells.

Phlebotomist One who practices phlebotomy; the individual drawing a specimen of blood.

Phlebotomy The puncture of a blood vessel to collect blood; literally, "the letting of blood in the treatment of disease."

Preanalytical errors Factors that affect specimens before tests are performed and that can lead to error if not controlled; they are classified as controllable or uncontrollable.

Preservative A substance or preparation added to a specimen to prevent changes in the constituents of a specimen.

Plasma The noncellular component of anticoagulated whole blood; plasma contains clotting factors.

Serum The watery portion of blood that remains after coagulation has occurred; it is obtained after centrifugation.

Sharps Any object which could readily puncture or cut the skin of an individual when encountered.

Sharps container a container designed for the disposal of sharps; required and regulated by the Occupational Safety and Health Administration (OSHA).

Skin puncture Collection of capillary blood usually from a pediatric patient by making a thin cut in the skin, usually at the heel of the foot.

Specimen A sample or portion of body fluid or tissue collected for examination, study, or analysis.

Venipuncture All of the steps involved in obtaining an appropriate and identified blood specimen from an individual's vein.

Venous occlusion Obstruction of the return of venous blood to the heart and distention of the veins; in phlebotomy, this is a temporary blockage caused by application of pressure, usually from a tourniquet.

Critical factors involved in collecting a valid specimen for analysis in the clinical laboratory include appropriate policies, procedures, and techniques for (1) collection, (2) identification, (3) processing, (4) storage, and (5) transport. Many errors have been known to occur when a specimen is collected; such errors are considered **preanalytical errors**. Other types of errors in laboratory testing are analytical errors (errors made during the testing process, such as [1] running the wrong test, [2] reagent or instrument failure, or [3] technologist error) and postanalytical errors (errors made in interpretation of analytical results, such as a wrong calculation or data entry errors when results are manually entered into the laboratory information system).

Minimizing specifically preanalytical errors through careful adherence to the concepts discussed here and to individual institutional policies will result in more reliable information for use by healthcare professionals in providing quality patient care.

Errors are considered controllable variables; however, uncontrollable variables are also present in the preanalytical phase of testing.[12,22] Such uncontrollable variables may be those associated with the physiology of the particular patient (age, sex, underlying disease, etc.) or variables associated with different specimen types from the same patient. Laboratorians need to understand these issues as well.

Types of Specimens

Types of biological **specimens** that are analyzed in clinical laboratories include (1) whole blood; (2) serum; (3) plasma; (4) urine; (5) feces; (6) saliva; (7) spinal, synovial, amniotic, pleural, pericardial, and ascitic fluids; and (8) various types of solid tissue. The Clinical and Laboratory Standards Institute (CLSI) has published several procedures for collecting many of these specimens under standardized conditions.[3-11] These procedures are updated as required, and the most current versions are listed on the CLSI website (www.CLSI.org; accessed July 5, 2013).

Blood

Blood for analysis may be obtained from (1) veins, (2) arteries, or (3) capillaries. Venous blood is usually the specimen of choice, and venipuncture is the method for obtaining this specimen. Arterial puncture is used mainly for blood gas analyses. In young children and for many point-of-care tests, skin puncture is frequently used to obtain what is mostly capillary blood. The process of collecting blood is known as **phlebotomy** (the letting of blood in the treatment of disease) and should always be performed by a trained **phlebotomist**.

Venipuncture

In the clinical laboratory, **venipuncture** is defined as all of the steps involved in obtaining an appropriate and identified blood specimen from a patient's vein. Patient and phlebotomist safety should be equally balanced during this process. Before any specimen is collected, the phlebotomist must confirm the identity of the patient using at least two methods of identification. In specialized situations, such as paternity testing or other tests of medico-legal importance, establishment of a chain of custody for the specimen may require additional patient identification, such as a photograph, provided as part

of the identification process or taken to confirm the identity of the patient. Identification must be an active process, and many hospitals now provide translation services for non–English-speaking patients. In the case of pediatric patients, the parent or guardian should be present and should provide active identification of the child. Finally, for some tests for genetic diseases, the performing laboratory may request a signed consent form from the patient; this should be completed at the time of collection if it was not provided by the requesting physician.

Before collecting a specimen, a phlebotomist should dress in personal protective equipment (PPE),[8] with additional precautions and equipment for patients in isolation as required by institutional policies. If appropriate, the phlebotomist should verify that the patient is fasting, what medications are being taken or have been discontinued as required, and so forth. The patient (1) should be comfortable, (2) should be seated or supine (if sitting is not feasible), and (3) should have been in this position for as long as possible before the specimen is drawn. At no time should venipuncture be performed on a standing patient. Either of the patient's arms should be extended in a straight line from the shoulder to the wrist. An arm with an inserted intravenous line should be avoided, as should an arm with extensive scarring or with a hematoma at the intended collection site. If a woman has had a mastectomy, arm veins on that side of the body should not be used because the surgery may have caused lymphostasis (blockade of normal lymph node drainage), affecting the blood composition. If a woman has had double mastectomies, blood should be drawn from the arm of the side on which the first procedure was performed.

The phlebotomist should estimate the volume of blood to be drawn and should select and collect the appropriate number and types of tubes for the blood, plasma, or serum tests requested. Sections that follow discuss in greater detail the recommended order of draw for multiple specimens and types of tubes. In addition to tubes, an appropriate needle must be selected. All needles must be (1) sterile, (2) sharp, and (3) without barbs. If blood is drawn for trace element measurements, the needle should be stainless steel and should be known to be free from contamination.

The preferred site for collecting venous blood in adults is the median cubital vein in the antecubital fossa, or the crook of the elbow because the vein is large and is close to the surface of the skin.[3,15] If fluid is being infused intravenously into a limb, the fluid should be shut off for 3 minutes before a specimen is obtained and a suitable note made in the patient's chart and on the result report form. Specimens obtained from the opposite arm are preferred. The area around the intended puncture site should be cleaned with whatever cleanser is approved for use by the institution. Cleaning of the puncture site should be done with a circular motion and from the site outward. The skin should be allowed to dry in the air. No alcohol or cleanser should remain on the skin because traces may cause hemolysis and may invalidate test results. Once the skin has been cleaned, it should not be touched until after the venipuncture has been completed.

The time at which a specimen is obtained is important for those blood constituents that undergo marked **diurnal variation** (e.g., corticosteroids, iron) and for those used to monitor drug therapy. For most current molecular diagnostic tests, the time of day is unlikely to contribute to altered or invalid test results.

After the skin is cleaned, a blood pressure cuff or a tourniquet is applied 4 to 6 inches (10 to 15 cm) above the intended puncture site (distance for adults). This obstructs the return of venous blood to the heart and distends the veins (**venous occlusion**). It is rarely necessary to leave a tourniquet in place for longer than 1 minute, but even within this short time, the composition of blood changes. Although the changes that occur in 1 minute are slight, marked changes have been observed after 3 minutes for many chemistry analytes (Table 6-1). No known changes affect molecular diagnostics.

The composition of blood drawn first—that is, the blood closest to the tourniquet—is most representative of the composition of circulating blood. The first-drawn specimen should therefore be used for those analytes such as calcium that are pertinent to critical medical decisions.[20] Blood drawn later shows a greater effect from venous stasis. Thus the first tube may show a 5% increase in protein, whereas the third tube may show a 10% change.[17] The concentration of protein-bound constituents is also influenced by stasis. Prolonged stasis may increase the concentration of protein or protein-bound constituents by as much as 15%.

Pumping of the fist before venipuncture should be avoided because it causes an increase in plasma potassium, phosphate, and lactate concentrations. Lowering of blood pH by accumulation of lactate causes the plasma ionized calcium concentration to increase.[20] The ionized calcium concentration reverts to normal 10 minutes after the tourniquet is released.

Stress associated with blood collection has been known to have effects on patients at any age. As a consequence, plasma concentrations of cortisol and growth hormone may increase. Stress occurs particularly in young children who are (1) frightened, (2) struggling, and (3) held in physical restraint. Collection under these conditions may cause adrenal stimulation, leading to an increased plasma glucose concentration, or may

TABLE 6-1 Changes in Composition of Serum When Venous Occlusion Is Prolonged from 1 Minute to 3 Minutes*†

Increase	%	Decrease	%
Total protein	4.9	Potassium	6.2
Iron	6.7		
Total lipids	4.7		
Cholesterol	5.1		
Aspartate aminotransferase	9.3		
Bilirubin	8.4		

*To estimate the probable effect of a factor on results, relate percent increase or decrease shown in table to analytical variation (±% CV) routinely found for analytes.
†Mean values obtained from 11 healthy individuals.

cause increases in the serum activities of enzymes that originate in skeletal muscle.

Order of Draw for Multiple Blood Specimens

Several types of evacuated tubes are used for venipuncture collection. They vary by the presence or absence and type of **additive**, as well as by the volume of the tube. The different types of additives are identified by the color of the stopper used (Table 6-2) and are covered in greater detail later in this section. For a variety of reasons, the most important of which is the possibility of cross-contamination between tube additives, blood should be collected into tubes in the order outlined in Table 6-2. This table also provides the recommended number of inversions for each tube type because it is critical that complete mixing of any additive with the blood collected be accomplished as quickly as possible.

A typical system for collecting blood directly into evacuated tubes includes a single-use device that incorporates a cover designed to be placed over the needle when collection of the blood is complete, thereby reducing the risk of puncture of the phlebotomist by the now contaminated needle.[8] A needle or a winged (butterfly) set is screwed into the collection tube holder, and the tube is then gently inserted into this holder. After the skin has been cleaned, the needle is guided gently into the patient's vein (Figure 6-1); once the needle is in place, the tube is pressed forward into the holder to puncture the stopper and release the vacuum. As soon as blood begins to flow into the tube, the tourniquet should be released without moving the needle (see earlier discussion on venous occlusion). The tube is filled until the vacuum is exhausted. It is critically important that the evacuated tube be filled completely. Many additives are provided in the tube based on a "full" collection; deviation or short draws can be a source of preanalytical error because they can significantly affect test results. Once the tube is filled completely, it should be withdrawn from the holder, mixed gently by inversion, and replaced by another tube, if this is necessary. Collection directly into a syringe follows the same process, except that the needle is attached directly to the syringe, and a single collection is performed.

When blood collection is complete and the needle withdrawn, the patient should be instructed to hold a dry gauze pad over the puncture site, with the arm raised to lessen the likelihood of leakage of blood. With a collection device, such as that described previously, the needle is covered, and the needle and the tube holder are immediately discarded into a **sharps container**. In the event that a winged (butterfly) set is used, the wings are pushed forward to cover the needle, or with newer available equipment, a button is pressed, releasing a spring that retracts the needle. If a syringe was used, the needle and syringe (still attached) should be discarded in a hazardous waste receptacle.

All tubes should be labeled per institutional policy. Most institutions have a written procedure prohibiting the advance labeling of tubes because this is seen as providing the potential for mislabeling, one of the most common sources of preanalytical error. Some institutions recommend showing the labeled tube to the patient to further confirm correct identification. Finally PPE should be discarded and institutional policies for cleaning between patients should be followed if there are additional patients to be drawn.

TABLE 6-2 Recommended Order of Draw for Multiple Specimen Collection With Tube Color Identification

Stopper Color	Contents	Inversions
Yellow	Sterile media for blood culture	8
Royal blue	No additive (for trace elements)	0
Clear/red	Non-additive; discard tube if no royal blue used	0
Light blue	Sodium citrate	3-4
Gold/red	Serum separator tube	5
Red/red, orange/yellow, royal blue	Serum tube, with or without clot activator, with or without gel	5
Green	Heparin tube with or without gel	8
Royal blue	Sodium EDTA	8
Lavender, pearl white, pink/pink, tan (plastic)	EDTA tubes, with or without gel	8
Gray	Glycolytic inhibitor	8
Yellow (glass)	ACD for molecular studies and cell culture	8

Blood Collection Through Skin Puncture

The techniques for venipuncture in children and adults are similar. However, in the pediatric population, alternative collection through skin puncture is often used. **Skin puncture** is an open collection technique in which the skin is punctured by a lancet, and a small volume of blood is collected into a micro-device or directly onto filter paper. Skin puncture blood is more like arterial blood than venous blood. In practice, it is used in situations in which (1) sample volume is limited (e.g., pediatric applications), (2) repeated venipunctures have resulted in severe vein damage, or (3) patients have been burned or bandaged and veins therefore are unavailable for venipuncture. This technique is also commonly used when the sample is to be applied directly to a testing device in a point-of-care testing situation or to filter paper. It is most often performed on (1) the tip of a finger, (2) an earlobe, and (3) the heel or big toe of infants (Figure 6-2).

The same steps of patient identification, appropriate PPE, and cleansing of the area to be pierced are followed as with venipuncture.[4] The skin is quickly punctured by a sharp stab with a lancet. If the finger is the site of puncture, it should be held in such a way that gravity assists collection of blood at the fingertip, and the lancet held to make the incision as close to perpendicular to the fingernail as possible.[15] Massage of the finger, or of any other site used, to stimulate blood flow should be avoided because this causes the outflow of debris and tissue fluid, which does not have the same composition as plasma. To improve circulation of the blood, the area to be pierced may be warmed by application of a warm, wet washcloth or a specialized device, such as a heel warmer, for 3 minutes before the lancet is applied. The first drop of blood is wiped off, and subsequent drops are transferred to the appropriate collection tube by gentle contact. Filling should be done rapidly to prevent clotting, and introduction of air bubbles should be prevented. A variety of collection tubes are commercially available, and available additives generally mirror those of full-sized collection devices. If multiple tubes are to be filled, the correct order of filling is the same as for evacuated blood tubes (see Table 6-2).

For collection of blood specimens on filter paper for molecular genetic testing and neonatal screening, the skin is cleaned and punctured as described previously. The first drop of blood should be wiped away. Then the filter paper is gently touched against a large drop of blood that is allowed to soak into the paper to fill the marked circle. Only a single application per circle should be made to prevent nonuniform analyte concentration. The filter paper should be air-dried (generally for 2 to 3 hours to prevent mold or bacterial overgrowth) before storage in a properly labeled paper envelope.

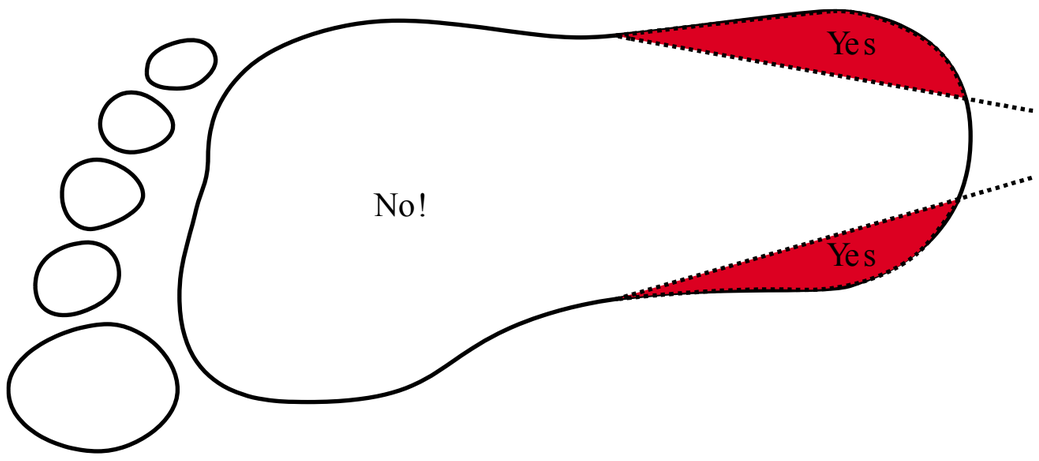

Figure 6-2 Acceptable sites for skin puncture to collect blood from an infant's foot. (Modifed from Blumenfeld TA, Turi GK, Blanc WA. Recommended site and depth of newborn heel punctures based on anatomical measurements and histopathology, Lancet 1979;1:230-3. Reprinted with permission from Elsevier.)

Arterial Puncture

Arterial puncture, reserved primarily for arterial blood gas analysis in acid-base measurements during critical illness, requires considerable skill and is usually performed only by physicians or specially trained technicians or nurses.[5] Preferred sites of arterial puncture are, in order, (1) the radial artery at the wrist, (2) the brachial artery in the elbow, and (3) the femoral artery in the groin. Because leakage of blood from the femoral artery tends to be greater, especially in the elderly, sites in the arm are used most often.

Serum and Anticoagulants Used for Plasma Collection

Serum is defined as the liquid portion of blood that remains after **coagulation** has occurred; it is the specimen of choice for many analyses, including viral screening and protein electrophoresis. Samples are collected into tubes with no additive or with a clot activator and must be allowed to complete the coagulation process before further processing. **Plasma** is defined as the noncellular component of anticoagulated whole blood; it is being used increasingly for routine chemistry testing because the ability to immediately centrifuge the sample without waiting for clotting decreases turnaround time. Sometimes considerable differences may be observed between the concentrations of analytes in serum and in plasma, as shown in Table 6-3. Additives used to collect anticoagulated blood are discussed in the following section.

TABLE 6-3 Differences in Composition Between Plasma and Serum*

Plasma Value > Serum Value, %		No Difference Between Serum and Plasma Values	Plasma Value < Serum Value, %	
Calcium	0.9	Bilirubin	Albumin	1.3
Chloride	0.2	Cholesterol	Alkaline phosphatase	1.6
Lactate dehydrogenase	2.7	Creatinine	Aspartate aminotransferase	0.9
Total protein	4.0		Bicarbonate	1.8
			Creatine kinase	2.1
			Glucose	5.1
			Phosphorus	7.0
			Potassium	8.4
			Sodium	0.1
			Urea	0.6
			Uric acid	0.2

From Ladenson JH, Tsai L-MB, Michael JM, Kessler G, Joist JH. Serum versus heparinized plasma for eighteen common chemistry tests. Am J Clin Pathol 1974;62:545-52. Copyright © 1974 by the American Society of Clinical Pathologists.

Heparin

Heparin is the most widely used **anticoagulant** for chemistry and hematology testing. It is a mucoitin polysulfuric acid that is available as (1) sodium (most often used for cytogenetic studies), (2) potassium, (3) lithium, and (4) ammonium salts, all of which adequately prevent coagulation. T is anticoagulant accelerates the action of antithrombin III, which neutralizes thrombin and thus prevents the formation of fibrin from fibrinogen.

It should be noted that heparin is unacceptable for most tests performed using the polymerase chain reaction (PCR) because of inhibition of the polymerase enzyme by this large molecule. DNA can be extracted from heparinized samples, but amplification may be reduced.

Ethylenediaminetetraacetic Acid (EDTA)

EDTA is a chelating agent of divalent cations such as Ca^{2+} and Mg^{2+}. Because it preserves the cellular components of blood, it is particularly useful for (1) hematologic examinations, (2) isolation of genomic DNA, and (3) qualitative and quantitative virus determinations by molecular techniques. It is used as the disodium, dipotassium, or tripotassium salt. EDTA prevents coagulation by binding calcium, which is essential for the clotting mechanism. Newer advances using EDTA include the inclusion of a gel barrier to separate plasma from cells (white tubes). In blue/black tubes, incorporation of a density gradient allows recovery of nucleated cells after centrifugation, thus increasing the yield of DNA.

EDTA, probably by chelation of metallic cofactors, inhibits the activity of enzymes that require a metallic cofactor such as (1) alkaline phosphatase, (2) CK, and (3) leucine aminopeptidase. Because it chelates calcium and iron, EDTA is unsuitable for specimens for calcium and iron analyses using photometric or titrimetric techniques.

Sodium Fluoride

Sodium fluoride is a weak anticoagulant that is often added as a preservative for blood glucose. As a preservative, together with another anticoagulant such as potassium oxalate, it is effective at a concentration of approximately 2 g/L of blood. It exerts its **preservative** action by inhibiting the enzyme systems involved in glycolysis, although such inhibition is not immediate[18] and a certain amount of degradation occurs during the first hour after collection. Without an antiglycolytic agent, the blood glucose concentration decreases approximately 10 mg/dL (0.56 mmol/L) per hour at 25 °C. T e rate of decrease is faster in newborns because of the increased metabolic activity of their erythrocytes and in leukemic patients because of the high metabolic activity of the white cells. Sodium fluoride is poorly soluble, and blood must be mixed well before effective antiglycolysis occurs. Fluoride is a potent inhibitor of many serum enzymes and in high concentrations also affects urease, which is used to measure urea nitrogen in many analytical systems.

Citrate

Sodium citrate solution, at a concentration of 34 to 38 g/L in a ratio of 1 part to 9 parts of blood, is widely used for coagulation studies, as the anticoagulation effect (chelation of Ca^{2+}) is easily reversible through the addition of Ca^{2+} to the plasma. However, the correct ratio of blood to anticoagulant is critical because modern analyzers add a standard amount of Ca^{2+} that is based on a proper collection volume. T is forms the basis of the first step for most modern coagulation assays. A citrate tube is rarely acceptable for chemistry testing but may be acceptable, if not centrifuged, for genomic DNA isolation.

Acid Citrate Dextrose (ACD)

As indicated previously, the collection of specimens into EDTA is often used for isolation of genomic DNA from the patient. However, additional and complementary diagnostic tests, such as cytogenetic testing, may be requested at the same time. For this reason, samples for molecular diagnostics are often collected into ACD anticoagulant, so as to preserve both the form and the function of the cellular components. T ere are two ACD tube designations: ACD A and ACD B. T ese differ only by the concentrations of the additives. Both enhance the viability and recovery of white blood cells for several days after collection of the specimen, thus they are suitable for both molecular diagnostic testing and cytogenetic testing.

Oxalates

Sodium, potassium, ammonium, and lithium oxalates inhibit blood coagulation by forming rather insoluble complexes with calcium ions. Potassium oxalate ($K_2C_2O_4 \cdot H_2O$), at a concentration of approximately 1 to 2 g/L of blood, is the most widely used oxalate. At concentrations of greater than 3 g oxalate per liter, hemolysis is likely to occur, so this is another example in which the volume of blood added to the tube is critical.

Iodoacetate

Sodium iodoacetate at a concentration of 2 g/L is an effective antiglycolytic agent (with the caveats mentioned earlier) and a substitute for sodium fluoride. Because it has no effect on urease, it is often used when glucose and urea tests are performed on a single specimen. It inhibits CK but appears to have no notable effects on other clinical tests.

Influence of Site of Collection on Blood Composition

Blood obtained from different sites differs in composition. Skin puncture blood is more like arterial blood than venous blood, although blood obtained by skin puncture is prone to contamination with interstitial and intracellular fluids. T us there are no clinically significant differences between freely flowing capillary blood and arterial blood in pH, PCO_2, PO_2, and oxygen saturation. T e PCO_2 of venous blood is up to 6 to 7 mm Hg (0.8 to 0.9 kPa) higher. Venous blood glucose is as much as 7 mg/L (0.39 mmol/L) less than capillary blood glucose. T e major differences between venous serum and capillary serum have been covered elsewhere.[14]

Hemolysis

Hemolysis is defined as disruption of the red cell membrane, resulting in the release of hemoglobin; it may be the

consequence of intravascular events (in vivo hemolysis) or may occur subsequent to or during blood collection (in vitro hemolysis). In vitro hemolysis can be caused by (1) alcohol left on the skin, (2) use of small bore needles, (3) underlying red cell disorders, (4) temperature extremes during transport, and (5) other causes. Serum and plasma show visual evidence of hemolysis when the hemoglobin concentration exceeds 50 mg/dL, and once the level exceeds 150 to 200 mg/dL, the plasma will appear bright red to most observers. Slight hemolysis has little effect on most test values. However, a notable effect may be observed on those constituents that are present at a higher concentration in erythrocytes than in plasma. Thus plasma activities or concentrations of (1) lactate dehydrogenase, (2) potassium, (3) magnesium, and (4) phosphate are particularly increased by hemolysis. The inorganic phosphate in serum increases rapidly as the organic esters in the cells are hydrolyzed. An additional band caused by hemoglobin may be observed on serum protein electrophoresis. Because the effect of free hemoglobin following hemolysis may be spectral (i.e., direct interference by the absorbance of hemoglobin at the wavelength at which an assay is measured), most manufacturers now provide data on the effects of hemolysis on the analytical performance of individual tests; this should be evaluated in the selection of individual methods.

In molecular diagnostic testing, hemoglobin may interfere with the amplification reaction, particularly when reverse transcriptase (RT)-PCR is the first step in the analysis of RNA. In some situations, the isolation of nucleic acid is sufficiently selective that free hemoglobin from the ruptured cells is removed and will not cause a problem. However, with hemolyzed blood, alternative or additional extraction methods are usually needed to ensure that RNA is fully and accurately transcribed, and that the greatest amplification of DNA is achieved.

Urine

The type of urine specimen and required preservation during collection are dictated by the tests to be performed. Untimed or random specimens are suitable for only a few chemical tests; usually, urine specimens must be collected over a predetermined interval of time, such as 4, 12, or 24 hours. A clean, early morning, fasting specimen is usually the most concentrated specimen and thus is preferred for microscopic examinations and for the detection of abnormal quantities of constituents, such as proteins, or of unusual compounds, such as chorionic gonadotropin. The clean timed specimen is one obtained at specific times of the day or during certain phases of the act of micturition. Bacterial examination of the first 10 mL of urine voided is most appropriate to detect urethritis, whereas the midstream specimen is best used for investigating bladder disorders. The double-voided specimen is the urine excreted during a timed period after complete emptying of the bladder; it is used, for example, to assess glucose excretion during a glucose tolerance test. Its collection must be timed in relation to the ingestion of glucose. Similarly, in some metabolic disorders, urine must be collected during or immediately after symptoms of the disease appear.

When they are to be tested for their alcohol and drugs of abuse content, urine specimens are often collected under rigorous conditions requiring chain of custody documentation, particularly if the results will be used for forensic purposes.

Catheter specimens are used for microbiological examination in critically ill patients or in those with urinary tract obstruction, but they should not normally be obtained just for examination of chemical constituents. The suprapubic tap specimen is a useful alternative.

Even though tests in the clinical laboratory are not usually affected by lack of sterile collection procedures, the patient's genitalia should be cleaned before each voiding to minimize the transfer of surface bacteria to the urine. Cleansing is essential if the true concentration of white cells is to be obtained.

Currently, urine is not a common specimen type in the molecular diagnostic laboratory for genomic testing, although some tests use urine samples for bladder cancer screening and monitoring of therapy for bladder cancer. Urine is frequently used for molecular testing for infectious agents, such as Chlamydia, a common sexually transmitted organism, or BK virus, associated with potential rejection and/or failure of transplanted kidneys. Because most requests involve a specific organism, an untimed or random urine specimen collected into a sterile container with no preservative is usually acceptable.

Timed Urine Specimens

The collection period for timed specimens should be long enough to minimize the influence of short-term biological variations. When specimens are to be collected over a specified period of time, the patient's close adherence to instructions is important. The bladder must be emptied at the time the collection is to begin, and this urine discarded. Thereafter, all urine must be collected until the end of the scheduled time, at which time the bladder should be emptied again as the final collection. If a patient has a bowel movement during the collection period, precautions should be taken to prevent fecal contamination of the urine. If a collection has to be made over several hours, urine should be passed into a separate container at each voiding and then emptied into a larger container for the complete specimen. This is two-step procedure prevents the danger of patients splashing themselves with a preservative, such as acid. The large container should be stored at 4 °C during the entire collection period.

Before beginning a timed collection, a patient should be given written instructions with regard to diet or drug ingestion, if appropriate, to avoid interference of ingested compounds with analytical procedures. Urine should not be collected at the same time for two or more tests requiring different preservatives. Aliquots for an analysis such as a microscopic examination should not be removed while a 24-hour collection is in process. Removal of aliquots is not permissible even when the volume removed is measured and corrected, because excretion of most compounds varies throughout the day, and test results will be affected. Appropriate information

regarding collection, including warnings with respect to handling of the specimen, should appear on the container label.

Before a specimen is transferred into small containers for each of the ordered tests, it must be thoroughly mixed to ensure homogeneity because the specific gravity, volume, and composition of the urine may vary throughout the collection period.

To obtain a sterile urine specimen for culture from an infant, a suprapubic tap is performed. The collection of specimens from older children is done as in adults, with assistance from a parent when this is necessary.

Urine Preservatives

Urine preservatives have different roles but usually are added to (1) reduce bacterial action, (2) reduce chemical decomposition, or (3) solubilize constituents that otherwise might precipitate out of solution. Some specimens should not have any preservatives added because of the possibility of interference with analytical methods.

One of the most acceptable forms of preservation of urine specimens is refrigeration immediately after collection; it is even more successful when combined with chemical preservation. Acidification to below pH 3 through the addition of (1) hydrochloric, (2) acetic, or (3) nitric acid to the specimen container before collection is widely used to preserve 24-hour specimens. Such acidification is particularly useful for specimens requiring determination of (1) calcium, (2) steroids, and (3) vanillylmandelic acid (VMA). However, precipitation of urates will occur, thereby rendering a specimen unsuitable for measurement of uric acid.

Sulfamic acid (10 g/L of urine) has also been used to reduce pH. Boric acid (5 mg/30 mL) has been used, but it too causes precipitation of urates. A mild base, such as sodium bicarbonate or a small amount of sodium hydroxide, is used to preserve (1) porphyrins, (2) urobilinogen, and (3) uric acid. A sufficient quantity should be added to adjust the pH to between 8 and 9.

Feces

A fecal sample is commonly used in the clinical laboratory for the identification of disease-causing organisms. Fecal material is also frequently analyzed to detect the presence of "hidden" blood—also known as "occult" blood. Detecting this blood is considered an effective means of discovering the presence of a bleeding ulcer or malignant disease in the gastrointestinal tract. Tests for occult blood should be done on aliquots of excreted stools rather than on material obtained on the glove of a physician doing a rectal examination, because this procedure may cause enough bleeding to produce a positive result.

In the newborn, the first specimen from the bowel (meconium) may be used for detection of maternal drug use during the gestational period; this requires specific attention to the details of collection and identification. Feces from infants and children may be screened for tryptic activity to detect cystic fibrosis.

In adults, measurement of fecal nitrogen and fat in 72-hour specimens is used to assess the severity of malabsorption; measurement of fecal porphyrins is occasionally required to characterize the type of porphyria. Usually no preservative is added to the feces, but the container should be kept refrigerated throughout the collection period, and care should be taken to prevent contamination from urine.

Testing of patient DNA in stool is uncommon, but DNA isolated from fecal samples is representative of the genetic composition of the colonic mucosa at the time of stool collection. The differential and quantitative analysis of stool DNA integrity has been proposed as a sensitive and specific biomarker that is useful for the detection of colorectal cancer.[1]

Cerebrospinal Fluid

Cerebrospinal fluid (CSF) is normally obtained from the lumbar region, although a physician may occasionally request analysis of fluid obtained during surgery from the cervical region or from a cistern or ventricle of the brain. CSF is examined when there is a question as to the presence of (1) a cerebrovascular accident, (2) meningitis, (3) demyelinating disease, or (4) meningeal involvement in malignant disease. Lumbar punctures should always be performed by a physician. The tubes used for collection do not contain any preservative but must be sterile, especially if microbiological tests are required. Because the initial specimen may be contaminated by tissue debris or skin bacteria, the first tube should be used for chemical or serologic tests, the second for microbiological tests, and the third for microscopic and cytologic examination.

The most common chemical test on CSF is glucose. Antiglycolytic agents are not added to the tube for glucose measurement, as CSF specimens are rapidly processed, thereby ensuring that little metabolism of glucose occurs even in the presence of many bacteria. To allow proper interpretation of spinal fluid glucose values, a simultaneous blood specimen should be obtained. The most common use of spinal fluid in molecular diagnostics is for the rapid identification of an infectious agent and for T- and B-cell gene rearrangements associated with hematologic malignancies.

Synovial Fluid

Synovial fluid is a clear thixotropic fluid that serves as a lubricant in a (1) joint, (2) tendon sheath, or (3) bursa. The technique used to obtain it for examination is called arthrocentesis. Synovial fluid is withdrawn from joints to aid characterization of the type of arthritis and to differentiate noninflammatory effusions from inflammatory fluids. Normally, only a very small amount of fluid is present in any joint, but this volume is usually very much increased in the presence of inflammatory conditions. Arthrocentesis should be performed by a physician using sterile procedures, and the technique is modified from joint to joint, depending on the anatomic location and the size of the joint. Sterile plain tubes should be used for culture and for glucose and protein measurements; an EDTA tube is necessary for (1) total leukocyte, (2) differential, and (3) erythrocyte counts.

The most common use of synovial (joint) fluid in molecular diagnostics is to assess the presence of infectious microorganisms that lead to complications of great severity. Examples of

organisms that the laboratory may test for include (1) Borrelia burgdorferi, the causative agent in Lyme disease; (2) Staphylococcus aureus for the presence of a staph infection; and (3) aerobic gram-negative bacilli for the presence of Salmonella, Pasteurella, or Pseudomonas.

Amniotic Fluid

Amniotic fluid is the liquid contained by the amniotic sac of a pregnant woman. It is collected using a technique termed amniocentesis—a technique performed by a physician. Amniotic fluid is analyzed (1) for prenatal diagnosis of congenital disorders, (2) to assess fetal maturity, or (3) to look for Rh isoimmunization or intrauterine infection. In addition to chemical analyses, virtually any molecular diagnostic assay has been applied to the DNA from an amniotic fluid specimen. Some of the more common molecular diagnostic assays include tests for (1) cystic fibrosis, (2) sickle cell anemia, (3) Tay-Sachs disease, and (4) thalassemia.

For prenatal determination of genetic disorders, the cellular content of the amniocentesis sample may not provide sufficient nucleic acid for analysis. In this situation, the fluid may be cultured under highly specialized conditions to expand the number of cells. Nine to 12 days of culturing are needed to obtain a sufficient number of cells for DNA extraction.

Chorionic Villus Sampling and Testing

Chorionic villus sampling (CVS) is the technique of inserting a catheter or needle into the placenta and removing some of the chorionic villi, or vascular projections, from the chorion of the womb during early pregnancy. This tissue has the same chromosomal and genetic makeup as the fetus and is used to test for disorders that may be present in the fetus.

In practice, the specimen is examined under a microscope by a physician at the time of collection to determine the (1) quality, (2) quantity, and (3) integrity of the chorionic villi. Once it is received by the laboratory, the quality of the specimen is further assessed by examination for (1) branching, (2) budding, and (3) veining, and for evaluation of maternal cell contamination. The specimen is then placed in culture medium and is allowed to grow for up to 3 weeks before DNA isolation.

CVS and subsequent testing allow for earlier diagnosis of inherited genetic disorders than is possible with amniotic fluid analysis. For example, with CVS, testing is performed at a gestation period of 10 to 12 weeks, whereas with amniotic fluid, testing generally is not performed until weeks 15 to 20 of gestation.

Pleural, Pericardial, and Ascitic Fluids

The (1) pleural, (2) pericardial, and (3) peritoneal cavities normally contain a small amount of serous fluid, which lubricates the opposing parietal and visceral membrane surfaces. Inflammation or infection affecting the cavities causes fluid to accumulate. The fluid may be removed to determine whether it is an effusion or an exudate—a distinction made possible by protein or enzyme analysis with, for example, a protein concentration higher in the fluid, indicating an exudate. The fluid may also be examined for cellular elements. The primary uses of these fluids in the molecular diagnostic laboratory are for infectious agent identification and possibly for the detection of cancer cells.[19]

The collection procedure is called paracentesis. When specifically applied to the pleural cavity, the procedure is a thoracentesis; if applied to the pericardial cavity, a pericardiocentesis. Paracentesis should be performed only by skilled and experienced physicians. Pericardiocentesis has now been largely supplanted by echocardiography.

Saliva

Although measurement of the concentrations of certain analytes in saliva (known formally as oral fluid) has been advocated,[2] clinical application of methods that use saliva has been limited. Exceptions include measurement of blood group substances to determine secretor status and genotype. Measurement of a drug in saliva has been suggested to estimate the free, pharmacologically active concentration of the drug in serum. However, a considerable difference in pH has been noted between saliva and serum, and ratios of bound to free drug may not be the same in the two sample types.

Buccal Cells

Collection of buccal cells (cells of the oral cavity of epithelial origin) has been identified as providing an excellent source of genomic DNA. Collection of buccal cells is often viewed as less invasive than collection of blood. It is particularly useful for collecting cells with the patient's genomic DNA when the patient has had blood transfusions and thus has blood with another person's (or persons') DNA. Similarly, it is useful after bone marrow transplantation when the circulating blood cells are derived wholly or partially from the donor of the bone marrow. Two methods are used commonly to collect buccal cells: rinsing with mouthwash and using swabs or cytobrushes.

Solid Tissue

Traditionally, the solid tissue most often analyzed in the clinical laboratory was malignant tissue from the breast for estrogen and progesterone receptors. During surgery, at least 0.5 to 1 g of tissue is removed and trimmed of fat and nontumor material. This tissue is quickly frozen within 20 minutes, preferably in liquid nitrogen or in a mixture of dry ice and alcohol. A histologic section should always be examined at the time of analysis of the specimen to confirm that the specimen indeed consists of malignant tissue.

The same procedure may be used to obtain and prepare solid tissue for toxicologic analysis; however, when trace element determinations are to be made, all materials used in the collection or handling of the tissue should be made of plastic or materials known to be free of contaminating trace elements.

Somatic gene analyses, such as T-cell receptor rearrangement and clonal expansion, are now providing important information to clinicians. Additionally, mutations in malignant tissues may be used to direct therapy. For these studies,

the molecular diagnostic laboratory often receives tissue that has been formalin-fixed and paraf n-embedded (FFPE). In general, neutral buffered formalin, which contains no heavy metals, will not interfere with amplification reactions. DNA can still be extracted from tissue embedded in paraf n, but the DNA will be degraded to low molecular weight fragments, suitable for most PCR reactions but not for Southern blot methods.

Also, it is possible to retain tissue structure without permanent fixation by freezing specimens in an optimal cutting temperature (OCT) compound. T is mixture of polyvinyl alcohol and polyethylene glycol surrounds but does not infiltrate the tissue. T e sample is then frozen at ≈−80 °C, and sections are prepared for review by a pathologist. OCT is fully water soluble and should be completely removed from a tissue specimen before it is used as a source of DNA. In general, DNA of higher molecular weight can be extracted from OCT-fixed tissues compared with that extracted from FFPE samples.

Hair and Nails

Currently, the use of hair or nail in molecular diagnostics is limited to forensic analysis (genomic DNA identification). Hair and fingernails or toenails have been used for trace metal and drug analyses. However, collection procedures have been poorly standardized, and quantitative measurements are better obtained from blood or urine.

Handling of Specimens for Analysis

Steps that are important for obtaining a valid specimen for analysis include (1) identification, (2) preservation, (3) separation and storage, and (4) transport.

Maintenance of Specimen Identif cation

Proper identification of the specimen must be maintained at each step of the testing process. All labels should conform to the laboratory's stated requirements to facilitate proper processing of specimens. No specific labeling should be attached to specimens from patients with infectious disease to suggest that these specimens should be handled with special care. All specimens should be treated as if they are potentially infectious.

In practice, every specimen container must be adequately labeled even if the specimen must be placed in ice, or if the container is so small that a label cannot be placed along the tube, as might happen with a capillary blood tube, where the label should be applied as a "flag" on the tube. For small volumes of urine submitted in a screw-cap urine cup and any specimen submitted in a screw-cap test tube or cup, the label should be placed on the cup or tube directly, not on the cap.

Preservation of Specimens

T e practitioner must ensure that specimens are collected into the correct container and are properly labeled; in addition, specimens must be properly treated both during transport to the laboratory and from the time the serum, plasma, or cells have been separated until analysis. For some tests, specimens must be kept at 4 °C from the time the blood is drawn until the specimens are analyzed; or until the serum or plasma is separated from the cells. Examples are specimens for (1) ammonia, (2) lactate, (3) certain hormone tests (e.g., gastrin and renin activity) and (4) blood gas determinations, such as PCO_2, PO_2, and blood pH. Transfer of these specimens to the laboratory must be done by placing the specimen container in ice water but in such a way as to maintain label integrity.

For all test constituents that are thermally labile, serum and plasma should be separated from cells in a refrigerated centrifuge. Specimens for bilirubin or carotene and for some drugs, such as methotrexate, must be protected from both daylight and fluorescent light to prevent photodegradation.

Hemolysis may also occur during specimen transport, particularly in pneumatic tube systems unless the tubes are completely filled and movement of the blood tubes inside the specimen carrier is prevented.[21] With many systems, the plasma hemoglobin concentration may be increased, and the serum activity of red cell enzymes, such as lactate dehydrogenase, may also be increased. Nonetheless, the amount of hemolysis is usually so small that it is often ignored. In special cases, such as when the cells of a patient who is undergoing chemotherapy are fragile, samples should be centrifuged before they are placed in the pneumatic tube system or identified as "messenger delivery only."

For the molecular diagnostic laboratory, it is challenging to recover RNA from transported specimens. Depending on the tissue source, RNA yields will vary, primarily because of the amount of RNA present at the time of collection. Specimens from liver, spleen, or heart have large amounts of RNA, but specimens from skin, muscle, and bone have lower RNA content. Increasingly, creative solutions to this issue continue to be produced with collection kits that contain stabilizers and even the first reagents required for extraction, all of which have the effect of maximizing the recoverable nucleic acid. Tissue samples should be frozen immediately. Alternatively, a blood specimen should never be frozen before separation of the cellular elements because of hemolysis and released heme that may interfere with subsequent amplification processes.

For specimens that are collected in a remote facility with infrequent transportation by courier to a central laboratory, proper specimen processing must be done in the remote facility so that appropriately separated and preserved plasma or serum is delivered to the laboratory. T is necessitates that the remote facility has ready access to all commonly used preservatives and to wet ice.

Separation and Storage of Specimens

Plasma or serum should be separated from cells, either by removal of the liquid to an aliquot tube or by migration of a gel barrier during centrifugation, as soon as possible and certainly within 2 hours.[16] Premature separation of serum, however, may permit continued formation of fibrin, which will clog sampling devices in testing equipment. If it is impossible to centrifuge a blood specimen within 2 hours, the specimen should be held at room temperature rather than at 4 °C to decrease hemolysis.

For most plasma samples used for molecular diagnostics, the plasma should be removed from the primary tube promptly after centrifugation and held at −20 °C in a freezer capable of maintaining this temperature. Frost-free freezers should be avoided for all specimens because they have a wide temperature swing during the freeze-thaw cycle. Note, however, that 4 °C or −20 °C is not the optimum storage temperature for all tests; some lactate dehydrogenase isoenzymes, for instance, are more stable at room temperature than at 4 °C.

Specimen tubes should be centrifuged with stoppers in place. Closure reduces evaporation, which occurs rapidly in a warm centrifuge with the air currents set up by centrifugation. Stoppers also prevent aerosolization of infectious particles. Specimen tubes containing volatiles, such as ethanol, must be stoppered while they are spun. Centrifuging specimens with the stopper in place maintains anaerobic conditions, which are important in the measurement of carbon dioxide and ionized calcium. Removal of the stopper before centrifugation allows loss of carbon dioxide and an increase in blood pH. Control of pH is especially important for the enzymatic measurement of acid phosphatase, which is labile under alkaline conditions engendered by CO_2 loss.

Cryopreservation of white blood cells and DNA is one method of storing and maintaining samples for extended periods. Whole blood specimens can be centrifuged, and white cells removed and cryopreserved at −20 °C until these cells are required for DNA extraction. For even longer periods of storage, isolated DNA can be stored at −70 °C. T e extracted DNA should not be exposed to repetitive cycles of freezing and thawing because this can lead to shearing of DNA. After these extracted DNA samples have completely thawed, it is important to fully mix the sample to ensure a homogeneous specimen.

Transport of Specimens

Although the remaining discussion uses the specific example of referral laboratory testing by another laboratory, many of the issues discussed, such as regulations related to shipping, are also relevant to a laboratory that receives specimens from outlying clinics via a (laboratory-owned and/or operated) courier service. T is may involve validating specific transport/storage conditions that are in conflict with existing CLSI recommendations.[13]

Before a referral laboratory is used for any tests, the quality of its work should be verified by the referring laboratory. For laboratories accredited by the College of American Pathologists (CAP), it is a requirement that the referring laboratory validate that the referral laboratory is Clinical Laboratory Improvement Amendments (CLIA) certified by obtaining a copy of the CLIA certificate before specimens are shipped. For molecular diagnostic testing, this is of particular importance because often the latest genetic test being requested by a physician has not yet been moved from research interest status to patient care status, and it may not be available in a CLIA-certified laboratory.

Specimen type and quantity and specimen handling requirements of the referral laboratory must be observed, and in laboratories operating under CLIA '88 regulations, test results reported by a referral laboratory must be identified as such when they are filed in a patient's chart.

In situations in which sample delivery for molecular analysis will be delayed, extracted nucleic acid, usually DNA only, is transported in a buffer solution or water, or it is dried down and shipped as a loose powder. With either method, DNA should be transported at ambient temperatures but should not be exposed to extremely high temperatures for an extended period because it will begin to degrade, and testing may be compromised.

Various laws and regulations apply to the shipment of biological specimens. Although these rules theoretically apply only to etiologic agents (known infectious agents), all specimens should be transported as if the same regulations applied. Airlines have rigid regulations covering the transport of specimens. Airlines deem dry ice a hazardous material; therefore the transport of most clinical laboratory specimens is affected by the regulations, and those who package the specimens should be trained in the appropriate regulations, such as those put forth by the U.S. Air International Transport Association (IATA).

T e various modes of transport of specimens influence the shipping time and cost, and each laboratory will need to make its own assessment as to adequate service. T e objective is to ensure that the properly (1) collected, (2) processed, and (3) identified specimen arrives at the testing facility in time and under the correct storage conditions, so that the analytical phase can then proceed.

Other Preanalytical Variables

Preanalytical variables are classified as either controllable or uncontrollable.[22] Some of the more common ones are discussed here. For additional information on this subject, interested readers are referred to Chapters 6 and 7 in the 5th edition of Tietz Texbook of Clinical Chemistry and Molecular Diagnostics and to texts by Young[22] and Guder and colleagues[12] on the subject.

Controllable Variables

Many of the preanalytical variables related to specimen collection discussed previously are examples of controllable variables. Others include physiological variables[12] and those associated with (1) diet, (1) lifestyle, (3) stimulants, (4) drugs, (5) herbal preparations, and (6) recreational drug ingestion.

Physiological Variables

Controllable personal variables that affect analytical results include (1) posture, (2) prolonged bed rest, (3) exercise, (4) physical training, (5) circadian variation, and (6) menstrual cycle.

Posture. In general, concentrations of freely diffusible constituents with molecular weights of less than 5000 Da are unaffected by postural changes. However, a significant increase in potassium (≈0.2 to 0.3 mmol/L) occurs after an individual stands for 30 minutes. Changes in the concentrations of some major serum constituents with change in posture are listed in Table 6-4.

TABLE 6-4 Change in Concentration of Serum Constituents With Change from Lying to Standing

Constituent	Average Increase (%)
Alanine aminotransferase	7
Albumin	9
Alkaline phosphatase	7
Amylase	6
Aspartate aminotransferase	5
Calcium	3
Cholesterol	7
IgA	7
IgG	7
IgM	5
Thyroxine	11
Triglycerides	6

From Felding P, Tryding N, Hyltoft Petersen P, Hørder M. Effects of posture on concentrations of blood constituents in healthy adults: practical application of blood specimen collection procedures recommended by the Scandinavian Committee on Reference Values. Scand J Clin Lab Invest 1980;40:615-21.

Exercise and Physical Training. In considering the effects of exercise, the nature and extent of the exercise should be taken into account. Static or isometric exercise, usually of short duration but of high intensity, uses previously stored ATP and creatine phosphate, whereas more prolonged exercise must use ATP generated by normal metabolic pathways. Changes in concentrations of analytes as a result of exercise are largely due to (1) shifts of fluid between intravascular and interstitial compartments, (2) changes in hormone concentrations stimulated by the change in activity, and (3) loss of fluid due to sweating. The physical fitness of an individual may also affect the extent of change in the concentration of a constituent. Whether any amount of exercise significantly affects laboratory results also depends on how long after an exercise activity a specimen was collected.

Circadian Variation. Circadian variation refers to the pattern of (1) production, (2) excretion, and (3) concentrations of analytes each 24 hours. Many constituents of body fluids exhibit cyclical variations throughout the day. Factors contributing to such variations include (1) posture, (2) activity, (3) food ingestion, (4) stress, (5) daylight or darkness, and (6) sleep or wakefulness. These cyclical variations may be quite large; therefore the drawing of the specimen must be strictly controlled. For example, the concentration of serum iron may change by as much as 50% from 0800 to 1400, and that of cortisol by a similar amount from 0800 to 1600. Serum potassium has been reported to decline from 5.4 mmol/L at 0800 to 4.3 mmol/L at 1400. The typical total variation of several commonly measured serum constituents over 6 hours is illustrated in Table 6-5; total variation is listed together with analytical error.

Hormones are secreted in bursts, and this, together with the cyclical variation to which most hormones are subject, may make it very difficult to interpret their serum concentration properly. Additionally, the effects of hormones on other analytes make the time of sample collection extremely important.

TABLE 6-5 Total and Analytical Variation for Serum Tests on Specimens Obtained at 0800 and 1400*

Constituent	Mean	Total Variation, %	Analytical Variation, %
Sodium, mmol/L	141	1.9	1.8
Potassium, mmol/L	4.4	7.1	2.8
Calcium, mg/dL	10.8	3.2	2.7
Chloride, mmol/L	102	3.8	3.4
Phosphate, mg/dL	3.8	10.7	2.4
Urea nitrogen, mg/dL	14	22.5	2.5
Creatinine, mg/dL	1.0	14.5	6.3
Uric acid, mg/dL	5.6	11.5	2.6
Iron, µg/dL	116	36.6	3.4
Cholesterol, mg/dL	193	14.8	5.7
Albumin, g/dL	4.5	5.5	3.9
Total protein, g/dL	7.3	4.8	1.7
Total lipids, g/L	5.3	25.0	3.6
Aspartate aminotransferase, U/L	9	25	6
Alanine aminotransferase, U/L	6	56	17
Acid phosphatase, U/L	3	15	8
Alkaline phosphatase, U/L	63	20	3
Lactate dehydrogenase, U/L	195	16	12

*11 male subjects, age 21-27 years, studied at 0800, 1100, 1400.

For example, basal plasma insulin is higher in the morning than later in the day, and its response to glucose is greatest in the morning and least about midnight. When a glucose tolerance test is given in the afternoon, higher glucose values occur than when the test is given early in the day. Higher plasma glucose occurs in spite of a greater insulin response, which nevertheless is delayed and less effective.

Menstrual Cycle. The plasma concentrations of many female sex hormones and other hormones are affected by the menstrual cycle. On the preovulatory day, the aldosterone concentration may actually be twice that of the early part of the follicular phase. The change in renin activity is almost as great. These changes are usually more pronounced in women who retain fluid before menstruation. Urinary catecholamine excretion increases at midcycle and remains high throughout the luteal phase. These changes within the menstrual cycle make it essential to do repetitive measurements on women at the same time during the cycle.

Travel

Travel across several time zones affects the normal circadian rhythm. Five days is required to establish a new stable diurnal rhythm after travel across 10 time zones. Changes in laboratory test results are generally attributable to altered pituitary and adrenal function. Urinary excretion of catecholamines is usually increased for 2 days; serum cortisol is reduced. During a flight, serum glucose and triglyceride concentrations increase, while glucocorticoid secretion is stimulated. During

a prolonged flight, fluid and sodium retention occurs, but urinary excretion returns to normal after 2 days.

Diet

Diet has considerable influence on the composition of plasma. Studies with synthetic diets have shown that day-to-day changes in the amount of protein are reflected within a few days in the composition of the plasma and in the excretion of end products of protein metabolism.

When dietary carbohydrates consist mainly of starch or sucrose rather than other sugars, the serum activities of ALP and LD are increased. Conversely, the plasma triglyceride concentration is reduced when sucrose intake is decreased. Flatter glucose tolerance curves are observed with a bread diet than when a high-sucrose diet is ingested. A high-carbohydrate diet decreases the serum concentrations of very low-density lipoprotein (VLDL) cholesterol, triglycerides, and protein. Individuals who eat many small meals throughout the day tend to have concentrations of total LDL and HDL cholesterol that are lower than when the same type and amount of food is eaten in three meals.

Food Ingestion

The concentration of certain plasma constituents is affected by the ingestion of a meal, with the time between ingestion of a meal and collection of blood affecting the plasma concentrations of many analytes. For example, fasting overnight for 10 to 14 hours noticeably decreases the variability in the concentrations of many analytes; this is seen as the optimal time for fasting around which to standardize blood collections, particularly lipids. The biggest increases in serum concentrations after a meal are seen in glucose, iron, total lipids, and ALP.

Vegetarianism

Concentrations of LDL cholesterol, total lipids, and phospholipids are reduced in individuals who have been vegetarians for a long time; their concentrations of cholesterol and triglycerides may be only two-thirds of those in people on a mixed diet. Both HDL and LDL cholesterol concentrations are affected. In strict vegetarians, the LDL concentration may be 37% less and the HDL cholesterol concentration 12% less than in nonvegetarians.

Malnutrition

In malnutrition, (1) total serum protein, (2) albumin, and (3) β-globulin concentrations are reduced. The increased concentration of γ-globulin does not fully compensate for the decrease in other proteins. Concentrations of (1) complement C3, (2) retinol-binding globulin, (3) transferrin, and (4) prealbumin decrease rapidly with the onset of malnutrition and are measured to define the severity of the condition.

Fasting and Starvation

As a consequence of fasting for longer than 24 hours or in response to starvation, the body attempts to conserve protein at the expense of other sources of energy, such as fat. The blood glucose concentration decreases by as much as 18 mg/dL (1 mmol/L) within the first 3 days of the start of a fast in spite of the body's attempts to maintain glucose production. Insulin secretion is greatly reduced, whereas glucagon secretion may double in an attempt to maintain normal glucose concentration. Lipolysis and hepatic ketogenesis are stimulated. Ketoacids and fatty acids become the principal sources of energy for muscle. This results in an accumulation of organic acids that leads to a metabolic acidosis with reduction of blood pH, PCO_2, and plasma bicarbonate concentrations.

Lifestyle

Smoking and alcohol ingestion are life-style factors that affect the concentrations of commonly measured analytes.

Smoking. Smoking, through the action of nicotine, may affect several laboratory tests. The extent of the effect is related to the number of cigarettes smoked and to the amount of smoke inhaled.

Through stimulation of the adrenal medulla, nicotine increases the concentration of epinephrine in the plasma and the urinary excretion of catecholamines and their metabolites. Glucose concentration may be increased by 10 mg/dL (0.56 mmol/L) within 10 minutes of smoking a cigarette. Typically the plasma glucose concentration is higher in smokers than in nonsmokers, and glucose tolerance is mildly impaired in smokers. The plasma growth hormone concentration is particularly sensitive to smoking. It may increase tenfold within 30 minutes after an individual has smoked a cigarette.

Smoking affects the body's immune response. For example, serum IgA, IgG, and IgM levels are generally lower in smokers than in nonsmokers, whereas the IgE concentration is higher. Smokers, more often than nonsmokers, may show the presence of antinuclear antibodies and may test weakly positive for carcinoembryonic antigen. The sperm count of male smokers is often reduced compared with that of nonsmokers: The number of abnormal forms is greater and sperm motility is less.

Alcohol Ingestion. A single moderate dose of alcohol has few effects on laboratory tests. Ingestion of enough alcohol to produce mild inebriation may increase the blood glucose concentration by 20% to 50%. The increase may be even greater in individuals with diabetes. Over time after ingestion, inhibition of gluconeogenesis occurs and becomes apparent as hypoglycemia and ketonemia as ethanol is metabolized to acetaldehyde and to acetate.

Intoxicating amounts of alcohol stimulate the release of cortisol, although the effect is more related to intoxication than to the alcohol per se. Sympatheticomedullary activity is increased by acute alcohol ingestion but without detectable effect on the plasma epinephrine concentration and with only a mild effect on norepinephrine. With intoxication, plasma concentrations of catecholamines are substantially increased. Acute ingestion of alcohol leads to a sharp reduction in plasma testosterone in men and an increase in the plasma luteinizing hormone concentration.

Chronic alcohol ingestion affects the activity of many serum enzymes. For example, increased activity of γ-glutamyltransferase (GGT) is often used as a marker of persistent drinking. Chronic alcoholism is associated with many characteristic biochemical

abnormalities, including (1) abnormal pituitary, (2) adrenocortical, and (3) medullary function. Measurement of carbohydrate-deficient transferrin is used to identify habitual alcohol ingestion. Increased mean cell volume (MCV) has also been used as a marker of habitual alcohol use and may be related to folic acid deficiency or may be a direct toxic effect of alcohol on red blood cell precursors.

Drug Administration

The effects of drugs on laboratory tests are complicated by known and unknown ingestion of (1) prescribed medications, (2) recreational drug use, and (3) herbal preparations.

Prescribed Medications. Typically, hospitalized patients receive medication. For certain medical conditions, more than 10 drugs may be administered at one time. Even many healthy individuals take several drugs regularly, such as (1) vitamins, (2) oral contraceptives, or (3) sleeping tablets. Individuals with chronic diseases often ingest drugs on a continuing basis. It is important to understand the differences between (1) the act of receiving a medication, (2) the physiological effects of the medication, and (3) analytical interference with the specific test method used.

Many drugs, when administered intramuscularly, cause sufficient muscle irritation to increase amounts of enzyme released, such as CK and LD, into the serum. These increased activities may persist for several days after a single injection, and consistently high values may be observed during a course of treatment. This is contrasts with the reduction in plasma potassium concentration and the possible hyponatremia that follow prolonged diuretic drug administration because of increased urinary output (physiological response). Analytical interferences vary significantly among test methods.

Recreational Drug Ingestion. Recreational drug ingestion refers to the ingestion of compounds for mood-altering purposes. Many commonly prescribed pain medications have migrated from pharmaceutical use to "drug of abuse" status. Among the more classical drugs of abuse, amphetamines increase the concentration of free fatty acids. Morphine increases the activity of (1) amylase, (2) lipase, (3) ALT, (4) AST, and (5) ALP, as well as the serum bilirubin concentration. Concentrations of gastrin, TSH, and prolactin are also increased. In contrast, concentrations of insulin, norepinephrine, pancreatic polypeptide, and neurotensin are decreased. Heroin increases the plasma concentrations of (1) cholesterol, (2) T_4, and (3) potassium. PCO_2 is increased, but PO_2 is decreased. The plasma albumin concentration is also decreased. Cannabis increases plasma concentrations of (1) sodium, (2) potassium, (3) urea, (4) chloride, and (5) insulin but decreases those of (1) creatinine, (2) glucose, and (3) uric acid.

Herbal Preparations

Herbal preparations are not regulated by standardized manufacturing practices, resulting in great variability in their composition and thus in their reported effects. Long-term use of (1) aloe vera, (2) sandalwood, and (3) cascara sagrada may cause hematuria and albuminuria. Through their laxative effects, prolonged use of (1) aloe vera, (2) Chinese rhubarb, (3) frangula bark, (4) senna, and (5) buckthorn may lead to hypokalemia, provoking hyperaldosteronism. Trailing arbutus may cause hemolytic anemia and liver damage. Green tea has been reported to cause microcytic anemia. Quinine and quinidine have been observed to cause thrombocytopenia. Cayenne (Capsicum annuum) increases fibrinolytic activity and induces hypocoagulability. Hyperthyroidism has been caused by the seaweed bladderwrack.

Many herbal preparations affect liver function. For example, germander has been reported to cause liver cell necrosis, and bishop's weed infrequently causes cholestatic jaundice. Tonka beans have been known to cause reversible liver damage. Comfrey has been associated with one death from liver failure. Bugleweed reduces the plasma concentration of prolactin and reduces the deiodination of T_4. Many of the reported effects of herbal preparation on liver function may be associated with contaminants from the unregulated manufacturing process, rather than the herbs themselves.

Uncontrollable Variables

Examples of uncontrollable preanalytical variables include those related to (1) biological, (2) environmental, and (3) long-term cyclical influences, and (4) those related to underlying medical conditions.

Biological Influences

Age, sex, and race of the patient influence the results of individual laboratory tests, which are discussed individually in various chapters of this book. Reference intervals for various analytes as a function of these biological influences are listed in Chapter 5.

Age. Age has a notable effect on reference intervals (particularly hormones), although the degree of change differs in various reports and may be dependent upon the analytical method used. In general, individuals are considered in four groups—the newborn, the older child to puberty, the sexually mature adult, and the elderly adult. Reference intervals for these age categories for affected analytes are found in Chapter 50 and in earlier editions of this book.

Sex. Until puberty, few differences in laboratory data are noted between young female and male humans. After puberty characteristic changes in the concentrations of sex hormones, including prolactin, become apparent. Also after puberty, higher activity of enzymes originating from skeletal muscle in men is related to their greater muscle mass. After menopause, the activity of ALP increases in women until it is higher than in men. Although total LD activity is similar in men and women, the activities of the LD-1 and LD-3 isoenzymes are higher, and LD-2 is less, in young women than in men. These differences disappear after menopause.

Race. Differentiation of the effects of race from those of socioeconomic conditions is often difficult, as may be the determination of the race of the patient. However, the total serum protein concentration is known to be higher in blacks than in whites. This is is largely attributable to a much higher γ-globulin, although usually the concentrations of α_1- and β-globulins are also increased. The serum albumin is typically

less in blacks than in whites. In black men, serum IgG is often 40% higher, and serum IgA may be as much as 20% higher, than in white men.

Carbohydrate and lipid metabolism differs in blacks and whites. Glucose tolerance is less in blacks, Polynesians, Native Americans, and Inuits than in comparable age- and sex-matched whites.

Environmental Factors

Environmental factors that affect laboratory results include (1) altitude, (2) ambient temperature, (3) geographical location of residence, and (4) seasonal influences.

Altitude. In individuals living at a high altitude, blood hemoglobin and hematocrit are greatly increased because of reduced atmospheric PO_2. Erythrocyte 2,3-diphosphoglycerate is also increased, and the oxygen dissociation curve is shifted to the right. The increased erythrocyte concentration leads to an increased turnover of nucleoproteins and excretion of uric acid. The fasting basal concentration of growth hormone concentration is high in individuals living at a high altitude, but concentrations of renin and aldosterone are decreased in healthy individuals. Plasma sodium and potassium concentrations are typically unaffected by high altitude, although the osmolality is reduced. Serum concentrations of C-reactive protein, transferrin, and β_2-globulin are notably increased with transition to a high altitude. Complete adaptation to a high altitude takes many weeks, whereas adjustment to lower altitudes takes less time.

Ambient Temperature. Ambient temperature affects the composition of body fluids. Acute exposure to heat causes the plasma volume to expand by an influx of interstitial fluid into the intravascular space and by reduction of glomerular filtration. The plasma protein concentration may decrease by up to 10%. Sweating may cause salt and water loss, but usually no changes in plasma sodium and chloride concentrations are noted. Plasma potassium concentration may decrease by as much as 10% as potassium is taken up by the cells. If sweating is extensive, hemoconcentration rather than hemodilution may occur.

Geographical Location of Residence. The geographical location where individuals live may affect the composition of their body fluids. For example, a statistically significant increase in serum concentrations of (1) cholesterol, (2) triglycerides, and (3) magnesium has been observed in people living in areas with hard water. Trace element concentrations are also affected by geographical location, for example, in areas where there is much ore smelting, serum concentrations of the trace elements involved may be increased. Carboxyhemoglobin concentrations are higher in areas where there is much heavier automobile traffic than in rural areas (as was true for blood lead in the 1970s in the United States). Individuals who primarily work indoors typically have lower concentrations of 25-hydroxy vitamin D than those who work outdoors, leading to higher serum calcium concentrations and greater urinary excretion of calcium.

Seasonal Influences. Seasonal influences on the composition of body fluids are small compared with those related to changes in posture or misuse of a tourniquet. Probable factors are dietary changes as different foods come into season and altered physical activity as more or different forms of exercise become feasible.

Underlying Medical Conditions

Some general medical conditions have an effect on the composition of body fluids and affect laboratory results. These include (1) obesity, (2) blindness, (3) pregnancy), (4) stress, (5) fever, (6) shock and trauma, and (7) transfusions and infusions.

Obesity. Serum concentrations of (1) cholesterol, (2) triglycerides, and (3) β-lipoproteins are positively correlated with obesity. The increase in the concentration of cholesterol is attributable to LDL cholesterol because HDL cholesterol is typically reduced. The serum uric acid concentration is also correlated with body weight, especially in individuals weighing more than 80 kg. Serum LD activity and glucose concentration increase in both sexes with increasing body weight. In men, serum (1) AST, (2) creatinine, (3) total protein, and (4) blood hemoglobin concentration increase with increasing body weight. In women, serum calcium increases with increasing body weight. In both sexes, serum phosphate decreases with increased body mass.

Fasting concentrations of (1) pyruvate, (2) lactate, (3) citrate, and (4) unesterified fatty acids are higher in obese individuals than in those of normal body weight. Serum iron and transferrin concentrations are low.

Blindness. Normal stimulation of the hypothalamic-pituitary axis is reduced with blindness. Consequently, certain features of hypopituitarism and hypoadrenalism may be observed. In some blind individuals, the normal diurnal variation of cortisol may or may not persist. Urinary excretion of 17-ketosteroids and 17-hydroxycorticosteroids is reduced. Plasma sodium and chloride are often low in blind individuals, probably as a result of reduced aldosterone secretion. Plasma glucose may be reduced in blind people, and insulin tolerance is often less. The excretion of uric acid is reduced. Renal function may be slightly impaired, as evidenced by slight increases in serum creatinine and urea nitrogen.

Pregnancy. Many changes in the concentrations of analytes occur during pregnancy, and proper interpretation of test results is dependent on knowledge of the duration of pregnancy.

Substantial hormonal changes occur during pregnancy, including several not normally associated with reproduction. Many of these changes are related to the great increase in blood volume that occurs during pregnancy, from about 2600 mL early in pregnancy to 3500 mL at about 35 weeks. This is hemodilution reduces the concentration of plasma proteins. However, the concentration of some transport proteins, including ceruloplasmin and thyroxine-binding globulin, is increased, resulting in increased concentrations of copper and T_4. The concentrations of cholesterol and triglycerides are notably increased. In contrast, pregnancy creates a relative deficiency of iron and ferritin.

Urine volume increases during pregnancy, so that it is typically 25% greater in the third trimester than in the nonpregnant

woman. The glomerular filtration rate increases by 50% during the third trimester. This results in increased urinary excretion of hydroxyproline and increased creatinine clearance. Pregnancy triggers many physiological stress reactions and is associated with increased concentrations of acute-phase reactant proteins. The erythrocyte sedimentation rate increases fivefold during pregnancy.

Stress. Physical and mental stress influences the concentrations of many plasma constituents. Anxiety stimulates increased secretion of (1) aldosterone, (2) angiotensin, (3) catecholamines, (4) cortisol, (5) prolactin, (6) renin, (7) somatotropin, (8) TSH, and (9) vasopressin. Plasma concentrations of (1) albumin, (2) cholesterol, (3) fibrinogen, (4) glucose, (5) insulin, and (6) lactate also increase.

Fever. Fever provokes many hormonal responses. For example, hyperglycemia occurs early and stimulates the secretion of insulin. This improves glucose tolerance, but insulin secretion does not necessarily reduce the blood glucose concentration because increased secretion of growth hormone and glucagon occurs. Fever appears to reduce the secretion of T_4, as do acute illnesses even without fever. In response to increased corticotropin secretion, the plasma cortisol concentration is increased and its normal diurnal variation may be abolished. The urinary excretion of (1) free cortisol, (2) 17-hydroxycorticosteroids, and (3) 17-ketosteroids is increased. As acute fever subsides, or if it lessens but still persists for a prolonged period, hormone responses diminish.

Shock and Trauma. Regardless of the cause of shock or trauma, certain characteristic biochemical changes result. For example, corticotropin secretion is stimulated to produce a threefold to fivefold increase in the serum cortisol concentration. 17-Hydroxycorticosteroid excretion is greatly increased, although excretion of 17-ketosteroids and metabolites of adrenal androgens may be unaffected. Aldosterone secretion is stimulated. Plasma renin activity is increased, as are secretions of (1) growth hormone, (2) glucagon, and (3) insulin. Anxiety and stress increase the excretion of catecholamines. The stress of surgery has been shown to reduce the serum T_3 by 50% in patients without thyroid disease. Changes in the concentrations of blood components reflect the physiological response to these hormonal changes. The general metabolic response to shock includes the normal response to stress.

Immediately after an injury, loss of fluid to extravascular tissue results in decreased plasma volume. If the decrease is enough to impair circulation, glomerular filtration is diminished. Diminished renal function leads to the accumulation of urea and other end products of protein metabolism in the circulation. In burned patients, serum total protein concentration falls by as much as 0.8 g/dL because of both loss to extravascular spaces and catabolism of protein. Serum α_1-, α_2-, and β-globulin concentrations are increased but not enough to compensate for the reduced albumin concentration. The plasma fibrinogen concentration responds dramatically to trauma and may double 2 to 8 days after surgery. The concentration of C-reactive protein rises at the same time.

Transfusion and Infusions. The protein-rich fluid lost from the intravascular space after trauma is replaced with protein-poor fluid from the interstitial spaces. Subsequently, this is replaced by a fluid similar in composition to plasma. Transfusion of whole blood or plasma raises the plasma protein concentration; the extent of increase depends on the amount of blood administered. Serum LD activity, primarily LD-1 and LD-2 isoenzymes, and bilirubin are increased by the breakdown of transfused erythrocytes. Transfusions to replace blood lost because of injury reduce sodium, chloride, and water retention precipitated by the injury. Serum iron and transferrin concentrations are reduced immediately after an injury, but extensive blood transfusions have been known to lead to siderosis and an increased serum iron concentration. Serum potassium may increase with transfusion of stored blood.

Normal Biological Variability

Data from studies of biological variation may be used to (1) assess the importance of changes in test values within an individual from one occasion to another, (2) determine the appropriateness of reference intervals, and, in conjunction with data from analytical variation, (3) establish laboratory analytical goals. Application by clinicians of information on biological variability enhances their ability to precisely identify important changes in test results in their patients. Categories of biological variation include (1) within an individual and (2) between individuals. The change in laboratory data around a hemostatic set point from one occasion to another within one person is called within-subject or intraindividual variation. The difference between the set points of different individuals is called interindividual variation. Intraindividual variability is great for different analytes, even within the same biochemical class of compounds.

Mechanisms used to assess variability include the delta check and reference change values.

Delta Check

When a patient's clinical condition is generally stable and differences between repeated test results are small, the difference between successive results may be used as a form of quality assurance. Most clinicians and healthcare providers arbitrarily decide when there is a clinically significant difference between repeated measurements of the same analyte. However, it is possible to address this issue more systematically and logically. The delta check concept is applied to two successive values regardless of the time interval between them. Delta check values are typically generated in one of two ways: The first is derived from differences between collected consecutive values for an analyte in many individuals, which are then plotted in a histogram with the central 95% or 99% of all values used to identify a clinically significant change in values. Delta checks may involve the absolute difference or the percent change between consecutive numbers. The second approach to establishing delta check values relies on a laboratorian's or a clinician's best estimate of an appropriate delta to yield a manageable number of flagged results for follow-up. Rate checks that involve dividing a delta check value by the time interval between successive measurements also are used. Several different delta check methods have been proposed, including (1) delta difference: current result minus previous

result; (2) delta percent change: (current result − previous result) × 100%/previous result; (3) rate difference: delta difference/delta time; and (4) rate percent change: delta percent change/delta time (where delta time is the interval between current and previous specimen collection times). Some laboratory information systems include delta checks in the reporting of test results but usually in the simplest way, as in delta difference or delta percent change.

In healthy individuals and in stable patients, the delta value between any two results should be small. Acceptable delta values may be calculated within a population of healthy individuals and then averaged, with the average used as a guide to determine whether a difference of possible clinical significance had occurred between serial measurements in patients.

Reference Change Values

To determine whether the difference between consecutive results for a single analyte in a patient might have clinical significance, Harris and Yasaka developed the concept of reference change values (RCVs). An RCV, also known as critical difference, is the value that must be exceeded before a change in consecutive test results is statistically significant at a predetermined probability. This concept introduces a scientific approach to an area where clinicians have largely relied on their intuition and experience. Historically, clinicians' impressions of clinically significant differences have varied significantly. Fraser and colleagues have shown that systematically calculated critical differences for many analytes tend to be less than physicians' assumptions of clinically significant differences.

An RCV takes into account both analytical and within-individual variations. To enhance the utility of the RCV, intraindividual variability should also be minimized with standardization of patient preparation and specimen collection and processing practices. Standardization is more readily achieved in hospital practice, where uniform timing of collections by trained phlebotomists is often possible, than in outpatient practices.

The change in values between successive measurements in a hospitalized patient is generally greater than the change in values reported in the literature derived from studies of healthy individuals because of the change in the patient's medical condition and his or her response to treatment. RCVs are not constant, and a significant change is likely to be smaller over the short term than over a longer time span. Thus application of RCVs from healthy individuals derived over a short time will identify an inappropriately large number of apparently significant changes in hospitalized patients.

Review Questions

1. Which blood specimen, in a multi-draw situation, most closely represents the composition of circulating blood?
   a. The blood drawn first
   b. The final tube drawn
   c. Only the serum tubes
   d. Only the plasma tubes
2. A blood collection tube containing sodium fluoride and an oxalate inhibits coagulation by:
   a. binding calcium, which is essential for the clotting mechanism.
   b. accelerating the action of antithrombin III.
   c. forming insoluble complexes with calcium ions.
   d. inhibiting the enzyme systems involved in glycolysis.
3. Why is pumping the fist before venipuncture inappropriate for blood collection?
   a. It causes venous stasis.
   b. It causes increased potassium, lower blood pH, and increased ionized calcium.
   c. It causes increased plasma concentrations of cortisol and growth hormone.
   d. It leads to premature separation of serum and fibrin clot formation.
4. One of the best and most acceptable methods of preserving a urine specimen is:
   a. thymol.
   b. refrigeration.
   c. incubation at 37 °C.
   d. phenol.
5. To allow for early diagnosis of an inherited genetic disorder at a gestational period of 10 to 12 weeks, the best specimen is:
   a. saliva.
   b. synovial fluid.
   c. amniotic fluid.
   d. chorionic villus sampling.
6. After centrifugation, plasma or serum is best separated from cells:
   a. within two hours.
   b. within six hours.
   c. within twelve hours.
   d. when it is convenient for the laboratorian.
7. The difference between serum and plasma is that:
   a. plasma contains all of the cellular elements of blood (WBCs, RBCs, etc.), but serum does not.
   b. plasma contains none of the clotting factors.
   c. serum is obtained by mixing anticoagulants with whole blood.
   d. serum is obtained when whole blood is allowed to clot and then is centrifuged.
8. Hemolysis is defined as:
   a. increased lipids in the blood that give the serum a milky appearance.
   b. excess bilirubin in serum that give it a greenish-yellow appearance.
   c. plasma that has been allowed to clot over time.
   d. damage to red blood cell membranes leading to release of the contents of red cells into the plasma.
9. An evacuated blood collection tube with a light blue stopper contains which of the following additives?
   a. Heparin
   b. EDTA
   c. Sodium citrate
   d. Sterile media for blood culture

10. An example of a controllable preanalytical variable for laboratory testing would be:
    a. diet.
    b. sex.
    c. age.
    d. underlying disease.

CHAPTER

7 Quality Management*

George G. Klee, M.D., Ph.D., and James O. Westgard, Ph.D.

Objectives

1. Define the following terms:

CLIA	Quality assessment
Control materials	Quality control
False rejections	Quality laboratory process
Five-Q framework	Six Sigma process
ISO 9000	Standard deviation interval
JCTLM	Total quality management
Lean production	Waived test
Proficiency testing	Westgard multirules
Quality	

2. List and describe three costs of conformance and three costs of nonconformance.
3. Discuss in-service training programs for laboratory personnel, including the need for such programs, components of a program, methods of program delivery, and implementation of a program.
4. Describe the five laboratory testing processes and potential errors that might occur during each process; relate these processes to preanalytical, analytical, and postanalytical variables that affect laboratory test results.
5. List and describe examples of preanalytical, analytical, and postanalytical variables that affect laboratory test results; state how each of these variables is controlled.
6. Explain the need for and use of control materials in the clinical laboratory; compare random and systematic error with regard to causes; state the usefulness of patient specimen measurements combined with liquid controls in monitoring analytical bias.
7. In considering the use of control charts in the clinical laboratory:
   - Explain the need for these charts.
   - Describe how control limits are calculated and how data are entered on a control chart.
   - Assess a Levey-Jennings control chart for error and out-of-limit control data.
   - Evaluate appropriate actions required to resolve errors.
8. List and explain the Westgard multirules used for interpretation of laboratory control data, and discuss how each multirule describes specific types of error; list the steps involved in the multirule procedure.
9. Compare internal quality control with external quality assessment programs, including needs, requirements, and features of each program; state the role of proficiency testing in laboratory accreditation, and calculate and interpret a standard deviation interval.
10. Assess and resolve case studies related to quality management in the laboratory.

Key Words and Definitions

Control procedure Statistical and/or nonstatistical check protocols implemented in a clinical laboratory to assess the performance of an analytical method.

Control rules Decision criteria that define when an analytical run is judged acceptable ("in control") or unacceptable ("out of control").

External quality assessment Procedures and programs that provide information about systematic errors and maintenance of long-term accuracy of analytical methods.

ISO 9000 A set of four standards used to ensure quality management and quality assessment developed by the International Organization for Standardization.

Lean Production A quality process that is focused on creating greater value by eliminating activities that are considered waste.

Levey-Jennings control chart A graphical display with observed control values plotted against an acceptable range of values, indicated on the chart by lines for upper and lower control limits, commonly indicated as the mean control value plus or minus three standard deviations.

Proficiency testing (PT) A process in which simulated patient specimens made from a common pool are analyzed by laboratories to determine the "quality" of laboratories' performance; considered to be part of external quality assessment.

*The authors gratefully acknowledge the original contribution of Susan M. Lehman, Director, Clinical Laboratory Science Program, Mayo Clinic, Rochester, Minnesota, who provided information on personnel competency and training.

Key Words and Definitions—cont'd

Quality Conformance to the requirements of users or customers and the satisfaction of their needs and expectations.

Quality assessment A quality laboratory process that is concerned primarily with broader measures and monitors of laboratory performance such as turnaround times and test utility.

Quality control A quality laboratory process that involves statistical analysis of internal control procedures through use of control materials for method performance assessment and nonstatistical check procedures such as linearity studies and reagent checks.

Six Sigma process control A quantitative framework for evaluating process performance and providing more objective evidence for process improvement, with a goal of having Six Sigmas or six standard deviations of process variation fitting within the tolerance limits of the process.

Total quality management (TQM) A management philosophy and approach that focuses on processes and their improvement as the means to satisfy customer needs and requirements; a quality system that is implemented to ensure quality.

Total testing process A broad definition of the laboratory testing and reporting process that includes preanalytical, analytical, and postanalytical phases.

Turnaround time (TAT) The time between when a test is ordered or a specimen is submitted for analysis and when the test results are reported.

Westgard multirules A series of control rules used to interpret control data.

The principles of quality management, assurance, and control have become the foundation by which clinical laboratories are managed and operated. This chapter begins with a discussion of the fundamentals of total quality management and follows with descriptions of (1) total quality management of the clinical laboratory, (2) control of preanalytical variables, (3) control of analytical variables (with emphasis on statistical quality control and identification of sources of analytical errors), (4) **external quality assessment** and **proficiency testing programs**, and (5) the combined use of liquid controls plus moving averages of patient values for quality control monitoring. The chapter concludes with discussions of new quality initiatives, including **Six Sigma** principles and metrics, **Lean Production,** and the **ISO 9000** certification process.

Fundamentals of Total Quality Management

Quality systems in healthcare organizations continue to evolve, with numerous sources of information available on the Internet.[15] Public and private pressures to contain costs now are accompanied by pressures for quality improvement (QI). The seemingly contradictory pressures for both cost reduction and QI require that healthcare organizations adopt new systems to manage quality. When faced with these same pressures, other industries have implemented a process termed **total quality management (TQM)**. This process is also referred to as total quality control (QC), total quality leadership, continuous quality improvement, quality management science, or, more generally, industrial quality management. It provides both a management philosophy for organizational development and a management process for improvement of quality in all aspects of work. Many healthcare organizations have adopted the concepts and principles of TQM.

Concepts

In this chapter, **quality** is defined as conformance to the requirements of users or customers and the satisfaction of their needs and expectations. The universal principles of total quality management include (1) customer focus, (2) management commitment, (3) training, (4) process capability and control, and (5) measurement through quality improvement tools.[28] The focus on users and customers is important, particularly in service industries such as healthcare. Users of healthcare laboratories are often the nurses and the doctors; their customers are the patients and other parties responsible for payment.

Costs must be understood in the context of quality. If quality means conformance to requirements, then "quality costs" must be understood in terms of "costs of conformance" and "costs of nonconformance," as illustrated in Figure 7-1. In industrial terms, costs of conformance are divided into prevention costs and appraisal costs. Costs of nonconformance consist of internal and external failure costs. For a laboratory testing process, calibration is a good example of a cost incurred to prevent problems. Likewise, quality control involves a cost for performance appraisal, a repeat run is an internal failure

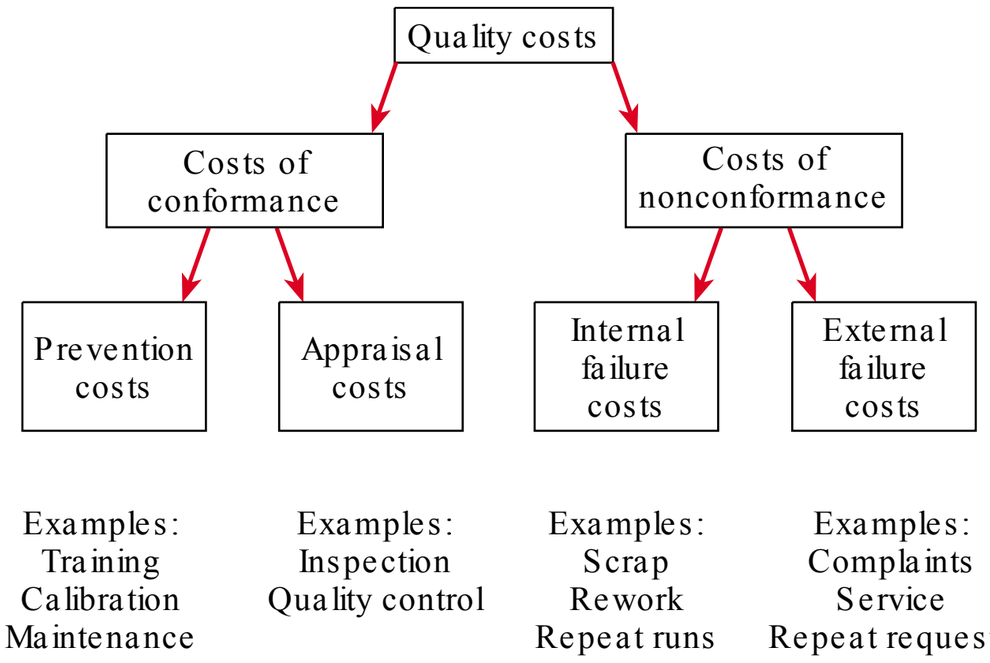

Figure 7-1 The cost of quality in terms of the costs of conformance and the costs of nonconformance to customer requirements. (From Westgard JO, Barry PL. Cost-effective quality control: managing the quality and productivity of analytical processes. Washington, DC: AACC Press, 1997.)

cost for poor analytical performance, and repeat requests for tests—because of poor analytical quality—constitute an external failure cost.

This understanding of quality and cost leads to a new perspective on the relationship between these two concepts. Improvements in quality lead to reductions in cost. For example, with better analytical quality, a laboratory eliminates repeat runs and repeat requests for tests. This repeat work is waste. If quality improves, waste is reduced, which, in turn, reduces cost. The father of this fundamental concept was the late W. Edwards Deming, who developed and internationally promulgated the idea that quality improvement reduces waste and leads to improved productivity, which, in turn, reduces costs and provides a competitive advantage.[11]

Methodology

Quality improvement occurs when problems are eliminated permanently. Problems arise primarily from imperfect processes, not from imperfect individuals. Industrial experience has shown that 85% of all problems are process problems, whereas the remaining 15% are problems requiring the action and performance improvement of individual employees. Thus, quality problems are primarily management problems because only management has the power to change work processes.

This emphasis on work processes leads to a new view of the organization as a system of processes (Figure 7-2).[7] For example, various disciplines will have different views of the work processes of a healthcare organization (Box 7-1). The total system for a healthcare organization involves the interaction of all of these processes and others.[15]

Given the primary importance of these processes for the organization, TQM views the organization as a support structure rather than a command structure. The most immediate processes required for delivery of services are those of frontline employees. The role of senior management is to support frontline employees and empower them to identify and solve problems in their own work processes.

The importance of empowerment is understood easily when a problem involves processes from two different departments. For example, if a problem involves the link between process A and process B (see Figure 7-2), the traditional management structure requires that a problem be passed up from the line workers to a section manager or supervisor, a department director, and an organization administrator. The administrator then works back through an equal number of intermediaries in the other department. Direct involvement of line workers and their managers should provide more immediate resolution of the problem.

However, solving such problem requires a carefully structured process to ensure that root causes are identified and proposed solutions are verified. Juran's "project-by-project" quality improvement process provides detailed guidelines that have been adopted widely and integrated into current team problem-solving methodology.[16] As listed in Box 7-2, this

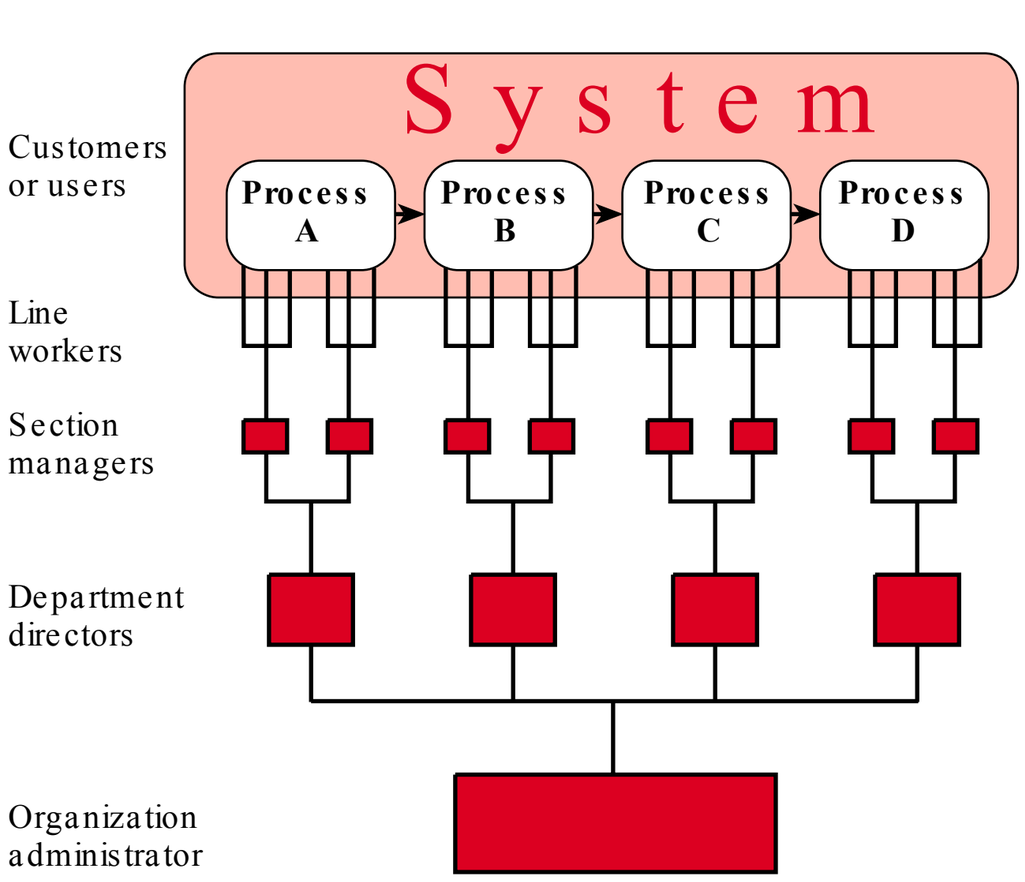

Figure 7-2 The total quality management view of an organization as a system of processes.

BOX 7-1 Different Views of the Work Processes of a Healthcare Organization as a Function of One's Position in the Organization

Physician/Healthcare Provider
- Patient examination
- Patient testing
- Patient diagnosis
- Patient treatment

Healthcare Administrator
- Processes for admission of patients
- Tracking of patient services
- Discharge of patients
- Billing for costs of services

Laboratory Director
- Processes for acquiring specimens
- Processing of specimens
- Analyzing of samples
- Reporting of test results

Laboratorian
- Acquisition of samples
- Analysis of samples
- Quality control measures
- Release of patient test results

BOX 7-2 Elements of a "Project-by-Project" Approach to Quality Improvement

Careful definition of the problem
Establishment of baseline measures of process performance
Identification of root causes of the problem
Identification of a remedy for the problem
Verification that the remedy actually works
"Standardization" or generalization of the solution for routine implementation of an improved process
Establishment of ongoing measures for monitoring and control of the process

methodology outlines distinct steps to be followed in such a quality improvement process.

Implementing TQM

The principles and concepts of TQM have been formalized into a quality management process (Figure 7-3). The traditional framework for quality management in a healthcare laboratory emphasizes establishment of (1) quality laboratory processes (QLPs), (2) quality control (QC), (3) **quality assessment (QA)**, and (4) quality systems (QSs).[7] QLPs include analytical processes, as well as the general policies, practices, and procedures that define how all aspects of the work are done. QC emphasizes statistical **control procedures** but also includes nonstatistical check procedures, such as (1) linearity checks, (2) reagent and standard checks, and (3) temperature monitors. QA, as currently applied, is concerned primarily with broader measures and monitors of laboratory performance, such as (1) **turnaround time**, (2) specimen identification, (3) patient identification, and (4) test utility. Note that quality assessment is the proper term for these activities, as opposed to **quality assurance**, which has been used incorrectly to describe these activities. Measuring performance does not by itself improve performance and often does not detect problems in time to prevent harmful effects. Quality assessment requires that causes of problems be identified through QI and eliminated through quality planning (QP), or that QC detect the problems early enough to prevent their consequences.

To provide a fully developed framework for quality management, QI and QP components must be established. QI provides a structured problem-solving process to help identify the root cause of a problem and a remedy for that problem. QP is necessary to (1) standardize the remedy, (2) establish measures for performance monitoring, (3) ensure that the performance achieved satisfies quality requirements, and (4) document the new QLP. The new process then is (1) implemented through QLP, (2) measured and monitored through QC and QA, (3) improved through QI, and (4) replanned through QP. These components, which work together in a feedback loop, illustrate how continuous QI is accomplished and quality assurance is built into laboratory processes.

The five-Q *f*ramework (see Figure 7-3) also defines how quality is managed objectively with the "scientific method," or the PDCA cycle (**p**lan, **d**o, **c**heck, **a**ct). QP provides the planning step, QLP establishes standard processes for the way things are done, QC and QA provide measures for checks on how well things are done, and QI provides a mechanism through which one can act on those measures. The methodology naturally applied in scientific experiments should serve as the basis for objective management decisions.

Objectivity, however, depends on the existence of quantitative quality requirements for evaluating the performance of existing processes and planning the performance of new processes. Laboratories must define their service goals and objectives and establish clinical and analytical quality requirements for process testing. Without such quality goals, no objective way exists to (1) determine whether acceptable quality is being achieved, (2) identify processes that need improvement, or (3) plan or design new processes that ensure the attainment of a specified level of quality.

TQM is considered a quality system that is implemented to ensure quality. For example, a Clinical Laboratory and Standards Institute (CLSI) document describes a quality management system (QMS) as a "set of key quality elements that must be in place for an organization's work operations to function in a manner to meet the organization's stated quality objectives."[7] Essentials of a QS (QSE) are listed in Box 7-3. These depict the infrastructure required by a laboratory to provide quality laboratory services. Details on how to implement QSs are given in the CLSI document.[7]

Personnel Competency and Training

People are critical components of a total quality system, and training and education are vital to the performance of personnel. A key factor for successful training and assessment of laboratory staff is the planning and implementation of targeted education programs. CLIA[24] identifies the following six areas as required components of a laboratory competency assessment program: (1) direct observation of routine patient test performance; (2) monitoring of the recording and reporting of test results; (3) review of intermediate test results, QC records, proficiency testing results, and preventive maintenance records; (4) direct observation and performance of instrument maintenance and function checks; (5) assessment of test performance through testing of previously analyzed specimens, internal blind testing of samples, or external proficiency testing of samples; and (6) assessment of problem-solving skills.[4]

Assessment of competence in job tasks as required by CLIA must be conducted semiannually the first year of employment and annually thereafter, and upon implementation of new test methodology before reporting of patient test results. Guidelines to assist in the development and documentation of competency assessment are available from the Clinical and Laboratory Standards Institute (CLSI). The CLSI Guideline, Training and Competence Assessment, gives detailed directions on how to develop and implement a training and competency assessment program that meets regulatory requirements, and provides examples of forms for documentation and record keeping.[5]

Design of an in-service training program based on instructional systems design includes the following elements: (1) analysis, (2) design, (3) implementation, and (4) evaluation. The program begins with a needs assessment or gap analysis to (1) determine employee performance requirements, (2) identify deficiencies, and (3) evaluate existing education and training resources. It requires the development of measurable instructional objectives that are based on the specific skills and competencies required of the employee to perform the job or task, and selection of an appropriate teaching strategy. The in-service training program also considers how an instructional program will be delivered and includes a range of organizational factors that may impact successful delivery of the instruction. These include (1) employee participation, (2) scheduling, (3) availability of subject matter experts to teach, (4) budget constraints, and (5) assessment of learning outcomes. It provides ways to evaluate the effectiveness of the instructional program.[10]

In the face of increased pressure to reduce operating costs, including expenses associated with attendance and travel to conferences, Internet education programs provide an effective, cost-efficient way to implement in-service training. Web-based training programs in quality control concepts are available through both professional organizations and private companies. As an example, the Mayo Clinic identified that a gap in academic education on basic quality control concepts existed based on the diversity of their workforce and the varying academic backgrounds required for their highly specialized laboratories. To provide the desired level of academic education to its employees in a way that could be readily accomplished, the Mayo Clinic enrolled employees in the course Basic QC Practices, available on the Web through Westgard QC, Inc. The e-learning content of the curriculum included the following modules: (1) statistical quality control; (2) construction and interpretation of **Levey-Jennings control charts**; (3) electronic checks and sources of error; (4) CLIA '88 regulations for QC; (5) control materials and limitations of QC; (6) multirule and multilevel interpretation of QC data; (7) false rejection and error detection; (8) troubleshooting; (9) regulatory guidelines; (10) QC documentation and record keeping; and (11) external quality assessment programs. In addition, the online curriculum was customized to employees' specific needs through the addition of staff lectures, six 2-hour laboratory sessions, assignments tailored to clinical laboratory practice, and pretesting and post-testing to assess competency.

Implementation of this in-house training program in basic quality control by the Mayo Clinic followed the education model designed for the Clinical Laboratory Science program. The didactic component is provided in an e-learning platform that consists of three modalities of learner interaction with content, instructor, and fellow learners. Each lesson plan includes a supplemental laboratory module taught by traditional methods of interaction between instructor and learner, which is closely anchored in the context of the work they perform. And finally, the curricular model implements the "reverse lecture-homework paradigm," whereby learners complete the Web-supported didactic modules asynchronously as "homework" assignments (Figure 7-4, A) and complete the laboratory lessons in the classroom (work setting) under the guidance and direction of the instructor/supervisor (Figure 7-4, B).

Implementing an e-learning platform allows the curricular model to expand the number of students over time toward an improved economy of scale. For academic programs, this approach allows for a potential increase in class size with minimal additional expenses. For in-service training, an electronic curriculum provides the opportunity to share training across different physical sites within a healthcare delivery system. This is sharing (1) eliminates the costs associated with duplication of effort, (2) reduces operating costs to cover additional employees, and (3) decreases startup costs for new academic and in-service programs at additional sites.

The Total Testing Process

Accurate and timely test reports are the responsibility of the laboratory. However, many problems arise before and after submitted specimens are analyzed (see Chapter 6). Therefore the **total testing process** must be managed properly in the (1) preanalytical, (2) analytical, and (3) postanalytical phases. Note: These are also known as (1) pre-examination, (2) examination, and (3) post-examination processes.

The many steps or subprocesses that take place from the time of the initial request for a test to the time of final interpretation of the test result are determined through performance of a "systems analysis." Table 7-1 lists the steps or subprocesses of a typical clinical laboratory testing process and the potential errors associated with them. Although such an analysis

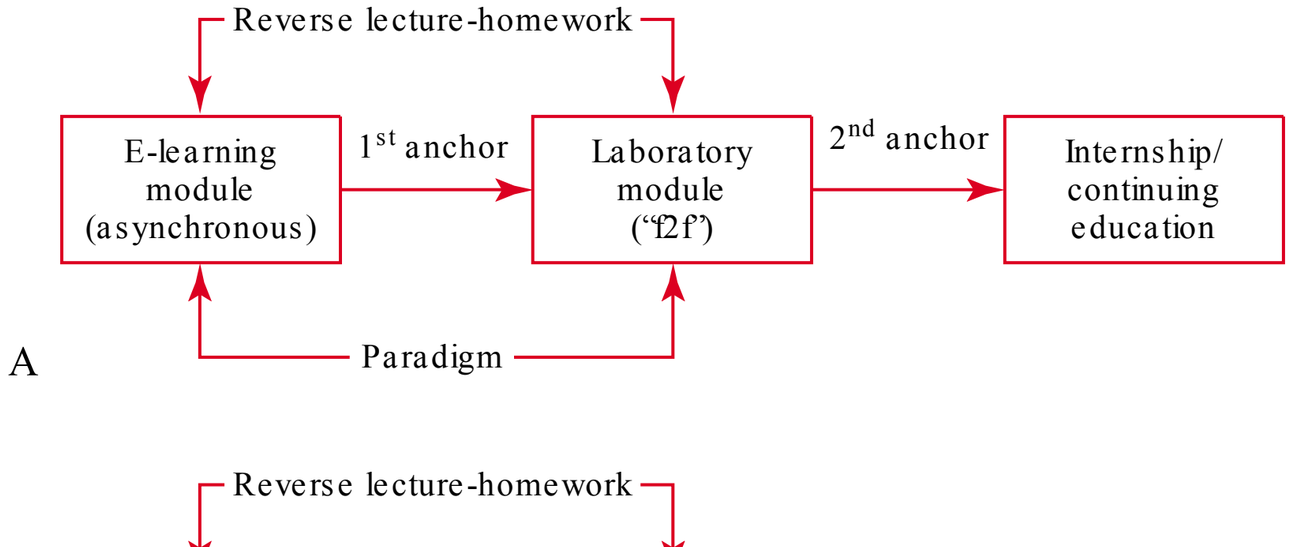

Figure 7-4 Examples of reverse lecture homework paradigms.

TABLE 7-1 Laboratory Testing Processes and Their Potential Errors

Process	Potential Errors
Test ordering	Inappropriate test
	Handwriting not legible
	Wrong patient identification
	Special requirements not specified
	Cost or delayed order
Specimen acquisition	Incorrect tube or container
	Incorrect patient identification
	Inadequate volume
	Invalid specimen (e.g., hemolyzed, too dilute)
	Collected at wrong time
	Improper transport conditions
Analytical measurement	Instrument not calibrated correctly
	Specimen mix-up
	Incorrect volume of specimen
	Interfering substance present
	Instrument precision problem
	Poorly written laboratory procedure
Test reporting	Wrong patient identification
	Report not posted in chart
	Report not legible
	Report delayed
	Transcription error
Test interpretation	Interfering substances not recognized
	Specificity of test not understood
	Precision limitations not recognized
	Analytical sensitivity not appropriate
	Previous values not available for comparison

identifies the critical processes for a typical laboratory, each laboratory situation is different, and additional processes and sources of error may be present. Thus, each laboratory should perform a systems analysis of its own laboratory testing system to identify those areas in which errors are likely to occur.

Once the processes have been documented, those processes most susceptible to error should be identified and should receive rigorous attention. Many times the processes that lead to the greatest number of complaints, such as lost specimens or delayed results, are judged most important. However, other factors, such as the appropriateness of test selection and the acceptability of a specimen, may be more important for achieving optimal medical care. Guidelines describing procedures for specimen handling are available from organizations such as the Clinical and Laboratory Standards Institute (CLSI). Documents put forth by accrediting agencies, such as the College of American Pathologists (CAP), the Centers for Disease Control and Prevention (CDC), and state regulatory agencies, are also helpful.[2,7,15]

Control of Preanalytical Variables

Establishing effective methods for monitoring and control of preanalytical variables is difficult because many such variables are outside the traditional laboratory areas (see Chapter 6). Monitoring of preanalytical variables requires the coordinated effort of many individuals and hospital departments, each of which must recognize the importance of these efforts in the maintenance of high-quality service. Accomplishing such monitoring may require support from outside the laboratory, particularly from the institution's clinical practice committee or some similar authority. Important variables for consideration are listed in Box 7-4 and are discussed in the following section of this chapter.

Test Utilization and Practice Guidelines

Traditionally, laboratory test utilization always has been monitored or controlled. However, current emphasis on the cost of medical care and government regulation of medical care have increased the importance of this factor.

Patient Identification

Correct identification of patients and specimens is a major concern for laboratories. The highest frequency of errors occurs with the use of handwritten labels and request forms.

BOX 7-4 Variables in the Preanalytical Process

Test utilization and practice guidelines
Patient identification
Turnaround time
Laboratory logs
Transcription errors
Patient preparation
Specimen collection
Specimen transport
Specimen separation and distribution of aliquots

The use of bar-coding technology for patient identification has minimized this potential source of error (see Chapter 16).

Turnaround Time (TAT)

The turnaround time (TAT) is defined as the time between when a test is ordered or a specimen is submitted for analysis and when the test results are reported. Delayed and lost test requisitions, specimens, and reports are major problems for laboratories. An essential feature of monitoring for the cause of delays is recording of actual times of (1) specimen collection, (2) receipt in the laboratory, and (3) reporting of test results and then calculating the TAT.

Laboratory Logs

When the serum aliquot tubes arrive in the laboratory, a request/report form generally accompanies the specimens. The patient name and identification number and the tests requested on the form should be checked against the information on the label of the specimen tube to ensure that they are the same. In addition, the specimen should be inspected to confirm adequacy of volume and freedom from problems that may interfere with the assay, such as lipemia or hemolysis. The specimens then should be stored appropriately, and the identifying information and arrival time recorded in a master log. In practice, this is now done electronically.

Transcription Errors

In laboratories where electronic identification and tracking have not been implemented, a substantial risk of transcription error is associated with manual entry of data, even when results are double-checked. Computerization reduces this type of transcription error because computerized systems have error detection routines programmed into the terminal entry functions. These routines may include (1) check digits, (2) limit checks, (3) test-correlation checks, and (4) verification checks with master hospital files.

Patient Preparation

Laboratory tests are affected by many patient factors, such as (1) recent intake of food, alcohol, or drugs, (2) smoking, (3) exercise, (4) stress, (5) sleep, (6) posture during specimen collection, and (7) other variables (see Chapter 6). Proper patient preparation is essential for obtaining meaningful test results. The laboratory must define the instructions and procedures for patient preparation and specimen acquisition.

Specimen Collection

The techniques used to acquire a specimen have affected many laboratory tests (see Chapter 6). Improper containers and incorrect preservatives also affect test results and make them inappropriate. One way to monitor and control this aspect of laboratory processing is to assign a specially trained laboratory team to handle specimen collection.

Specimen Transport

The stability of specimens during transport from the patient to the laboratory is critical for some tests performed locally and for most tests sent to regional centers and commercial laboratories. For control of specimen transport, the essential feature is the authority to reject specimens that arrive in the laboratory in an obviously unsatisfactory condition (such as a thawed specimen that should have remained frozen).

Specimen Separation and Distribution of Aliquots

Separation of blood specimens and distribution of aliquots are functions usually performed under the direct control of the laboratory. The main variables are (1) the centrifuges, (2) the containers, and (3) personnel. Centrifuges should be monitored through checks on speed, time, and temperature (see Chapter 8). Sources of calcium and trace metal contamination include (1) collection tubes, (2) pipettes, (3) stoppers, and (4) aliquot tubes; each lot number of materials used should be tested for contamination by calcium and possibly other elements.

Control of Analytical Variables

In practice, analytical variables are carefully controlled to ensure accurate measurements by analytical methods. Reliable analytical methods are identified through a careful process of (1) selection, (2) evaluation, (3) implementation, (4) maintenance, and (5) control (see Chapter 2). Smooth and uninterrupted laboratory service requires many procedures performed to prevent the occurrence of problems. Different laboratories have experienced different problems with the same analytical methods because different amounts of effort were allocated to the care, maintenance, and support of those methods.

Certain variables such as (1) water quality, (2) calibration of analytical balances, (3) calibration of volumetric glassware and pipettes, (4) stability of electrical power, and (5) the temperature of heating baths, refrigerators, freezers, and centrifuges should be monitored on a laboratory-wide basis because they affect many laboratory methods (see Chapter 8). In addition, certain variables specifically affect individual analytical methods, and these require the development of procedures to deal specifically with characteristics of the methods.

Documentation of Analytical Protocols

The CLSI[6] defines a process as a set of interrelated or interacting activities that transform inputs into outputs (ISO 9000; http://www.iso.org/iso/iso_9000/; accessed July 24. 2013). In practice, a process may be documented as a flowchart or a table that describes operations within the laboratory. A

BOX 7-5 Outline for a CLSI Policy, Process or Procedure Document

A CLSI document[5] describes the following sections as included in a laboratory policy, process, or procedure:

A. Purpose: Describes what the document is meant to achieve.
B. Scope or Applicability: Describes the extent of the activity or the area over which the activity extends.
C. References:
   Names the source document from which the content was directly taken.
   The use of online references is acceptable. The Web link for the reference and the date accessed need to be included.
D. Related Documents: This is a list of documents referred to in the body of the document, or whose content the reader will need to complete the task or process. If used, this section provides a listing of other procedures that were referred to in this procedure description.
F. Attachments or Appendixes: These may include information in tables, examples of completed forms, or useful diagrams, thereby giving additional information to readers.

procedure document provides step-by-step instructions that a single individual needs to follow to successfully complete one activity in the process. Such a procedure is critical if a method is to achieve the same results when used by different laboratorians over a long time. Box 7-5 outlines the information contained in a procedure document. More detailed guidelines are provided in the CLSI document.[6] Contents required in a laboratory manual are listed in Box 7-6. Such a manual should be reviewed annually and revised whenever changes occur, and this should be documented. In addition, retaining outdated procedures in an archival file (hard copy or electronic) is a good practice.

Monitoring of Technical Competency

Proper training of laboratory personnel to establish uniformity in technique is important, as is scheduling of sufficient routine service to maintain proper techniques. A written list of objectives that outline critical tasks and knowledge is a helpful tool in training of personnel on new analytical methods. These objectives ensure systematic instruction that covers the critical points. Before analyses for clinical use are performed, the technical competence of personnel should be checked and practice runs performed. Periodic monitoring of competency may be difficult, but incident reports and results from internal and external QC checks will identify specific problems; these problems should be discussed directly with the personnel involved. In-service and continuing education programs help to maintain and improve competence. Employee conferences help to uncover nontechnical problems that may affect work quality.

Statistical Control of Analytical Methods

Performance of analytical methods typically is monitored through analysis of specimens with known concentrations and subsequent comparison of observed values with known values. The known values usually are represented by an interval of acceptable values, or by upper and lower limits for control (control limits). When observed values fall within control limits, the laboratorian is assured that the analytical method is performing properly. When observed values fall outside control limits, the laboratorian is alerted to the possibility of problems in the analytical determination. A variety of available sources of information describe the application of statistical QC in the clinical laboratory.[13,26]

Control Materials

Specimens that are analyzed for QC purposes are known as control materials. They need to be available (1) in a stable form, (2) in aliquots or vials, and (3) for analysis over an extended time. In addition, only minimal vial-to-vial variation should exist, so that differences between repeated measurements are attributed to the analytical method alone. The control material preferably should have the same matrix as the test specimens of interest, for example, a protein matrix should be present when serum is the test material to be analyzed by the analytical method. Materials from human sources generally are preferred, but because of limited availability and biohazard considerations, animal materials offer a certain advantage in terms of safety and are often more readily available. The concentration of analyte should be within healthy and abnormal reference intervals, corresponding to concentrations that are critical in the medical interpretation of test results.

In practice, laboratories purchase control materials from one of several companies that manufacture control sera or "control products." These products generally are supplied in lyophilized or freeze-dried forms that are reconstituted by the addition of water or a specific diluent solution. Also available are materials with matrices representing (1) urine, (2) spinal fluid, and (3) whole blood. Liquid control materials also are available and offer the advantage of eliminating errors caused by reconstitution. However, the matrices of these liquid materials contain other materials that constitute a potential source of error with some analytical methods and instruments.

In addition to the product's matrix, several other factors must be considered in the selection of commercial control materials. Stability is critical because the laboratory often purchases a year's supply of one manufacturing lot or batch. Different batches (or lot numbers) of the same material have different concentrations, which require new estimates of the mean and the standard deviation (SD). The size of the aliquots

or vials should be convenient for the analytical methods to be monitored. Larger vials generally are less expensive (on a per-milliliter basis), but unused materials may eliminate potential savings. Two or three different materials should be selected to obtain concentrations that monitor performance at different medical decision levels.

Control products are purchased as assayed or unassayed materials. Assayed materials come with a list of values for the concentrations or activities expected for that material. T is list often includes both the mean and the SD for several common analytical methods and preferably for a reference method used to measure a particular analyte. Because of the work required to determine these values, the assayed materials are more expensive. Although stated assay values are useful in selection of desired materials, determination of the mean and the SD in the user's laboratory is advisable because this process improves the performance characteristics of statistical control procedures.

General Principles of Control Charts

One method commonly used to compare values observed for control materials with their known values is the use of control charts.* Control charts are simple graphical displays in which the observed values are plotted versus the time when the observations are made. Known values are represented by an acceptable range of values, as indicated on the chart by lines for upper and lower control limits. When plotted points fall within control limits, this occurrence generally is interpreted to mean that the method is performing properly; points falling outside control limits are problematic.

Control limits usually are calculated from the mean (x) and the SD (s) obtained from repeated measurements on known specimens by the particular analytical method that is to be controlled (see Chapter 2). When the method is performing properly, initial estimates should be based on measurements obtained over a period of at least 1 month. In practice, this initial estimate may not be entirely reliable because of the low number of data points and possible outliers in the data. Estimates are revised when additional data have been accumulated by recording of n and summations of x_i and (x_i^2), and when cumulative totals in the previous equations are subsequently used to determine cumulative means and SDs. T e effects of outliers are minimized by elimination of values exceeding the mean by more than ± 3.1 to 3.8 s's (where the exact factor depends on the total number of data points: 3.14 for n = 30; 3.22, n = 40; 3.33, n = 60; 3.41, n = 80; 3.47, n = 100; 3.66, n = 200; and 3.83, n = 400).

Error distribution of the analytical method is assumed to be Gaussian (i.e., symmetrical and bell-shaped; see Chapter 2). T e control limits are set to include most of the control values, usually 95% to 99.7%, which correspond to the mean ± 2 or 3 SDs (s). Because observance of a value in the tails of the distribution should be a relatively rare occurrence (only 1 out of 20 times for 2 s limits, 3 out of 1000 for 3 s limits), such an observation is suspect and suggests that something may have happened to the analytical method. Such an occurrence could have caused a shift in the mean (an accuracy problem), which would result in a higher probability of exceeding the limits, or it could have caused an increase in the SD (a precision problem), which would widen the distribution and result in a higher probability of exceeding the control limits of acceptability.

Figure 7-5, A, illustrates how the distributions of control values appear for three different situations: (1) stable performance in which only an occasional observation exceeds control limits, (2) occurrence of a systematic error that shifts the mean of the distribution and causes a much higher expectation or probability that control values may be observed outside one of the control limits, and (3) occurrence of an increase in random error or imprecision, which widens the distribution and causes a much higher probability that a control value may be observed outside either of the control limits.

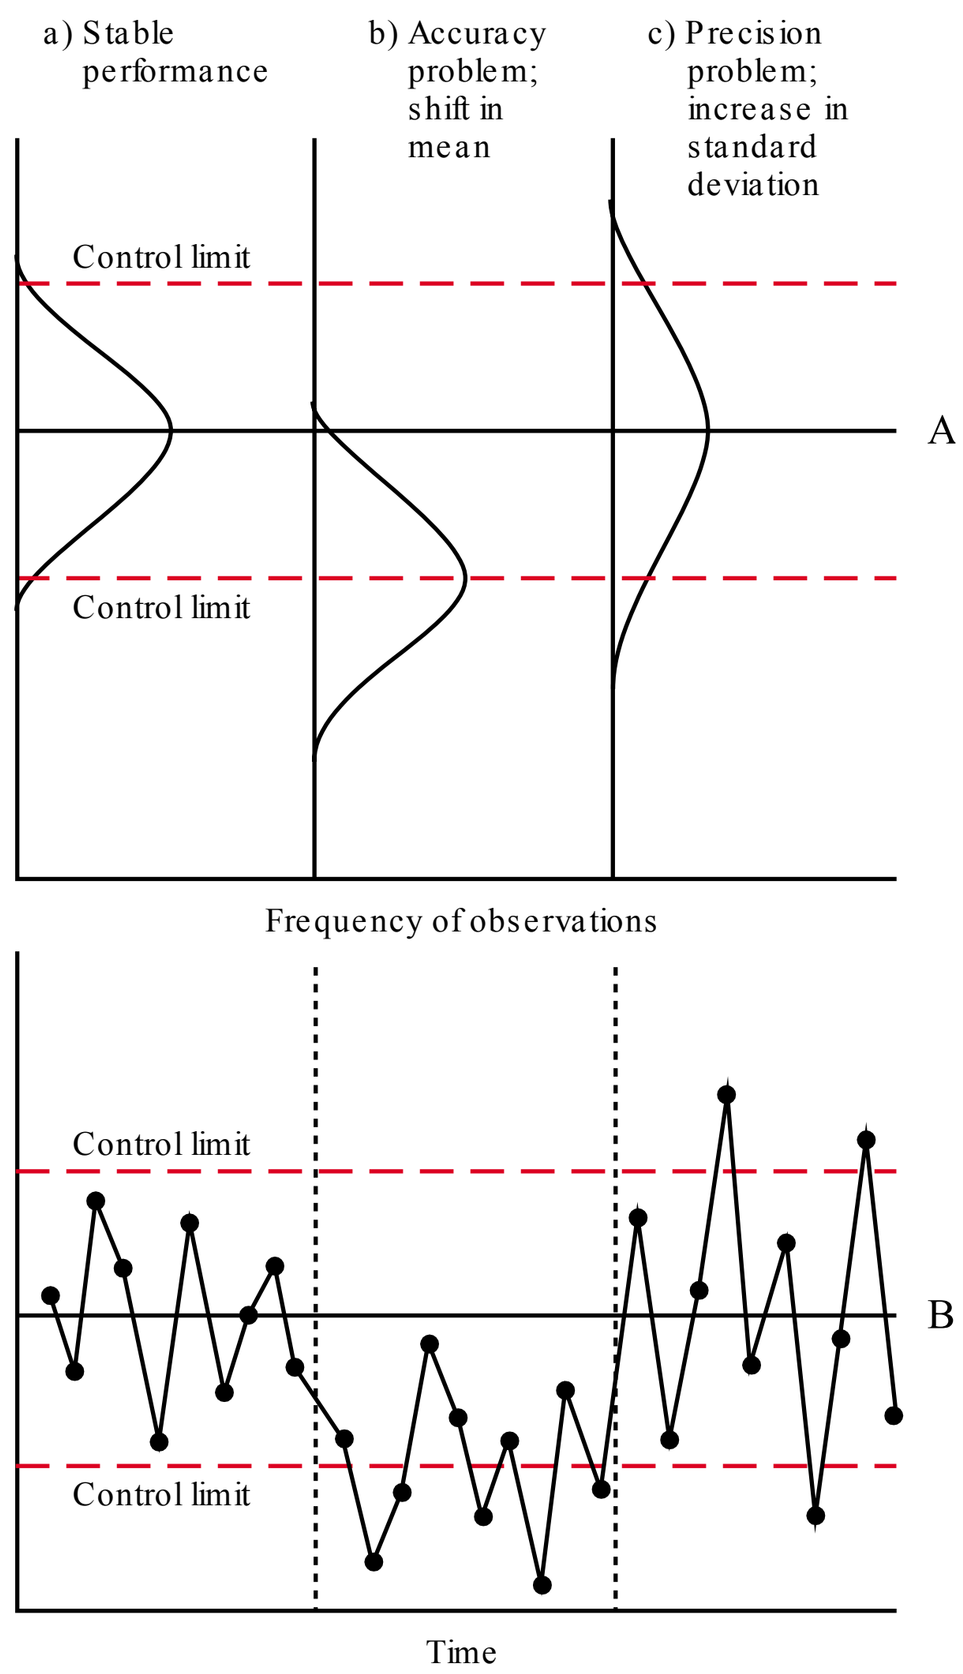

Figure 7-5 Conceptual basis of control charts. A, Frequency distributions of control observations for different error conditions. B, Display of control values representing those distributions for which concentration is plotted versus time on a control chart.

*Control charts were introduced into the clinical chemistry laboratory by Levey and Jennings in 1950. T ey demonstrated how industrial control procedures could be used with the mean and the range of duplicate measurements derived from clinical chemical methods.

In practice, control charts are used to compare observed control values with control limits and to provide a visual display that is inspected and reviewed quickly. On these charts, the concentration or observed value is plotted on the y-axis versus time of observation on the x-axis. Commonly, one month's data are plotted on a chart, usually only one or two points a day, but the time axis should be appropriate for the method being monitored. An example of a Levey-Jennings control chart is shown in Figure 7-5, B, where control values represent the three situations in Figure 7-5, A, with 10 values per situation (for a total of 30 values). If the analytical method is operating properly, control values fall predominantly within control limits. When an accuracy problem exists, control values are shifted to one side and several values in a row may fall outside one of the limits. When a precision problem exists, control values fluctuate much more widely and may exceed both upper and lower control limits.

Interpretation of control data is guided by certain decision criteria or **control rules**, which define when an analytical run is judged "in control" (acceptable) or "out of control" (unacceptable). The term analytical run is used in this discussion to refer to that segment of data for which a decision on acceptability is to be made. This is the group of patient results to be reported, based on control results available for inspection at that time. The total number of control observations available for inspection when a decision is to be made on the acceptability of an analytical run is designated as N. For example, when one control observation precedes and one follows a group of 10 patient samples whose results are to be reported, two control observations exist in that analytical run. The control rules are given symbols such as A_L, or n_L, where A is the abbreviation for a statistic, n is the number of control observations, and L refers to the control limits. For example, 1_{3s} refers to a control rule in which 1 observation exceeding the mean ± 3 s control limits is the criterion for rejection of the analytical run. Similarly, 1_{2s} refers to a control rule in which 1 observation exceeds the mean ± 2 s.

Performance Characteristics of a Control Procedure

The different control procedures discussed previously have different performance capabilities, depending on the control rules and the number of control observations chosen. For example, a Levey-Jennings control chart with control limits set as the mean ± 2 s has a high rate of "false alarms" (i.e., rejections when the method is actually performing satisfactorily). Use of 3 s control limits, such as a 1_{3s} control rule, reduces the false alarms to 1% or less; however, the true alarms or error detection also experiences a reduction.

Selection of control rules and the numbers of control measurements are related to the quality goals set by the laboratory.[8] For example, practical knowledge of the performance characteristics of control procedures is necessary to select control rules that detect relevant laboratory problems without causing too many false alarms. Experienced laboratorians often use a series of informal rules or judgments to reduce the number of false alarms without knowing their effects on the detection of real problems or true alarms. Some quantitative assessment of these two characteristics—false alarms and true alarms—should take place whenever capabilities of new control procedures are assessed, or when established control procedures are reviewed.

Recognizing the seriousness of the false-rejection problem and its relationship to the control limits chosen for the Levey-Jennings chart is important. These false rejections are in effect an inherent property of the control procedure. They occur because of the control limits that have been selected, not because of any problems with the analytical method. Therefore the use of 2 s control limits generally is not recommended. With the use of 3 s control limits, the false-rejection problem is eliminated, but error detection unfortunately is reduced.

Westgard Multirule Chart

The "multirule" procedure developed by Westgard and associates[25] uses a series of control rules to interpret control data. The probability for false rejections is kept low through selection of only those rules with low individual probabilities for false rejection (≤0.01). The probability of error detection is improved through selection of those rules that are particularly sensitive to random and systematic errors. The **Westgard multirule procedure** requires a chart with lines for control limits drawn at the mean ± 1 s, 2 s, and 3 s (i.e., adapted to existing Levey-Jennings charts by the addition of one or two sets of control limits).

The following control rules are used:

- 1_{2s}: one control observation exceeding the mean ± 2 s; used only as a "warning" rule that initiates testing of control data by other control rules
- 1_{3s}: one control observation exceeding the mean ± 3 s; primarily sensitive to random error
- 2_{2s}: two consecutive control observations exceeding the same mean plus 2 s or mean minus 2 s limit; sensitive to systematic error
- R_{4s}: one observation exceeding the mean plus 2 s and another exceeding the mean minus 2 s; sensitive to random error
- 4_{1s}: Four consecutive observations exceeding the mean plus 1 s or the mean minus 1 s; sensitive to systematic error
- 10_x: 10 consecutive control observations falling on one side of the mean (above or below, with no other requirement on the size of deviations); sensitive to systematic error

Use of the multirule procedure is similar to use of a Levey-Jennings chart, but data interpretation is more structured and rigorous. In performing the multirule procedure, the following steps are followed:

1. Samples of the control material are analyzed by the analytical method to be controlled on at least 20 different days. Two different materials with appropriate concentrations are recommended. The mean and the SD are calculated for the results for each control material being used.
2. A control chart is constructed for each of the control materials being used. The observed concentration or control value is plotted on the y-axis, setting the range of concentrations to include the mean ± 4 s. Horizontal lines are drawn for the mean, the mean ± 1 s, the mean ± 2 s, and the mean ± 3 s. In practice, the use of different colors for these lines, perhaps green, yellow, and red for the 1 s, 2 s, and 3 s

limits, respectively, is helpful. The x-axis is scaled for time, day, or run number and is labeled accordingly.

3. Two control specimens are introduced into each analytical run—one for each of the two concentrations (when two different materials have been selected). Control values are recorded and plotted for each on its respective control chart.
4. When both control observations fall within the 2 s limits, the analytical run is accepted and the patient results reported. When one of the control observations exceeds a 2 s limit, the patient results are held and additional rules applied. For example, the control data are inspected using the 1_{3s}, 2_{2s}, R_{4s}, 4_{1s}, and 10_x rules. When any of these rules indicates that the run is out of control, the analytical run is rejected, and the patient results are not reported. When all rules indicate that the run is in control, the analytical run is accepted, and the patient results are reported.
5. When a run is out of control, the type of error is determined on the basis of the control rule that has been violated. This involves looking for sources of that type of error. The problem is then corrected, and the analysis of the entire run is repeated, including both control and patient samples.

An example of the application of the multirule procedure is shown in Figure 7-6, where the top chart illustrates a high-concentration control material and the bottom chart a low-concentration material. Of note is that the R_{4s} rule is applied only within a run, so that between-run systematic errors are not wrongly interpreted as random errors. However, the rule may be applied "across" materials, meaning that one of the observations is on the low material and the other on the high material, as long as they are within the same run. Alternatively, note that the 2_{2s}, 4_{1s}, and 10_x rules are applied across runs and materials. This application effectively increases n and improves the error detection capabilities of the procedure.

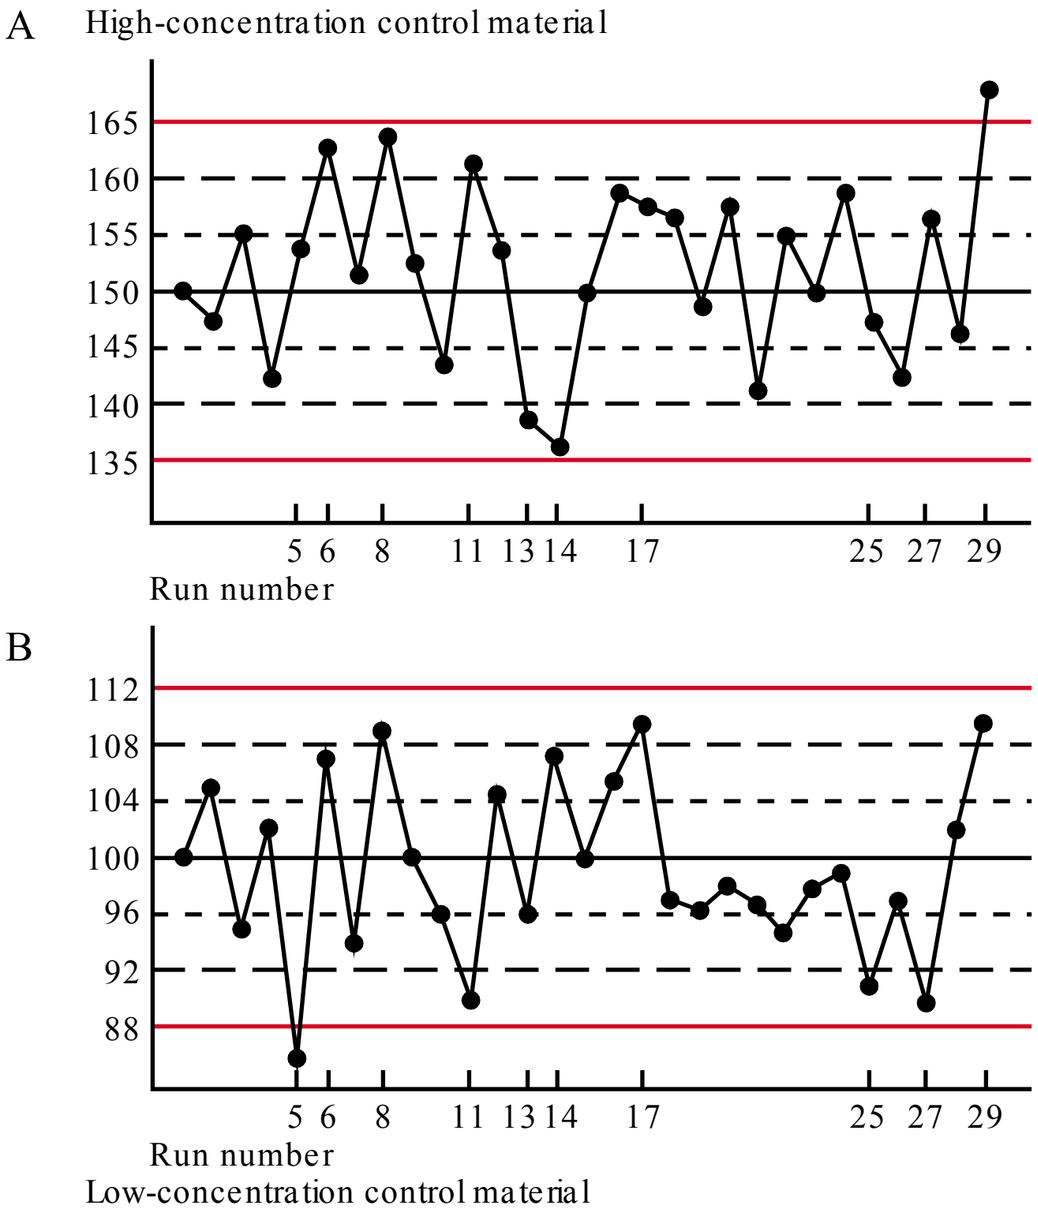

Figure 7-6 Westgard multirule control chart with control limits drawn at the mean ± 1 s, 2 s, and 3 s. Concentration is plotted on the y-axis versus time (run number) on the x-axis. A, Chart for high-concentration control material. B, Chart for low-concentration control material. s, Standard deviation. (From Westgard JO, Barry PL, Hunt MR, et al: A multi-rule Shewhart chart for quality control in clinical chemistry, Clin Chem 1981;27:493-501.)

Identifying Sources of Analytical Errors

Statistical control procedures provide a way to alert the laboratorian to analytical problems that cause the quality of analytical performance to be less than the goals set for the laboratory. However, these control procedures do not identify the sources of the analytical errors and do not solve the control problems. The laboratorian must respond to the out-of-control signal to correct the problem and prevent future occurrences.

QC guidelines from a CLSI document[8] emphasize the importance of problem correction, as opposed to routine repeat of controls, which, in effect, consists of just repeating tests until the controls are within an acceptable range. When control procedures are selected properly on the basis of the quality required for the test and the imprecision and inaccuracy observed with the method, false rejections should be minimized; therefore routine repetition wastes time and effort. Practical tools for selection of appropriate QC procedures have been described in the literature.[26] A laboratorian, when alerted to a control problem, should conduct an inspection of the analytical method, equipment, reagents, and specimens to ensure that the test is performing correctly. An inspection may appear to be a qualitative and sensory technique, but it is a very powerful tool when combined with checklists developed for specific analytical methods. This inspection should include a review of records documenting changes that occur with the instrument and the reagents. Brief instrument function checks often are performed to verify proper system performance and to separate chemical and instrumental sources of error. Experienced laboratorians often spot the problem by performing this kind of inspection, whereas inexperienced laboratorians are aided by formal checklists.

The type of error itself provides a clue to the source of the error. For example, systematic errors often related to calibration problems are listed in Box 7-7. Random errors more likely

BOX 7-7 Systematic Errors Often Related to Calibration Problems

- Impure calibration materials
- Improper preparation of calibrating solutions
- Erroneous set point and assigned values
- Unstable calibrating solutions
- Contaminated solutions
- Inadequate calibration techniques
- Nonlinear or unstable calibration functions
- Inadequate sample blanks
- Unstable reagent blanks

are due to (1) lack of reproducibility in the pipetting of samples and reagents, (2) dissolving of reagent tablets and mixing of sample and reagents, and (3) lack of stability of temperature baths, timing regulation, and photometric and other sensors. Individual analytical methods may not be subject to all of these possible sources of error; rather only a few plausible sources may exist for a particular type of error. Experienced laboratorians often know what these common sources are for their particular analytical methods and quickly identify the source once the type of error is known.

A clue to type of error is the control rule that is violated. Different control rules have different sensitivities to detect random and systematic errors. For example, 1_{3s} and R_{4s} rules tend to respond to random error; 2_{2s}, 4_{1s}, and 10_{x} rules to systematic error. Control procedures that use patient samples rather than stable control materials help identify preanalytical sources of error, such as sample handling and processing. External quality assessment procedures may provide more extensive information about systematic errors than can be obtained from internal procedures. Information derived from all these procedures is complementary and, when used in combination, provides a complete assessment of the types of errors and their possible sources.

Combined Use of Liquid Controls and Moving Averages of Patient Values for Quality Control Monitoring

Distributions of measured test values for patients have been used to supplement traditional liquid controls for monitoring analytical bias. T ese patient specimen measurements generally have much larger variances than liquid controls because they contain (1) biological, (2) pathophysiological, and (3) preanalytical sources of variation, in addition to analytical variation. However, if some of these sources of variation are controlled, averaging techniques often are used to generate tracking parameters that have variations of the same order of magnitude as liquid controls. Demographic information about specific patients such as (1) age, (2) sex, and (3) medical provider service area has been used to normalize test values, resulting in smaller variances of group means for the monitoring parameters. T e larger the window size used for averaging patient values, the smaller the variance. T e coefficient of variation (CV) of the group mean decreases approximately proportionately to the square root of the number of samples. Various statistical techniques have been used to average patient values, such as the exponentially adjusted moving mean. In general, a balance is present between decreased variance and increased time for error detection when larger numbers of patient values are used in these moving averages. For most chemistry tests, window sizes that use 50 to 100 sample values often are necessary.[18] An advantage of test value distributions over liquid controls is the inclusion of preanalytical variation caused by specimen collection, transport, and storage. T is allows patient value–derived parameters to detect changes in these variables, in addition to changes in analytical testing.

Figure 7-7 illustrates an algorithm for combining liquid controls with a patient value–derived parameter. T e same multirule evaluation systems used for liquid controls have been used for tracking the patient value–derived QC statistic. Set points and

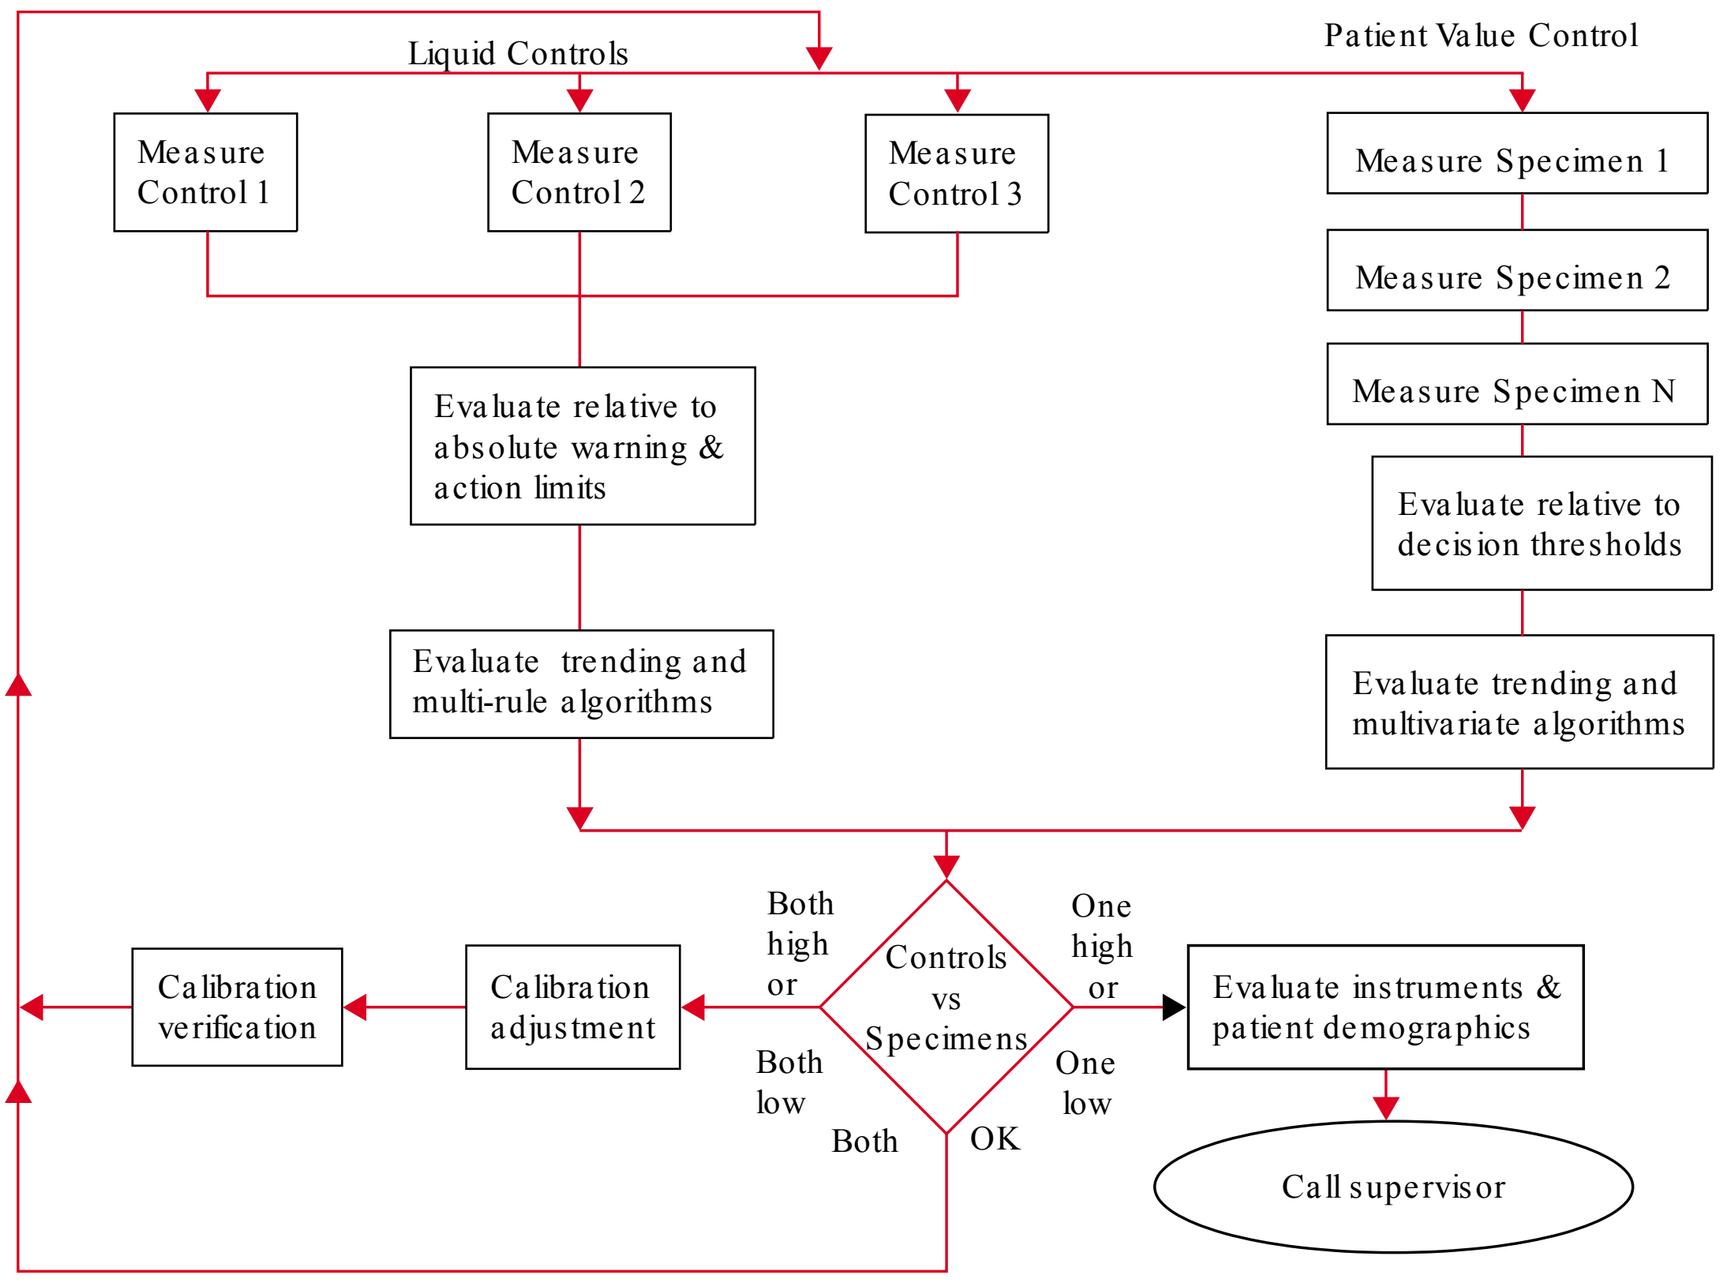

Figure 7-7 Protocol for combining liquid controls and a patient value–derived control.

threshold values are assigned to this derived parameter to optimize the power for error detection for systematic error. Note that the averaging algorithms used to generate these derived parameters average out random errors, so these derived parameters are not useful for detecting random errors. As illustrated in the figure, this combined control protocol is most accurate when both the liquid control and the patient-derived control move in the same direction (both high or both low). When the controls move discordantly, further investigation is necessary to determine whether the problem is related to instability of liquid controls, changes in patient characteristics (such as many sick patients seen at one time), preanalytical test changes, or other causes.

External Quality Assessment and Proficiency Testing Programs

All control procedures described previously have focused on monitoring by a single laboratory. These procedures constitute what is often called internal QC, to distinguish them from procedures used to compare the performances of different laboratories, the latter known as external QA. The two procedures are complementary: Internal QC is necessary for daily monitoring of the precision and accuracy of the analytical method, and external QA is important for the maintenance of long-term accuracy of analytical methods.

Participation in an external proficiency testing program is required for all U.S. laboratories that perform tests classified by CLIA as moderate- and high-complexity tests.[24] Many point-of-care testing sites perform some of these tests and must enroll in proficiency testing programs. Current approved providers of proficiency testing programs deliver sets of up to five specimens for analysis by the laboratory 3 times per year. The laboratory reports its results to the provider, who then makes them available to the regulatory agencies.

Features of External Quality Assessment Programs

Several external QA programs available to the clinical laboratory are sponsored by professional societies and manufacturers of control materials. The basic operation of these programs involves all participating laboratories analyzing the same lot of control material, usually daily as part of internal QC activities. The results are tabulated monthly and are sent to the sponsoring group for data analysis. Summary reports are prepared by the program sponsor and are distributed to all participating laboratories.

The reports generated from external QA programs often include extensive data analysis, statistical summaries, and plots. The overall mean of all laboratories in the program or the mean of values of all laboratories is taken as the "true" or correct value and is used for comparison with the individual laboratory's mean. Different programs do this in different ways. For example, the t-test is used to test the statistical significance of any differences between an individual laboratory's observed mean and the group mean. When the difference is significant, the laboratory is alerted that its results are biased in comparison with the results of most other laboratories. Another approach is to divide the difference by the overall SD of the group and then express the difference in terms of the number of SDs.

$$\text{SDI} = \frac{\text{Lab Result} - \text{Group Mean}}{\text{Group s}}$$

where SDI is the standard deviation interval or index, and group s is the SD for the group or for a selected subset of the group. Differences greater than 2 indicate that a laboratory is not in agreement with the rest of the laboratories in the program. These calculations reduce all test results to the same values, which makes possible interpretation of the data from different analytes without reference to the exact mean and s for each analytical method. For example, a value of ±2.0 has the same meaning for any test, indicating that the value is 2 s above or below its established mean.

Additional information about the nature of the systematic error is obtained when two different control materials are analyzed by each laboratory. The laboratory's observed mean for material A is plotted on the y-axis versus its observed mean for material B on the x-axis. These graphs are called Youden plots. Ideally, the point for a laboratory should fall at the center of the plot. Data points falling from the center but on the 45° line suggest a proportional analytical error. Data points falling from the center but not onto the 45° line suggest an error that is constant for both materials or one that occurs with just one material.

The report also may include Levey-Jennings plots of the data, but because this information is not available in real time, it does not effectively serve the purposes of internal QC. Blank control charts set up for each analyte and each control material save the laboratory the time required to prepare these charts manually.

Role of Proficiency Testing in Accreditation

Proficiency testing (PT) is the process by which simulated patient specimens made from a common pool are analyzed by laboratories; the results of this procedure are evaluated to determine the "quality" of the laboratories' performance. In 1988, the U.S. Congress to passed revisions to the Clinical Laboratory Improvement Act of 1967 (CLIA '67) and the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). One of the revisions mandate PT as a major part of the laboratory accreditation process. The final legislative rule for this legislation was published on January 24, 2003.[21] Additional interpretative guidelines, however, were published by the Centers for Medicare & Medicaid Services (CMS) in January 2004 in the form of the State Operations Manual.[24] Appendix C of that document refers specifically to guidelines for laboratories and laboratory testing services.

CLIA requires that all U.S. laboratories register with the government and identify the tests that they perform. Tests may be classified as "waived" or "nonwaived." Waived tests are those that any laboratory is able to perform as long as it follows the manufacturer's directions. No other requirements have been put forth for quality management of those tests. Laboratories that perform "nonwaived" tests are subject to complete CLIA regulations and must be inspected periodically by the government or by certain professional organizations deemed to have standards at least as stringent as CLIA requirements.

Two such organizations are the College of American Pathologists (CAP) and The Joint Commission (TJC). Note that this latter organization was formerly known as the Joint Commission on Accreditation of Healthcare Organizations (JCAHO), and previous to that the Joint Commission on Accreditation of Hospitals (JCAH). The CLIA implementation rules and interpretative guidelines outline the criteria for acceptable performance in laboratory inspection and accreditation.

The CLIA requirements cover several broad classes: (1) Subpart J, Facility Administration; (2) Subpart K, Quality Systems; (3) Subpart M, Personnel; and (4) Subpart Q, Inspection. The final rule dealt mainly with changes to the subpart on Quality Systems,[21] with particular attention to preanalytical, analytical, and postanalytical systems. It places increased emphasis on having quality systems in place to monitor preanalytical and postanalytical processes, yet the biggest impact of the final rule is on analytical quality assessment and analytical quality systems.

The CLIA '88 proposed criteria that group laboratory tests into "specialty" and "subspecialty" categories and specify representative tests to be monitored in each category. To succeed in a given category, a laboratory must produce correct results on four of five specimens for each of the analytes in that category and must score overall at least 80% for three consecutive challenges. If more than two incorrect results are produced for any analyte, the laboratory is considered "on probation." If a laboratory has two or more incorrect results for any analyte or an overall score less than 80% on two of three consecutive surveys, it is classified as "suspended" and must cease testing of all analytes in that specialty category until it is reinstated.

An additional requirement of the final CLIA regulations is that laboratories must perform method validation studies on all new tests introduced after April 24, 2003. Before this time, laboratories that implemented new methods and analytical systems that had been cleared by the U.S. Food and Drug Administration (FDA) could simply follow manufacturers' directions for operation and assume that the manufacturers' performance claims were valid. With the issuance of the final rule, the performance of all new tests must be validated in each laboratory to document (1) reportable range, (2) precision, (3) accuracy, and (4) reference intervals. For some methods, it may also be necessary to (5) determine the detection limit and (6) test for possible interferences.

Another major change in the final rule was the elimination of an earlier provision that would have required the FDA to review a manufacturer's QC instructions. This was a key provision for allowing laboratories to simply follow a manufacturer's directions. However, with elimination of this provision, laboratories now have greater responsibility for establishing effective QC systems that will (1) monitor the complete analytical process, (2) take into account the performance specifications of the method, (3) detect immediate errors, and (4) monitor long-term precision and accuracy.

A controversial change in the final rule was the introduction of "equivalent QC procedures" (EQCs) that allowed laboratories to reduce daily QC to weekly or even monthly QC for analytical systems that have built-in procedural controls. The provision was targeted for point-of-care testing (POCT) or near patient testing (NPT), in cases where personnel lack the skills to perform QC and instead rely on instrument checks, most notably electronic checks or electronic QC. Although at least one example is known of an analytical system with improved QC technology that requires little or no external QC,[27] most analytical systems have yet to demonstrate the performance that would justify reduction of daily QC to only weekly or monthly QC. Because of the controversy involving EQC, CMS announced in 2012 that EQCs would be phased out and recommended that alternative QC procedures be developed on the basis of risk management.[9] The CMS refers to this new approach as an individualized QC plan (IQCP).

However, one should recognize that PT programs are far from ideal monitors of laboratory performance. For example, in a study of PT survey problems at the Mayo Clinic, more than one-half of the errors on surveys were related directly to deficiencies in the surveys (e.g., invalid specimens, inappropriate evaluation criteria), and only 28% could be linked to specific analytical problems.[17]

New Quality Initiatives

Several additional quality initiatives have been developed and implemented to ensure that laboratories incorporate the principles of quality management and QA in their daily operations. These include implementation of the (1) Six Sigma Process, (2) Lean Production, and (3) ISO 9000 standards. In addition, the Joint Committee for Traceability in Laboratory Medicine (JCTLM) has been organized to give guidance on internationally recognized and accepted equivalence of measurements in laboratory medicine and traceability to appropriate measurement standards

The Six Sigma Process

Six Sigma is an evolution in quality management that is being widely implemented in business and industry in the new millennium.[14] Six Sigma metrics are being adopted as the universal measure of quality to be applied to industry processes and the processes of suppliers. The principles of Six Sigma are traceable to Motorola's approach to TQM in the early 1990s and the performance goal that "6 sigmas or 6 standard deviations *of* process variation should fit within the tolerance limits *for* the process"; hence, the name Six Sigma (http://mu.motorola.com/; accessed July 25, 2013).

In practice, the Six Sigma process provides a more quantitative framework for evaluating process performance and more objective evidence for process improvement. The goal for process performance is illustrated in Figure 7-8, which shows an error distribution of a measurement procedure that fits acceptably within tolerance specifications or quality requirements for that measurement. In practice, a process is evaluated in terms of a sigma metric that describes how many sigmas fit within the tolerance limits. For processes in which poor outcomes are counted as errors or defects, the defects are expressed as defects per million (DPM), then are converted to

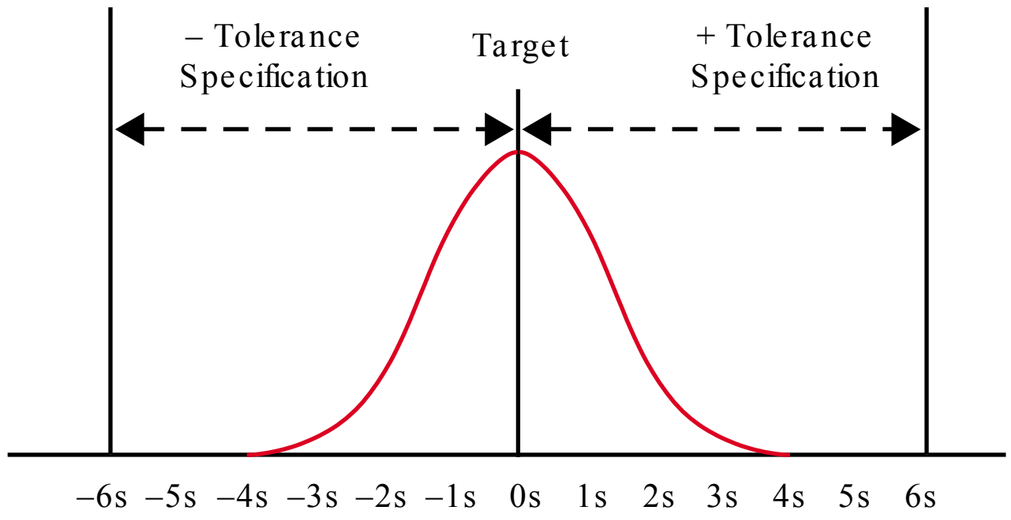

Figure 7-8 Six Sigma goal for process performance "tolerance specifcation" represents the quality requirement.

a sigma metric using a standard table available in Six Sigma textbooks.[14] As optimizing healthcare outcomes and reducing medical errors are of great interest, Six Sigma provides a general method that can be used to describe process outcomes on the sigma scale. The Six Sigma process is used in many industries[1,20] and institutions, and a primer for healthcare facilities is now available.[3]

Lean Production

Lean Production is a quality process that is focused on creating greater value by eliminating activities that are considered waste. For example, any inefficient activity or process that consumes resources or adds cost or time without creating value is revised or eliminated. In practice, it focuses on "system-level" improvements (as opposed to "point improvements").

Because of its success in increasing efficiency environments, the Lean approach has proven useful wherever a defined set of activities is working to produce a product or service. For example, a "Lean team" at Saint Mary's Hospital, a Mayo Clinic hospital in Rochester, Minnesota, used Lean Production to improve the efficiency of its paper ordering system for lab work in its intensive care unit.[19] Because the goal of Lean Production is to increase efficiency and the Six Sigma process to improve quality, these approaches have been combined and integrated into the management of several organizations, including healthcare facilities and clinical laboratories.[12]

ISO 9000

The International Organization for Standardization (ISO), in Geneva, Switzerland (http://www.iso.ch/; accessed July 25, 2013), has developed and promulgated the ISO 9000 standards. ISO is a worldwide federation of national standards bodies from some 100 countries. The mission of ISO is to promote the development of standardization and related activities in the world with a view toward facilitating the international exchange of goods and services and developing cooperation in the spheres of (1) intellectual, (2) scientific, (3) technological, and (4) economic activities. The work of ISO results in international agreements, which are published as International Standards. The ISO 9000 standards are examples of such standards, and they have been applied worldwide. ISO also has organized several technical advisory groups that address quality issues of interest to clinical laboratorians.

ISO 9000 is a set of four standards enacted to ensure quality management and QA in manufacturing and service industries.[23] They were first published in 1987 and are used worldwide; more than 80 countries have adopted them.

The ISO 9000 standards represent an international consensus on the essential features of a quality system designed to ensure the effective operation of any business, whether a manufacturer or a service provider or any other type of organization, in the public or private sector. ISO certification is provided by accredited organizations known as registrars. Registrars review the organization's quality manual and audit the process to ensure that the system documented in the manual is in place and effective.

Preparing for ISO Accreditation

In 2002 Burnett compared ISO standards and synthesized an "ideal standard," which became a practical guide for laboratories preparing for ISO accreditation.[22] In his comparison, Burnett supplements the original ISO standards, illustrates their application, and provides many examples of specific forms and policies that would be appropriate for a laboratory. He provides additional technical information about the quality required for the "intended use" of laboratory tests, which is important if the goal of uniform quality is to be achieved for a patient who moves from place to place and from country to country.

Joint Committee for Traceability in Laboratory Medicine (JCTLM)

Many organizations have been involved in developing a traceable accuracy base for analytes of clinical interest (Figure 7-9). A driver for current efforts to develop such a base is the European Directive 98/79/EC on in vitro diagnostic medical devices (www.ce-mark.com/ivd.pdf/; accessed July 25, 2013), which requires that "the traceability of values assigned to calibrators and/or control materials must be assured through available reference measurement procedures and/or available reference materials of a higher order."

In 2002 the JCTLM was created to meet the requirement for a worldwide platform to promote and give guidance on internationally recognized and accepted equivalence of measurements in laboratory medicine and traceability to appropriate measurement standards (www.bipm.org/en/committees/jc/jctlm/; accessed July 25, 2013). The three principal participants in JCTLM are the International Bureau of Weights and Measures (BIPM), the International Federation for Clinical Chemistry and Laboratory Medicine (IFCC), and the International Laboratory Accreditation Cooperation.

The JCTLM has created two working groups: (1) JCTLM WG-I, Reference Materials and Reference Procedures, and (2) JCTLM WG-II, Reference Laboratory Networks. These groups are responsible for providing practical support to the worldwide in vitro diagnostics (IVD) industry in establishing metrological traceability for values assigned to calibrators and/or control materials as required by the forthcoming European Directive on IVD and by comparable regulations in other countries.

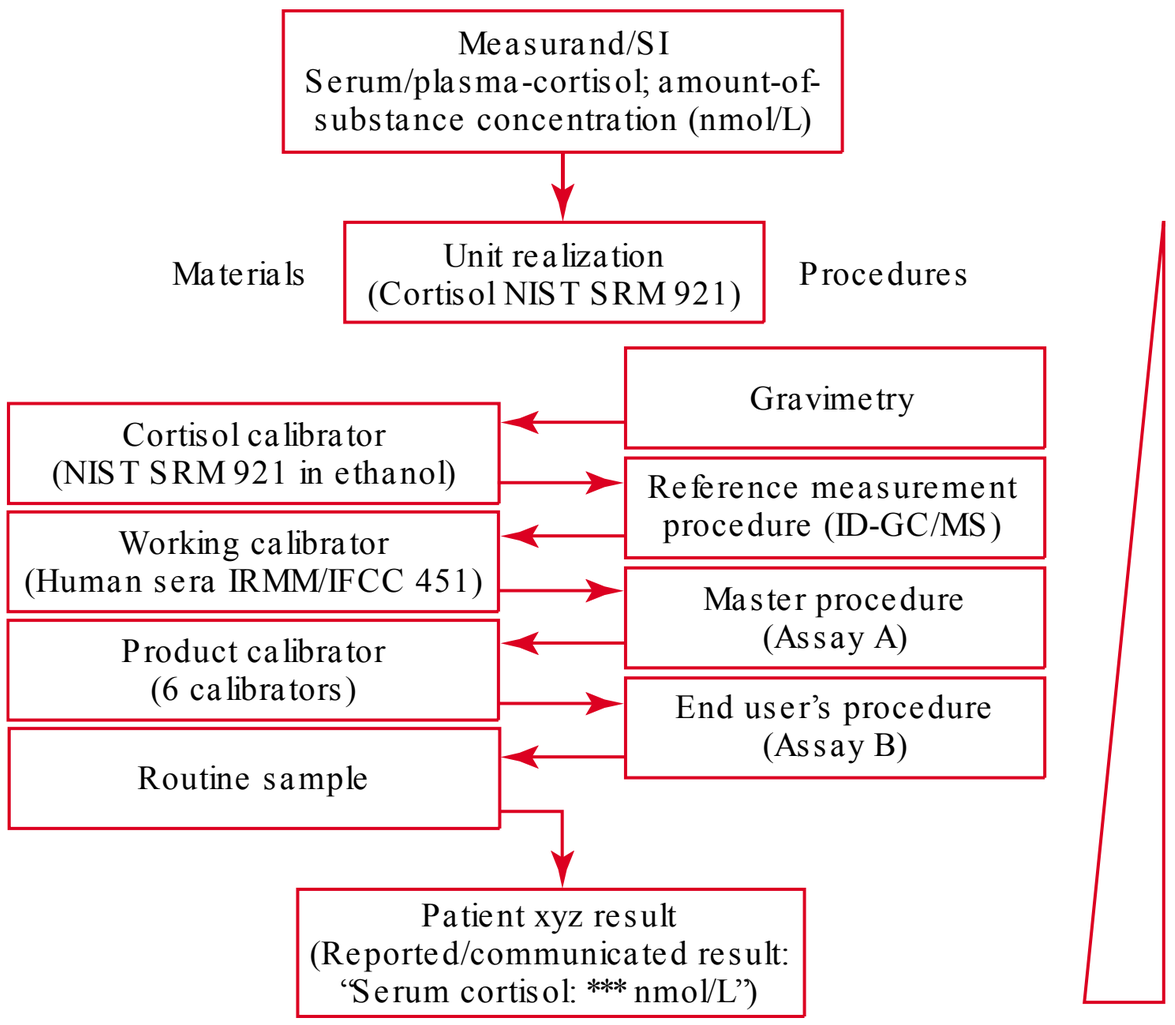

Figure 7-9 Example of a traceability chain developed for serum cortisol measurements. Arrows pointing to the left indicate value assignment activity using the procedure; arrows pointing to the right indicate calibration activity using the material. Publishing for Clinical Chemistry Journal.)

Review Questions

1. The process by which simulated patient specimens made from a common pool are analyzed by laboratories to determine the "quality" of the laboratories' performance is referred to as:
   a. quality control.
   b. proficiency testing.
   c. total quality management
   d. Six Sigma process control.
2. The Westgard multirules for quality control were designed to interpret control data and to aid in troubleshooting analytical processes. The multirule stated as 1_{2s} indicates that:
   a. one control value has exceeded ±2 s from the mean.
   b. two consecutive control values have exceeded ±2 s from the mean.
   c. two consecutive control values have exceeded ±1 s from the mean.
   d. the numerical difference between two control values exceeds 1 s.
3. Choosing an incorrect colored-stopper blood collection tube to obtain a blood specimen is referred to as a(n) _____ variable.
   a. statistical
   b. analytical
   c. preanalytical
   d. controlled
4. With regard to statistical quality assessment in the laboratory, a _____ is a graphical plot of data that uses statistically derived means and standard deviations to determine analytical precision and accuracy.
   a. Levey-Jennings chart
   b. Gaussian distribution
   c. normal curve
   d. Youden plot
5. Conformance to the requirements of a laboratory's users (physicians, patients, etc.) is the definition of:
   a. multirules.
   b. cost.
   c. the total quality method.
   d. quality.
6. What is the role of quality improvement in the five-Q framework of quality?
   a. To monitor the laboratory as a whole for result quality
   b. To monitor the statistical analysis of results
   c. To ensure that the laboratory's policies, procedures, and practices are followed
   d. To identify the cause of a problem and find a remedy for that problem
7. Quality assessment, as part of the five-Q framework of total quality management, involves and monitors which of the following?
   a. Statistical control procedures such as Westgard multirules and Levey-Jennings charts
   b. Laboratory performance such as turnaround times, specimen and patient ID procedures, and test usage
   c. General policies and procedures such as manuals and employee handbooks
   d. Identification of the causes of problems in the laboratory and the solutions to those problems

8. Two types of error may be encountered during analysis of a control material. The type of error that reflects imprecision is:
   a. systematic error.
   b. imprecision error.
   c. random error.
   d. analytical error.
9. With regard to costs in the context of quality, which of the following would be considered a cost of conformance?
   a. Cost of analyzer calibration
   b. Cost of repeating analytical runs
   c. Cost of service calls
   d. Cost of repeated test requests
10. Westgard multirule R_{4s} indicates that one control value has exceeded the mean +2 s and another has exceeded the mean −2 s. This control rule is sensitive to which type of analytical error?
    a. Systematic error
    b. Analytical error
    c. Imprecision error
    d. Random error

CHAPTER 8

Principles of Basic Techniques and Laboratory Safety*

Stanley F. Lo, Ph.D., D.A.B.C.C., F.A.C.B.

Objectives

1. Define the following:
   - Analyte
   - Buffer
   - Centrifugation
   - Dilution
   - Evaporation
   - Filtration
   - Gravimetry
   - LOINC system
   - Lyophilization
   - Primary/Secondary reference material
   - Relative centrifugal force/field
   - Solution
   - Universal Precautions
2. Describe the expressions of concentrations of solutions, including molarity, % concentration, normality, and molality; convert mg/L to mmol/L; calculate solution concentration, given appropriate data.
3. State the units of measure used in the clinical laboratory; describe metric units and the International System of Units, and relate the differences between units.
4. List and compare the three types of water used in the laboratory, and state the uses of each type; describe three methods of preparing reagent grade water.
5. List and compare the different grades of reagents available, and state which are appropriate for use in a clinical laboratory.
6. Compare the two types of reference materials used in the clinical laboratory, and state the specific uses of each type.
7. List and describe three types of pipettes used in the clinical laboratory; state the proper use and the specific uses of each type.
8. For the process of centrifugation:
   - State the principle.
   - List six uses of centrifugation in the clinical laboratory.
   - Calculate RCF and rpm when given the appropriate information.
   - Determine the time required for centrifugation using an alternate rotor.
   - Outline proper operation and operation practice of a centrifuge.
9. Describe three types of balances used in the clinical laboratory and how they are calibrated.
10. Compare serial dilutions with simple dilutions; state and calculate the formula used to prepare a solution of lesser concentration from one of greater concentration.
11. List and describe the elements of an OSHA-approved chemical hygiene plan, a hazard exposure plan, and a tuberculosis control plan; describe the Universal Precautions document, including source and specific mandates; state the CAP requirements for a laboratory ergonomics program.
12. For the following hazard types, interpret laboratory hazard signage, and state the appropriate work practice used to control these hazards:
    - Biological
    - Chemical
    - Electrical
    - Fire

Key Words and Definitions

Analyte A solute dispersed in a solution that is measured in laboratory practice; also referred to as a measurand.

Buffer solution A solution containing either a weak acid and its salt or a weak base and its salt, which is resistant to changes in pH.

Chemical hygiene plan (CHP) An Occupational Safety and Health Administration (OSHA)-required listing of responsibilities for laboratory employers, employees, and a chemical hygiene officer, and including a complete chemical inventory that is updated annually, along with a copy of the Material Safety Data Sheet (MSDS) that defines each chemical as toxic, carcinogenic, or dangerous, and that must be on file and available to all employees 24 hours a day, 7 days a week.

Centrifugation The process of using centrifugal force to separate the lighter portions of a solution from the heavier portions; a centrifuge is a device by which centrifugation is effected.

CLSI The Clinical and Laboratory Standards Institute (formerly the National Committee for Clinical Laboratory Standards, or NCCLS) that guides the development and implementation of standards and guidelines that help all laboratories fulfill their goals.

*The author gratefully acknowledges the original contributions of Drs. Edward W. Bermes, Jr., Stephen E. Kahn, and Donald S. Young.

Key Words and Definitions—cont'd

Ergonomics The study of capabilities in relationship to work demands completed by defining postures that minimize unnecessary static work and reduce the forces working on the body.

Exposure control plan An Occupational Safety and Health Administration (OSHA)-required plan that ensures the protection of laboratory workers against potential exposure to bloodborne pathogens, while ensuring that medical wastes produced by the clinical laboratory are managed and handled in a safe and effective manner.

International System of Units (SI) A system of units for analytical results that is based on the cubic meter as the reference volume and is an internationally (except in the United States) adopted system of measurement. The units of the system are called SI units.

Material Safety Data Sheet (MSDS) A technical bulletin that contains information about a hazardous chemical, such as chemical composition, chemical and physical hazard, and precautions for safe handling and use.

Measurand See Analyte.

Metric system A system of weights and measures based on the meter as a standard unit of length, the liter as a standard unit of volume, and the gram as a standard unit of mass.

OSHA Occupational Safety and Health Administration, formed by the federal government of the United States to formally regulate the oversight of employee safety.

pH A measure of acidity and alkalinity of a solution.

Pipette Device used for the transfer of a volume of liquid from one container to another.

Reagent Chemical used in many high-purity applications.

Reference material A material or substance, one or more physical or chemical properties of which are sufficiently well established to be used for the calibration of an apparatus, the verification of a measurement method, or the assigning of values to materials. Certified, primary, and secondary are types of reference materials.

Relative centrifugal force or field (RCF) Force required to separate two phases (liquid and solid) in a centrifuge.

Universal Precautions Approach to infection control that treats all human blood and certain human body fluids as if they were known to be infectious for bloodborne pathogens.

To reliably perform qualitative and quantitative analyses on body fluids and tissue, the clinical laboratorian must understand the basic principles and procedures that affect the analytical process and operation of the clinical laboratory. These include knowledge of (1) the concept of solute and solvent; (2) units of measurement; (3) chemicals and **reference materials**; (4) basic techniques, such as (a) volumetric sampling and dispensing, (b) **centrifugation**, (c) gravimetry, (d) thermometry, (e) **buffer solution**, and (f) processing of solutions; and (5) safety.[†]

Concept of Solute and Solvent

Many analyses in the clinical laboratory are concerned with determination of the presence or measurement of concentrations of substances in solutions, the solutions most often being (1) blood, (2) serum, (3) urine, (4) spinal fluid, or (5) other body fluids (see Chapter 6).

Definitions

A solution is a homogeneous mixture of one or more solutes dispersed molecularly in a sufficient quantity of a dissolving solvent. In laboratory practice, solutes are typically measured and are frequently referred to as **analytes** or **measurands**. A solution may be (1) gaseous, (2) liquid, or (3) solid. A clinical laboratorian is concerned primarily with the measurement of gases or solids in liquids, where the amount of solvent is relatively large when compared with the amount of solute.

[†]Note: Additional discussions on topics of interest to the clinical laboratorian are found in Lo SF. Principles of basic techniques and laboratory safety. In: Burtis CA, Ashwood ER, eds. Tietz textbook of clinical chemistry, 5th edition. Philadelphia: WB Saunders, 2012:207-31.

Expressing Concentrations of Solutions

In the United States, analytical results typically are reported in terms of mass of solute per unit volume of solution, usually the deciliter. However, the **Système Internationale d'Unités (SI)** recommends the use of moles of solute per volume of solution for analyte concentrations (substance concentrations) whenever possible, and the use of liter as the reference volume.[9] In addition, mass concentration is reported in terms of grams percent or percent. This is typically how concentrations of ethanol in blood are expressed. This terminology indicates an amount of solute per mass of solution (e.g., grams per 100 g) and would be appropriate only if reference materials against which the unknowns were compared were measured in the same terms. An exception to the general expression of analyte concentrations in terms of volume of solution is the measurement of osmolality, in which concentrations are expressed in terms of mass of solvent (mOsmol/kg or mmol/kg).

When both the solution and the solvent are liquids, as in alcohol solutions, the concentration of such a solution is frequently expressed in terms of volume per volume (vol/vol). By adding 70 mL of alcohol to a flask and mixing it to 100 mL with water, a solution whose concentration is 700 mL/L would be achieved. The expression "700 mL/L" is preferred to the alternatives of 70 volumes percent and 70% (vol/vol).

The following equations define the expression of concentrations:

$$\text{Mole} = \frac{\text{mass (g)}}{\text{gram molecular weight (g)}}$$

$$\text{Molarity of a solution} = \frac{\text{number of moles of solute}}{\text{number of liters of solution}}$$

$$\text{Molarity of a solution} = \frac{\text{number of moles of solute}}{\text{number of kilograms of solvent}}$$

$$\text{Normality of a solution} = \frac{\text{number of gram equivalents of solute}}{\text{number of liters of solution}}$$

$$\text{Gram equivalent weight (as oxidant or reductant)} = \frac{\text{formula weight (g)}}{\text{difference in oxidation state}}$$

For example, using these equations, a 1 molar solution of H_2SO_4 contains 98.08 g H_2SO_4 per liter of solution. (Note: The symbol M, to denote molarity, is no longer acceptable and has been replaced by mol/L.) A molal solution contains 1 mol of solute in 1 kg of solvent. Molality is properly expressed as mol/kg.

In the past, milliequivalent (mEq) was used to express the concentration of electrolytes in plasma. Now, the recommended unit for expressing the concentration of an electrolyte in plasma is millimoles per liter (mmol/L). For example, if a sample contains 322 mg of Na per liter, the molar concentration of Na is:

$$\text{mmol/L} = \frac{\text{mg/L}}{\text{mg molecular mass}} = \frac{322 \times 10 \times 1}{23} = 140 \text{ mmol/L}$$

In clinical laboratory practice, a titer is thought of as the lowest dilution at which a particular reaction takes place. Titer is customarily expressed as a ratio, for example, 1:10, or 1 to 10.

Regarding gases in solution, Henry's law states that the solubility of a gas in a liquid is directly proportional to the pressure of the gas above the liquid at equilibrium. Thus as the pressure of a gas is doubled, its solubility is also doubled. The relationship between pressure and solubility varies with the nature of the gas. When several gases are dissolved at the same time in a single solvent, the solubility of each gas is proportional to its partial pressure in the mixture. The solubility of most gases in liquids decreases with an increase in temperature, and boiling a liquid frequently drives out all dissolved gases. Traditionally the unit used to describe the concentration of gases in liquids has been percent by volume (vol/vol). Using the SI, gas concentrations are expressed in moles per cubic meter (mol/m^3).

Units of Measurement

A meaningful measurement is expressed with both a number and a unit. The unit identifies the dimension—mass, volume, or concentration—of a measured property. The number indicates how many units are contained in the property.

Traditionally, measurements in the clinical laboratory have been made in metric units. In the early development of the **metric system**, units were referenced to length, mass, and time. The first absolute systems were based on the centimeter, gram, and second (CGS), and then on the meter, kilogram, and second (MKS). The SI is a different system that was accepted internationally in 1960. The units of the system are called SI units.

International System of Units

Base, derived, and supplemental units are the three classes of SI units.[13] The eight fundamental base units are listed in Table 8-1. A derived unit is derived mathematically from two or more base units (Table 8-2). A supplemental unit is a unit

TABLE 8-1 Système Internationale d'Unités (SI) Base Units

Quantity	Name	Symbol
Length	meter	m
Mass	kilogram	kg
Time	second	s
Electrical current	ampere	A
Thermodynamic temperature	kelvin	K
Amount of substance	mole	mol
Luminous intensity	candela	cd
Catalytic amount	katal	Kat

TABLE 8-2 Examples of SI-Derived Units Important in Clinical Medicine, Expressed in Terms of Base Units

Quantity	Name	SI Symbol	Expression in Terms of Other SI Units	Expression in Terms of SI Base Units
Volume	cubic meter	m^3		m^3
Mass density	kilogram per cubic meter	kg/m^3		kg/m^3
Concentration of amount of substance	mole per cubic meter	mol/m^3		mol/m^3
Frequency	hertz	Hz		s^{-1}
Force	newton	N		$m \cdot kg \cdot s^{-2}$
Pressure	pascal	Pa	N/m^2	$m^{-1} \cdot kg \cdot s^{-2}$
Energy, work, quantity of heat	joule	J	$N \cdot m$	$m^2 \cdot kg \cdot s^{-2}$
Power	watt	W	J/s	$m^2 \cdot kg \cdot s^{-3}$
Electrical potential, potential difference, electromotive force	volt	V	$W \cdot A^{-1}$	$m^2 \cdot kg \cdot s^{-3} \cdot A^{-1}$

SI, Système Internationale d'Unités.

that conforms to the SI but has not been classified as base or derived. At present only the radian (for plane angles) and the steradian (for solid angles) are classified this way.

The Conférence Générales des Poids et Mésures (CGPM) recognizes that some units outside the SI continue to be important and useful in particular applications. An example is the liter as the reference volume in clinical analyses. Liter is the name of the submultiple (cubic decimeter) of the SI unit of volume, the cubic meter. Considering that 1 cubic meter represents some 200 times the blood volume of an adult human, the SI unit of volume is neither a convenient nor a reasonable reference volume in a clinical context. The minute, hour, and day have had such long-standing use in everyday life that it is unlikely that SI units derived from the second will supplant them. Some other non-SI units are still accepted; although they are rarely used by most individuals in their daily lives, they have been very important in some specialized fields. Details of the SI system are found in an expanded version of this chapter.[9]

TABLE 8-3 Metric Prefixes of SI Units*

Factor	Prefix	Symbol	Factor	Prefix	Symbol
10^{24}	yotta	Y	10^{-1}	deci	d
10^{21}	zetta	Z	10^{-2}	centi	c
10^{18}	exa	E	10^{-3}	milli	m
10^{15}	peta	P	10^{-6}	micro	μ
10^{12}	tera	T	10^{-9}	nano	n
10^{9}	giga	G	10^{-12}	pico	p
10^{6}	mega	M	10^{-15}	femto	f
10^{3}	kilo	k	10^{-18}	atto	a

SI, Système Internationale d'Unités.
*The Eleventh Conférence Générale des Poids et Mésures (CGPM) (1960, Resolution 12) adopted a first series of prefixes and symbols of prefixes to form the names and symbols of the decimal multiples and submultiples of SI units. Prefixes for 10^{-15} and 10^{-18} were added by the Twelfth CGPM (1964, Resolution 8) and those for 10^{15} and 10^{18} by the Fifteenth CGPM (1975, Resolution 10); those for 10^{21}, 10^{24}, and 10^{-24} were proposed by the Comité International des Poids et Mesures CIPM (1990) for approval by the Nineteenth CGPM (1991).
†Outside the United States, the spelling "deca" is used extensively.
From The International System of Units (SI). Washington, DC: National Institute of Standards and Technology, 1991.

Decimal Multiples and Submultiples

In practical application of units, certain values are too large or too small to be expressed conveniently. Numerical values are brought to convenient size when the unit is appropriately modified by official prefixes (Table 8-3).

Applications of SI in Laboratory Medicine

Many international clinical laboratory organizations and national professional societies have accepted the SI unit in its broad application. The United States is one of the few countries that have yet to accept SI units. A comparison of results of some of the commonly measured serum constituents, at a concentration found in healthy individuals, is shown in Table 8-4.

Standardized Reporting of Test Results

To describe test results properly, it is important that all necessary information be included in the test description. Systems developed for expressing the results produced by the clinical laboratory include the Logical Observation Identifier Names and Codes (LOINC) system and the International Federation of Clinical Chemistry/International Union of Pure and Applied Chemistry (IFCC/IUPAC) system.[10]

LOINC System

The LOINC system is a universal coding system for reporting laboratory and other clinical observations to facilitate electronic transmission of laboratory data within and between institutions (http://loinc.org/; accessed on July 22, 2013).[10]

TABLE 8-4 Typical Values for Analytes and Reporting Increments

	Conventional Units	Recommended Units	Rounded Recommended Units	Smallest Recommended Reporting Increment
Albumin	3.8 g/dL	550.6 μmol/L	550.0 μmol/L	10.0 μmol/L
Bilirubin	0.2 mg/dL	3.42 μmol/L	3 μmol/L	2 μmol/L
Calcium	9.8 mg/dL	2.45 mmol/L	2.45 mmol/L	0.02 mmol/L
Cholesterol	200 mg/dL	5.17 mmol/L	5.2 mmol/L	0.05 mmol/L
Creatinine	0.8 mg/dL	90.48 μmol/L	90 mmol/L	10 μmol/L
Glucose	90 mg/dL	5.00 mmol/L	5.0 mmol/L	0.1 mmol/L
Phosphorus	3.0 mg/dL	0.97 mmol/L	1.0 mmol/L	0.05 mmol/L
Thyroxine	7.0 μg/dL	90.09 nmol/L	90 nmol/L	10 nmol/L
Triglycerides	100 mg/dL	1.14 mmol/L	1.15 mmol/L	0.05 mmol/L
Urea nitrogen*	10 mg/dL	3.57 mmol/L	3.5 mmol/L	0.05 mmol/L
Uric acid	5.0 mg/dL	297 μmol/L	300 μmol/L	10 μmol/L

*Urea nitrogen is reported as urea (mmol/L) when SI units are used.
SI, Système Internationale d'Unités.

These codes are intended to be used in context with existing standards, such as ASTM E1238 (American Society for Testing and Materials), HL7 version 2.2 (Health Level Seven; http://www.hl7.org/; accessed July 22, 2013), and the Systematized Nomenclature of Medicine, Reference Technology (SNOMED-RT). A similar standard, known as CEN ENV 1613, is being developed by the European Committee for Standardization of the Comité Européen de Normalisation (CEN) Technical Committee 251 (http://www.cen.eu; accessed July 22, 2013).

The LOINC database currently carries records for more than 30,000 observations.[10] For each observation, (1) a code, (2) a long formal name, (3) a short 30-character name, and (4) synonyms are listed. A mapping program termed "Regenstrief LOINC Mapping Assistant" (RELMA) is available to map local test codes to LOINC codes and to facilitate searching of the LOINC database. Both LOINC and RELMA are available at no cost from http://loinc.org/ (accessed July 22, 2013).

IFCC/IUPAC System

The IFCC/IUPAC system known as the NPU (Nomenclature, Properties, and Units) recommends that the following items be included with each test result:

1. The name of the system or its abbreviation
2. A dash (two hyphens)
3. The name of the analyte (never abbreviated) with an initial capital letter
4. A comma
5. The quantity name or its abbreviation
6. An equals sign
7. The numerical value and the unit or its abbreviation

Application

On April 1, 2009, the owners of LOINC, NPU, and SNOMED CT began an operational trial of prospective divisions of labor in the generation of laboratory test terminology content. It is expected this trial will provide practical experience and important information on opportunities to decrease duplication of effort in the development of laboratory test terminology and to ensure that SNOMED CT works effectively in combination with either LOINC or NPU.

Chemicals

The quality of the analytical results produced by the laboratory is a direct indication of the purity of the chemicals used as analytical **reagents**. The availability and quality of the reference materials used to calibrate assays and to monitor their analytical performance also are important.

Laboratory chemicals are available in a variety of grades. The solutes and solvents used in analytical work are reagent grade chemicals, among which water is a solvent of primary importance.

Reagent Grade Water

The preparation of many reagents and solutions used in the clinical laboratory requires "pure" water. Single-distilled water fails to meet the specifications for Clinical Laboratory Reagent Water (CLRW) established by the **Clinical Laboratory and Standards Institute (CLSI)**.[7] Because the term "deionized water" and the term "distilled water" describe preparation techniques, they should be replaced by "reagent grade water," followed by the designation of CLRW, which better defines the specifications of the water and is independent of the method of preparation (Table 8-5).

Preparation of Reagent Grade Water

The following sections describe processes used to prepare reagent grade water. In practice, water is filtered before any of these processes are used.

Distillation

Distillation is the process of vaporizing and condensing a liquid to purify or concentrate a substance or to separate a volatile substance from less volatile substances. However, water

TABLE 8-5 CLSI Specifications for Reagent Water

	CLRW
Microbiological content,* colony-forming units per mL, cfu/mL (maximum)	<10
pH	NA
Resistivity,† MΩ · centimeter (MΩ·cm), 25 °C	≥10 (in line)
Particulate matter‡‡	Water passed through 0.22-µm filter
Organics ‡	Total Organic Content (TOC) <500 ng/g

*The microbiological content of viable organisms, as determined by total colony count after incubation at 36 ± 1 °C for 14 hours, followed by 48 hours at 25 ± 1 °C, and reported as colony-forming units per mL (cfu/mL).

†Specific resistance or resistivity. The electrical resistance in ohms measured between opposite faces of a 1-cm cube of an aqueous solution at a specified temperature. For these specifications, the resistivity will be corrected for 25 °C and reported in MΩ-cm. The greater the quantity of ionizable materials, the lower the resistivity, and the higher the conductivity.

‡When water is passed through a membrane filter with a mean pore size of 0.22 µm, it is considered to be free of particulate matter. When water is passed through a bed of activated carbon, it is considered to contain minimum organic material.

CLRW, Clinical Laboratory Reagent Water; CLSI, Clinical Laboratory Standards Institute; NA, not applicable.

From Clinical Laboratory Standards Institute (CLSI): Preparation and testing of reagent water in the clinical laboratory, 4th edition. CLSI Document C3-A4-AMD (new document code GP40-A4-AMD). Wayne, Pa: CLSI, 2006.

treated by distillation alone does not meet the specific conductivity requirement of type I water.

Ion Exchange

Ion exchange is a process that removes ions to produce mineral-free deionized water. Such water is most conveniently prepared using commercial equipment. In practice, a single-bed deionizer generally is capable of producing water that has a specific resistance in excess of 1 MΩ·cm. When connected in series, mixed-bed deionizers usually produce water with a specific resistance that exceeds 10 MΩ·cm.

Reverse Osmosis

Reverse osmosis is the process by which water is forced through a semipermeable membrane that acts as a molecular filter. The membrane removes 95% to 99% of organic compounds, bacteria, and other particulate matter and 90% to 97% of all ionized and dissolved minerals but fewer of the gaseous impurities. Although the process is inadequate for producing reagent grade water for the laboratory, it may be used as a preliminary purification method.

Ultraviolet Oxidation

Ultraviolet oxidation is another method that is used as part of a total system. The use of ultraviolet radiation at the biocidal wavelength of 254 nanometers eliminates many bacteria and cleaves many ionizing organics that are then removed by deionization.

Types of Purified Water

Other types of purified water used in the clinical laboratory are defined by the purpose.[7] These types are:

- Special reagent water
- Instrument feed water
- Water supplied by a method manufacturer for use as a diluent or reagent
- Commercially bottled, purified water
- Autoclave and wash water applications

Testing for Water Purity

At a minimum, water should be tested for (1) microbiological content, (2) organic impurities, (3) resistivity, and (4) particulate and colloid content.[7] Once the type of water is validated as fit for its purpose, the frequency of the maintenance of the system should occur no less than manufacturer's recommendations.

Reagent Grade or Analytical Reagent Grade (AR) Chemicals

Chemicals that meet the specifications of the American Chemical Society (ACS) are described as reagent or analytical reagent grade. These specifications have also become the de facto standards for chemicals used in many high-purity applications. They are available in two forms: (1) lot-analyzed reagents, in which each individual lot is analyzed and the actual amount of impurity reported, and (2) maximum impurities reagents, for which maximum impurities are listed. The Committee on Analytical Reagents of the ACS periodically publishes "Reagent Chemicals" listing specifications (http://pubs.acs.org/reagents/index.html; accessed July 22, 2013). These reagent grade chemicals are of very high purity and are recommended for quantitative or qualitative analyses.

Ultrapure Reagents

Many analytical techniques require reagents whose purity exceeds the specifications of those described previously. No uniform designation is used for these chemicals and organic solvents. Terms such as "spectrograde," "nanograde," and "HPLC pure" have been used. Data of interest to the user (e.g., absorbance at a specific ultraviolet [UV] wavelength) are supplied with the reagent.

Reference Materials

A reference material is a material or substance, one or more physical or chemical properties of which are sufficiently well established for it to be used for (1) calibration of instruments, (2) validation of methods, (3) assignment of values to materials, and (4) evaluation of the comparability of results. Reference materials also are of prime importance in establishing metrological transferability (http://www.bipm.org/; accessed July 22, 2013), a term defined as "the property of a measurement result whereby the result is related to a reference through a documented unbroken chain of calibrations, each contributing to the measurement uncertainty."

Primary, secondary, standard, and certified are types of reference materials.

Primary Reference Materials

Primary reference materials are highly purified chemicals that are directly weighed or measured to produce a solution whose concentration is exactly known. The IUPAC has proposed a degree of 99.98% purity for primary reference materials. These highly purified chemicals may be weighed out directly for the preparation of solutions of selected concentration or for the calibration of solutions of unknown strength. They are supplied with a certificate of analysis for each lot.

Secondary Reference Materials

Secondary reference materials are solutions whose concentrations cannot be prepared by weighing the solute and dissolving a known amount into a volume of solution. The concentration of secondary reference materials is typically determined by analysis of an aliquot of the solution by an acceptable reference method, using a primary reference material to calibrate the method.

Standard Reference Materials (SRMs)

Standard Reference Materials (SRMs) for clinical and molecular laboratories are available from the National Institute of Standards and Technology (NIST; http://ts.nist.gov/; accessed July 22, 2013). Cholesterol, the first SRM developed by the NIST, was issued in 1967. It should be noted that not all standard reference materials have the properties and the degree of

TABLE 8-6 Standard Reference Materials (SRMs)—Pure Crystalline Standards

SRM Number	Analyte
998	Angiotensin 1 (human)
916a	Bilirubin
915b	Calcium carbonate
911c	Cholesterol
921	Cortisol (hydroxycortisone)
914a	Creatinine
917b	d-Glucose (dextrose)
920	d-Mannitol
937	Iron metal (clinical)
928	Lead nitrate
924a	Lithium carbonate
929a	Magnesium gluconate dihydrate
918b	Potassium chloride
919b	Sodium chloride
1595	Tripalmitin
912a	Urea
913a	Uric acid
925	VMA (4-hydroxy-3-methoxy-dl-mandelic acid)
8327	Peptide reference materials (for molecular mass and purity measurements)

From Montgomery RR. NIST standard reference materials catalog, 2012. Washington, DC: National Institute for Standards and Technology, July 23, 2013; and Lo SF. Principles of basic techniques and laboratory safety. In: Burtis CA, Ashwood ER, eds. Tietz textbook of clinical chemistry, 5th edition. Philadelphia: WB Saunders, 2012:207-31.

purity specified for a primary standard, but each has been well characterized for certain chemical or physical properties and is issued with a certificate that gives the results of the characterization. These details may then be used to characterize other materials.

Examples of SRMs available from the NIST for use in clinical and molecular diagnostics laboratories include (1) pure crystalline standards, (2) human-based standards, (3) animal blood standards, (4) standards containing drugs of abuse in urine and human hair, and (5) SRMs used for DNA profiling/crime scene investigations. For example, compounds available as pure crystalline standards are listed in Table 8-6. Other compounds are found in the SRM catalog (Montgomery RR. NIST standard reference materials catalog, 2013. Washington, DC, National Institute for Science and Technology, November 6, 2012).[9]

Certified Reference Materials (CRMs)

Certified reference materials (CRMs) are available for clinical and molecular laboratories from the Institute for Reference Materials and Measurements (IRMM) in Geel, Belgium (http://www.irmm.jrc.be/; accessed July 22, 2013). The IRMM is one of seven institutes of the Joint Research Centre (JRC), a Directorate-General of the European Commission (EC). Other acronyms used to label IRMM reference materials include ERM (European Reference Materials), BCR (Community Bureau of Reference of the Commission of the European Communities), and IFCC (International Federation of Clinical Chemistry). Examples of available IRMM standards are listed in Table 8-7 and are described in Reference 1. Reference materials also are available from the World Health Organization (WHO; http://www.who.int/biologicals Accessed July 22, 2013. http://ts.nist.gov/; accessed October 17).

TABLE 8-7 Reference Materials Available from the Institute for Reference Materials and Measurements

Number	Description
BCR-304	Lyophilized Human Serum
BCR-573; 574; &575	Creatinine in Human Serum
IRMM-468 &469	Thyroxine (T_4) and Triiodothyronine (T_3), two concentrations each
ERM-DA451/IFCC	Cortisol Reference Panel of Fresh Frozen Human Serum
ERM-DA192 &193	Cortisol in Human Serum
BCR-348R & BCR-DA347	Progesterone in Human Serum
BCR-576; 577; &578	17-β-Estradiol in Human Serum
ERM-CE-194; 195; &196	Pb and Cd in Lyophilized Bovine Blood
BCR-634; 635; &636	Pb and Cd in Lyophilized Human Blood
BCR-637; 638; &639	Al, Se, and Zn in Human Serum
BCR-393	Lyophilized APO A1 from Human Serum
BCR-457	Human Thyroglobin (Tg)
BCR-486	Purified Alpha Fetoprotein (AFP)
BCR-613	Prostate-Specific Antigen (PSA) in the Reconstituted Material
BCR-405	Glycated Hemoglobin (HbA_{1c}) in Human Hemolysate
ERM-DA470k	Human Serum Proteins
ERM-DA472/IFCC	C-Reactive Protein (CRP)
BCR-522	Hemiglobincyanide (HCN) in Bovine Blood Lysate
IRMM/IFCC-466 &467	Hemoglobin Isolated from Whole Blood
BCR-410	Prostatic Acid Phosphatase from Human Prostate
BCR-647	Human Adenosine Deaminase (ADA1) from Human Erythrocytes
BCR-693	Human Pancreatic Lipase from Pancreatic Juice
BCR-6974	Human Pancreatic Lipase (Recombinant)
ERM-AD452/IFCC	γ-Glutamyltransferase from Pig Kidney
ERM-AD453/IFCC	Human Lactate Dehydrogenase Isoenzyme 1
ERM-AD454/IFCC	Alanine Aminotransferase from Pig Heart
ERM-AD455/IFCC	Creatine Kinase (CK-MB) from Human Heart
IRMM/IFCC-456	Human Pancreatic α-Amylase
ERM-AD457/IFCC	Aspartate Transaminase (AST)

Basic Techniques and Procedures

Basic practices used in the clinical and molecular diagnostic laboratories include (1) optical, (2) chromatographic, (3) electrochemical, (4) electrophoretic, (5) mass spectrometric, (6) enzymatic, and (7) immunoassay techniques. These techniques are discussed in detail in Chapters 9 through 15. Here we discuss the basic techniques of (1) volumetric sampling and dispensing, (2) centrifugation, (3) gravimetry, (4) thermometry, (5) control of hydrogen ion concentration, and (6) use of procedures for processing solutions.

Volumetric Sampling and Dispensing

Analytical procedures require accurate volumetric measurements to ensure accurate results. For accurate work, only Class A glassware should be used. Class A glassware is certified to conform to the specifications outlined in NIST Circular C-602.

Pipettes

Pipettes are used for the transfer of a volume of liquid from one container to another. They are designed (1) to contain (TC) a specific volume of liquid or (2) to deliver (TD) a specified volume. Pipettes used in clinical, molecular diagnostic, and analytical laboratories include (1) manual transfer and measuring pipettes, (2) micropipettes, and (3) electronic and mechanical pipetting devices. Developments in improved design of pipetting systems include robotic automation, the capability to provide electronic and personal computer (PC) control of pipetting devices, and careful attention to advanced **ergonomic** design features. Automatic photometric pipette calibration systems are also available that reduce the time required to periodically check pipettes and potentially provide more efficient use of personnel.

Transfer and Measuring Pipettes

A transfer pipette is designed to transfer a known volume of liquid. Measuring and serological pipettes are scored in units such that any volume up to a maximum capacity can be delivered.

Transfer Pipettes. Transfer pipettes include both volumetric and Ostwald-Folin pipettes (Figure 8-1). They consist of a cylindrical bulb joined at both ends to narrower glass tubing. A calibration mark is etched around the upper suction tube, and the lower delivery tube is drawn out to a gradual taper.

A volumetric transfer pipette (Figure 8-1, A) is calibrated to deliver accurately a fixed volume of a dilute aqueous solution.

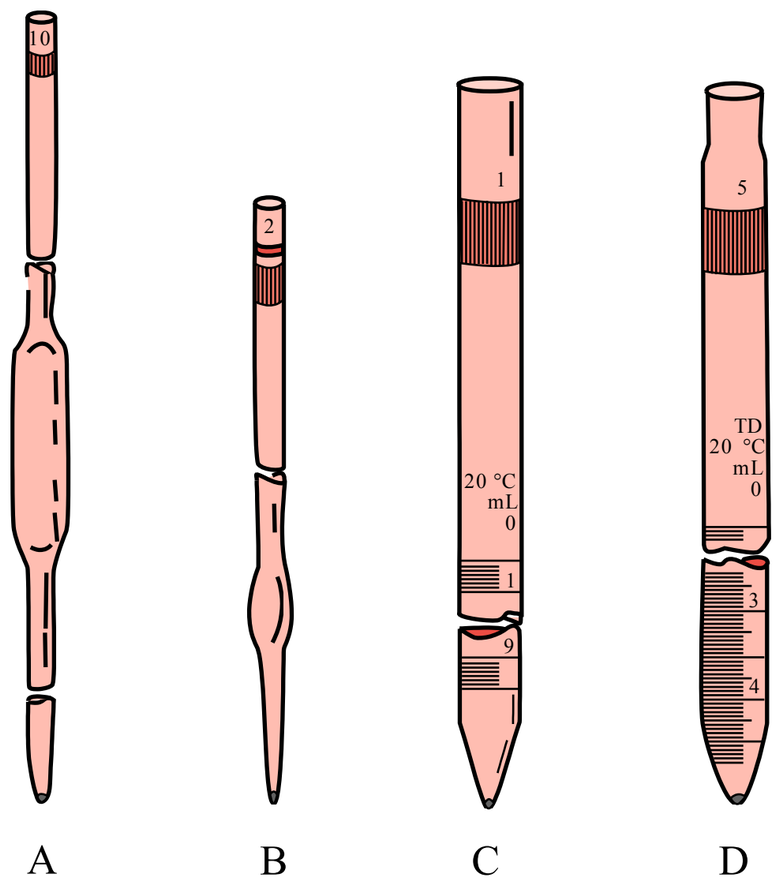

Figure 8-1 Pipettes. A, Volumetric (transfer). B, Ostwald-Folin (transfer). C, Mohr (measuring). D, Serological (graduated to the tip).

Ostwald-Folin pipettes (Figure 8-1, B) are similar to volumetric pipettes but have their bulb closer to the delivery tip and are used for the accurate measurement of viscous fluids, such as blood or serum. In contrast to a volumetric pipette, an Ostwald-Folin pipette has an etched ring near the mouthpiece, indicating that it is a blow-out pipette. With the use of a pipetting bulb, the liquid is blown out of the pipette only after the blood or serum has drained to the last drop in the delivery tip. When filled with opaque fluids, such as blood, the top of the meniscus is read. Controlled slow drainage is required with all viscous solutions so that no residual film is left on the walls of the pipette.

Measuring Pipettes. The second principal type of pipette is the graduated or measuring pipette (Figure 8-1, C). This is a piece of glass tubing that is drawn out to a tip and is graduated uniformly along its length. Two kinds are available. The Mohr pipette is calibrated between two marks on the stem, whereas the serological pipette has graduated marks down to the tip. The serological pipette (Figure 8-1, D) must be blown out to deliver the entire volume of the pipette and has an etched ring (or pair of rings) near the bulb end of the pipette signifying that it is a blow-out pipette. Mohr pipettes require controlled delivery of the solution between the calibration marks. Serological pipettes have a larger orifice than do Mohr pipettes and thus drain faster. In practice, measuring pipettes are principally used for the measurement of reagents and generally are not considered sufficiently accurate for measuring samples and calibrators.

Pipetting Technique

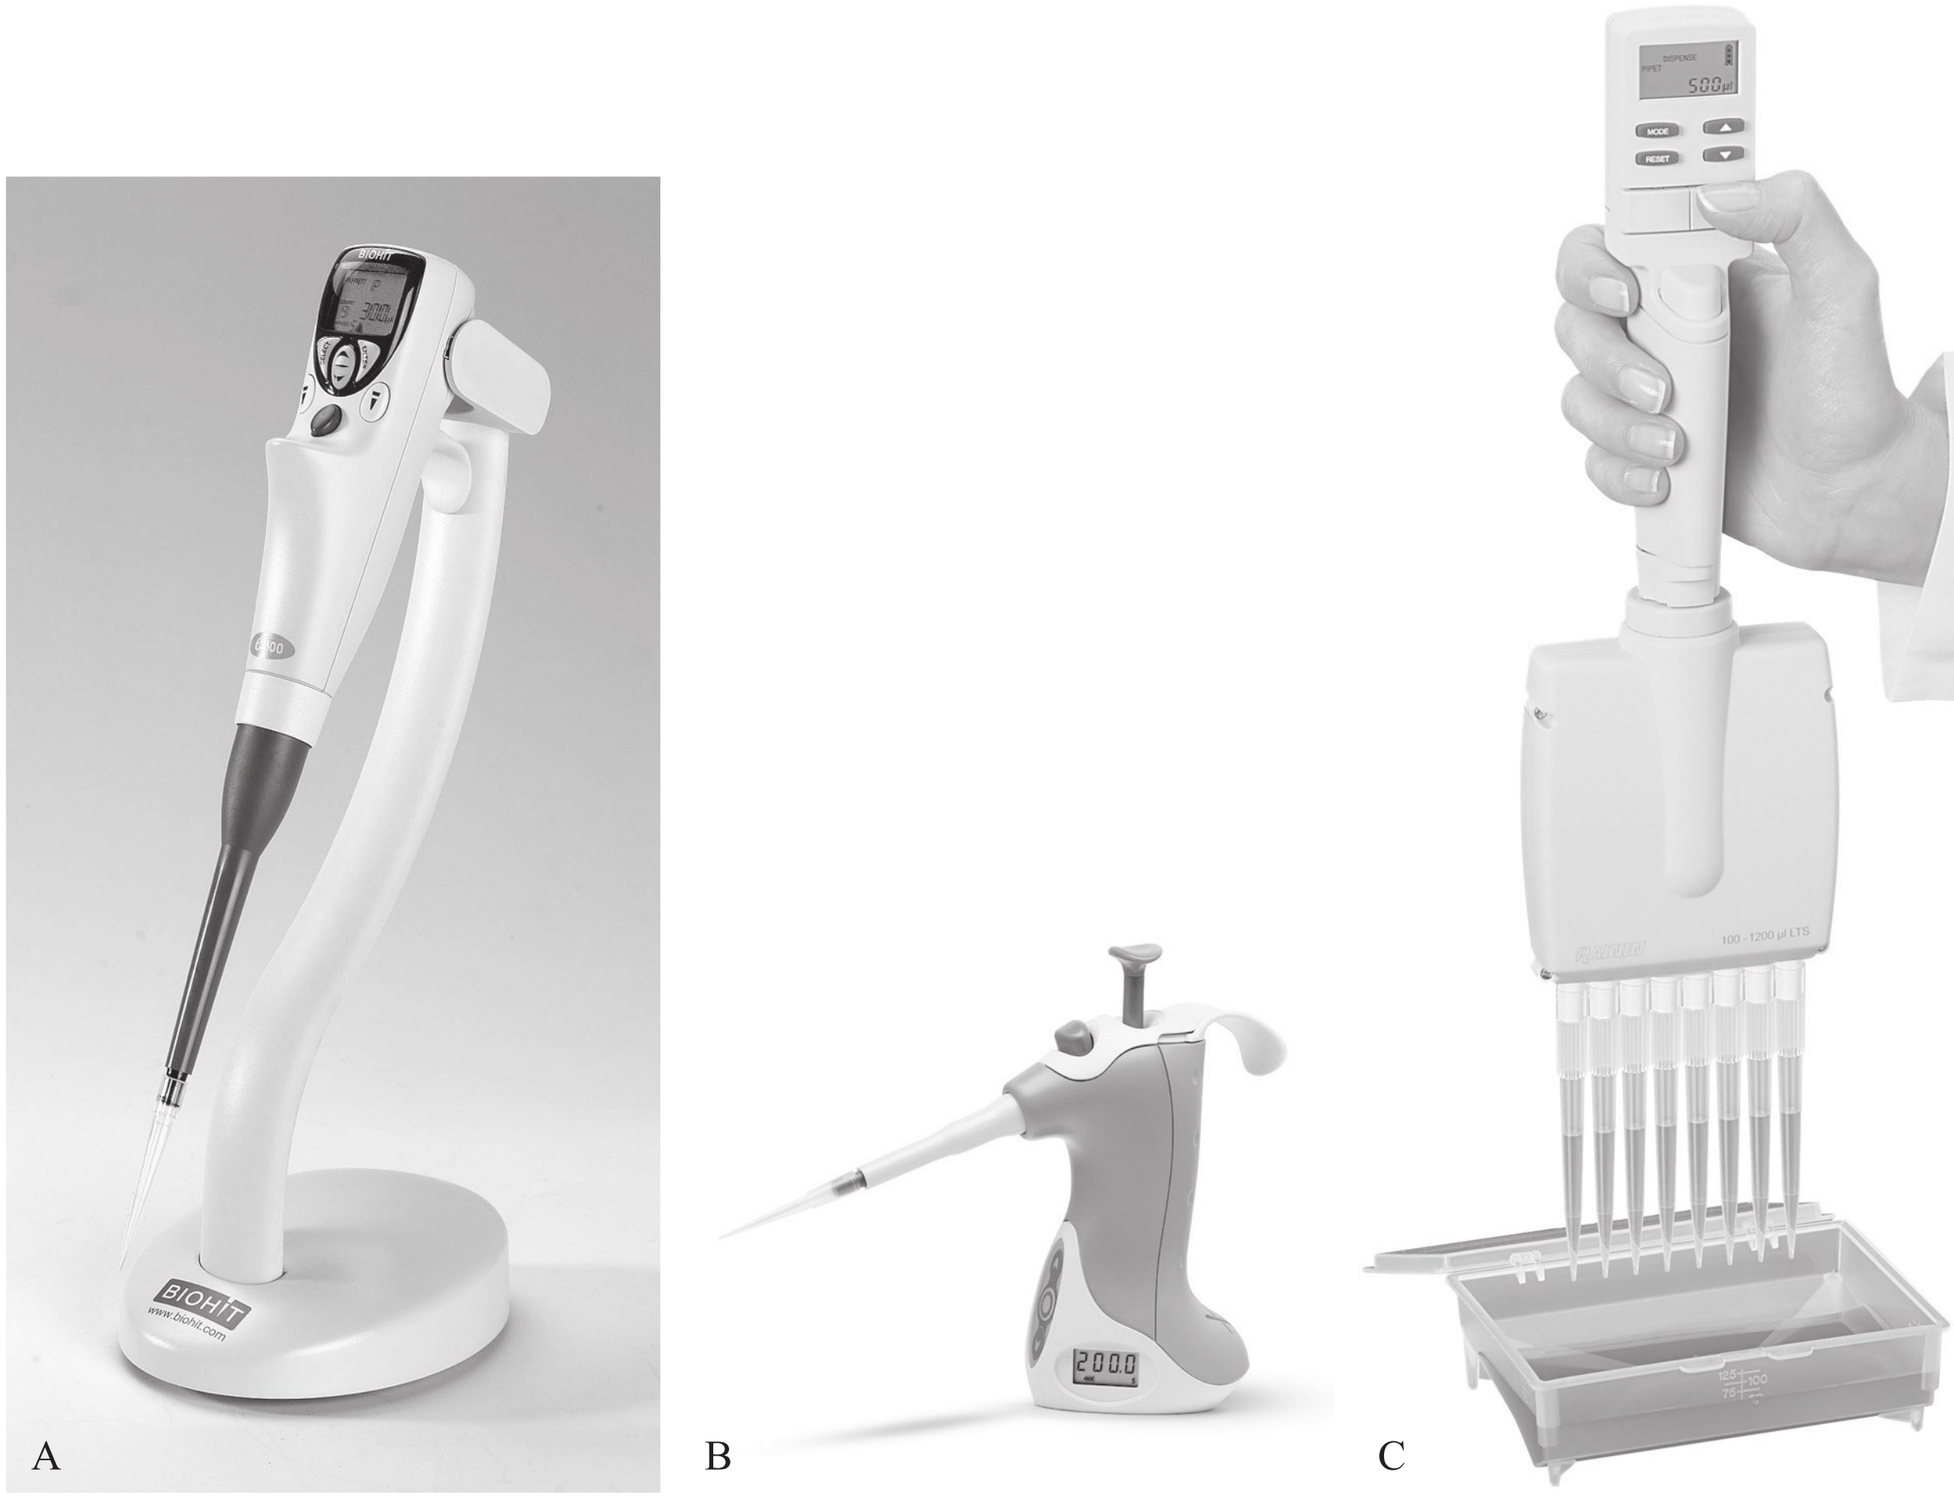
General pipetting techniques apply to the pipettes described previously. For example, pipetting bulbs should always be used, and pipettes must be held in a vertical position when the liquid level is adjusted to the calibration line and during delivery. When it is sighted at eye level, the lowest part of the meniscus should be level with the calibration line on the pipette. The flow of the liquid should be unrestricted when volumetric pipettes are used, and the tips should be touched to the inclined surface of the receiving container for 2 s after the liquid has ceased to flow.

With graduated pipettes, the flow of liquid may have to be slowed during delivery. Serological pipettes are calibrated to the tip, and the etched glass ring on top of the pipette signifies that it is to be blown out. First, the pipette is allowed to drain, and then the remaining liquid is blown out with a pipetting bulb.

Micropipettes

Micropipettes are pipettes that are used for the measurement of microliter volumes. With such devices, the remaining volume that coats the inner wall of a pipette causes notable error. For this reason, most micropipettes are calibrated TC the stated volume rather than TD it. Proper use requires rinsing of the pipette with the final solution after the contents have been delivered into the diluent. Volumes are expressed in microliters (μL); the older term lambda is no longer recommended. (One lambda [λ] = 1 μL = 0.001 mL.)

Micropipettes are generally available in small sizes, ranging from 0.2 to 500 µL.



Semiautomatic and Automatic Pipettes and Dispensers

Figure 8-2, A and B, illustrates two types of adjustable micropipetting devices that demonstrate unique ergonomic design features. These devices are programmable and are used to simultaneously dispense aliquots of liquid into multiple wells. In practice, with the use of disposable plastic tips, they allow simultaneous aspiration and delivery of solutions to multiple sample micro wells. Each channel is piston driven to allow the user to pipette with as few or as many tips as necessary. Aliquots of liquid as small as 0.2 µL are dispensed at three different aspiration or dispense rates.

Semiautomatic manual and electronic versions of pipettes and dispensers are available in sizes from 0.5 µL to 10 mL. Figure 8-2, C, illustrates an electronically operated, positive-displacement multichannel pipettor. This device aspirates and dispenses its predefined volumes (from 0.5 to 200 µL) when its plunger is moved through a complete cycle. Its disposable fluid containment tips are made of a plastic material that tends to retain less inner surface film than does glass. Such pipettes (1) avoid the risk of cross contamination among samples, (2) eliminate the necessity for washing between samples, and (3) improve the precision of measurements. Models that allow for digital adjustment of the volumes aspirated and dispensed are available.

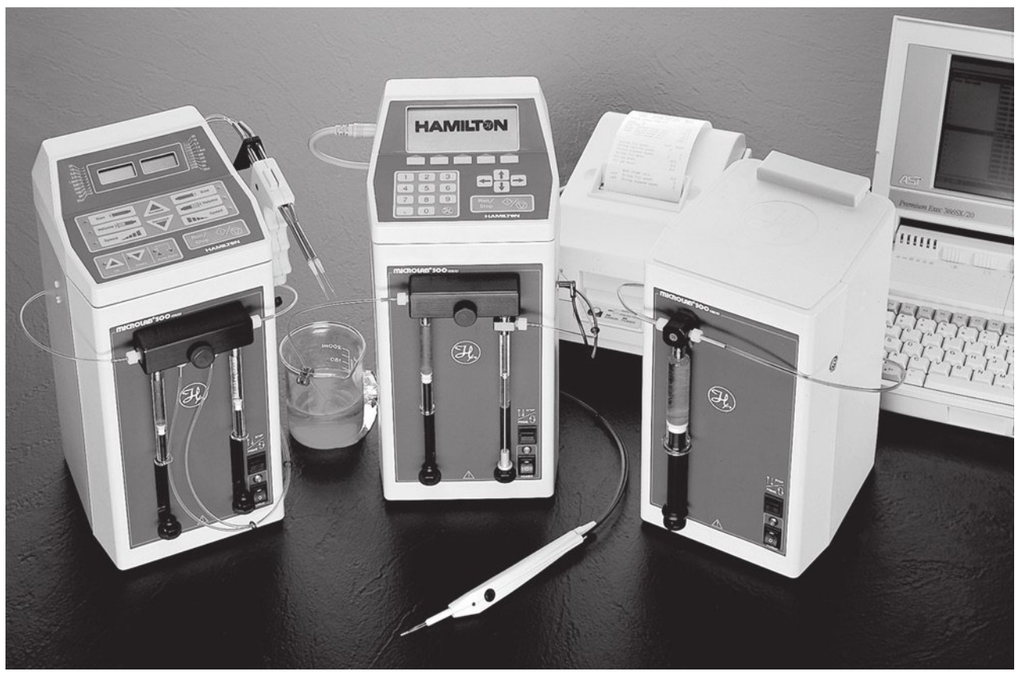


Figure 8-3, A, shows an automatic dispensing apparatus that aspirates and dispenses preset volumes of two different liquids by means of two motor-driven syringes—one for metering a volume of the sample and one for metering a volume of the diluent. It is possible to adjust this device to aspirate as little as 1 µL of one liquid and to deliver it with as much as 999 µL of the other. This type of device, available as a dilutor or a dispenser, is obtainable as a (1) manual, (2) electronic, or (3) computer-controlled device. The latter is microprocessor controlled and is easily programmed. Twenty-one dispensing programs are stored in memory and retrieved.

A more versatile piece of equipment is the robotic liquid handling workstation shown in Figure 8-3, B. This automated pipetting station is used with individual reaction tubes and with 96- and 384-well microtiter plates. Depending on the

design of the system, a single probe or multiple probes may be used rapidly to transfer programmed volumes of solution from one container to a multiple of chambers in one microtiter plate. For example, with a 96-well plate, up to 96 aliquots are transferred to all 96 wells in 1 minute. With some systems, liquid sensing is incorporated into the sample probes to minimize contact with sample and reagents, even though automatic washing of the probes is performed between specimens. Two-dimensional (X-Y) movement of probes and tubes or microtiter plates is built into the pipetting stations to minimize the necessity for operator intervention. T is device dispenses programmed volumes from 0.5 µL to 1000 µL in serial dilutions from 4 to 16 channels employing an autoloaded system with bar codes for positive identif cation.

Volumetric Flasks

Volumetric flasks (Figure 8-4) are used to measure exact volumes; they are commonly found in sizes ranging from 1 to 4000 mL. In practice, they are used primarily to prepare solutions of known concentration, and they are available in various grades. T e most accurate are certif ed to meet standards set forth by the NIST.

An important factor in the use of a volumetric apparatus is the requirement for an accurate adjustment of the meniscus. A small card that is half black and half white is most useful. T e card is placed 1 cm behind the apparatus with the white half uppermost and the top of the black area about 1 mm below the meniscus. T e meniscus then appears as a clearly def ned, thin black line. T is device is also useful in reading the meniscus of a burette.

Volumetric equipment should be used with solutions equilibrated to room temperature. Solutions diluted in volumetric flasks should be repeatedly mixed during dilution so that the

A B

Figure 8-4 Volumetric flasks. A, Macro. B, Micro.

contents are homogeneous before the solution is made up to final volume. Errors caused by expansion or contraction of liquids on mixing are thereby minimized.

Volumetric flasks should be thoroughly cleaned and dried before calibration. The flask is then weighed and filled with carbon dioxide–free deionized water until just above the graduation mark. The neck of the flask just above the water level should be kept free of water. The meniscus mark is set at the graduation line by removing excess water, and the flask is reweighed. The final weight is corrected for the equilibrated water and the air temperature to obtain the volume of the flask.

Centrifugation

Centrifugation is the process of using centrifugal force to separate the lighter portions of a solution, mixture, or suspension from the heavier portions. A centrifuge is a device by which centrifugation is effected.

In the clinical laboratory, centrifugation is used to:

1. Remove cellular elements from blood to obtain cell-free plasma or serum for analysis (see Chapter 6)
2. Concentrate cellular elements and other components of biological fluids for microscopic examination or chemical analysis
3. Remove chemically precipitated protein from an analytical specimen
4. Separate protein-bound or antibody-bound ligand from free ligand in immunochemical and other assays (see Chapter 15).
5. Extract solutes in biological fluids from aqueous to organic solvents
6. Separate lipid components such as chylomicrons from other components of plasma or serum, and lipoproteins from one another (see Chapter 23).

Types of Centrifuges

Types of centrifuges used in the clinical laboratory include (1) horizontal-head or swinging-bucket, (2) fixed-angle or angle-head, (3) ultracentrifuge, and (4) axial. Automatic balancing centrifuges are also available.

Principles of Centrifugation

The correct term to describe the force required to separate two phases in a centrifuge is relative centrifugal force **(RCF)**, also called relative centrifugal field. Units are expressed as number of times greater than gravity (e.g., 500 × g).

RCF is calculated as follows:

$$RCF = 1.118 \times 10^{-5} \times r \times rpm^2$$

where

1.118×10^{-5} = an empirical factor;

r = radius in centimeters from the center of rotation to the bottom of the tube in the rotor cavity or bucket during centrifugation; and

rpm = the speed of rotation of the rotor in revolutions per minute.

The RCF of a centrifuge may also be determined from a nomogram distributed by manufacturers of centrifuges. RCF is derived from the distance from the rotor center to the bottom of the tube, whether the tube is horizontal to, or at an angle to, the rotor center.

The time required to sediment particles depends on (1) rotor speed, (2) radius of the rotor, and (3) effective path length travelled by sedimented particles. Following is a useful formula for calculating the speed required of a rotor whose radius differs from the radius with which a prescribed RCF was originally defined:

$$\text{rpm (alternate rotor)} = 1000 \times \sqrt{\frac{\text{RCF, original rotor}}{11.18 \times r\ \text{(cm), alternate rotor}}}$$

The length of time for centrifugation is calculated so that running with an alternate rotor of a different size is equivalent to running with the original rotor:

$$\text{time (alternate rotor)} = \frac{\text{time} \times \text{RCF (original rotor)}}{\text{RCF (alternate rotor)}}$$

Operation of the Centrifuge

For proper operation of a centrifuge, only those tubes recommended by the manufacturer should be used. The material used for the tube must withstand the RCF to which the tube is expected to be subjected. Polypropylene tubes are generally capable of withstanding RCFs of up to 5000 × g. The tubes should have a tapered bottom, particularly if a supernatant is to be removed, and should be of an appropriate size to fit securely into the rack to be centrifuged. The top of the tube should not protrude so far above the bucket that the swing into a horizontal position is impeded by the rotor.

For smooth operation of the centrifuge, the rotor must be properly balanced. The weight of racks, tubes, and their contents on opposite sides of a rotor should not differ by more than 1% or by an acceptable limit established by the manufacturer. Tubes of collected blood should be centrifuged before they are unstoppered to reduce the probability that an aerosol will be produced when the tube is opened. The practice of using a wooden applicator to release a clot stuck to the top of the tube or to its stopper should be avoided; it is a potential cause of hemolysis. Centrifugation at an appropriate RCF usually ensures that the clot is released from the tube wall and is drawn to the bottom of the tube.

Despite years of experience with centrifuges, just a few specific recommendations have been put forth for RCF or time for centrifugation of blood specimens. For example, one tube manufacturer recommends for their non-gel tubes an RCF ≤1300 × g for 10 minutes, and for their gel tubes an RCF of 1000 to 1300 × g for 10 minutes in a swinging bucket or 15 minutes in a fixed-angle centrifuge (http://www.bd.com/vacutainer/faqs/#tubes. Accessed July 22, 2013). CLSI standard H18-A3[2] proposes an RCF of 1000 to 1200 × g for 10 ± 5 minutes. Standards have not been established for centrifugation of other specimens, such as serum to which a protein precipitant has been added.

Operating Practice

Cleanliness of a centrifuge is important in minimizing the possible spread of infectious agents, such as hepatitis viruses. With proper operation of a centrifuge, few tubes break. In case of breakage, the racks and chamber of the centrifuge must be carefully cleaned. Any spillage should be considered a possible bloodborne pathogen hazard. Gray dust arising from the sandblasting of the chamber by fragments of glass indicates tube breakage and possible contamination, necessitating cleaning of the chamber. Broken glass embedded in cushions of tube holders may be a continuing cause of breakage if cushions are not inspected and replaced in the cleanup procedure.

The speed of a centrifuge should be checked at least once every 6 months. The measured speed should not differ by more than 5% from the rated speed under specified conditions. All speeds at which the centrifuge is commonly operated should be checked. The centrifuge timer should be checked at least once every 6 months against a reference timer (such as a stopwatch) and should not be more than 10% in error. Commutators and brushes should be checked at least every 6 months. Brushes (where used) should be replaced when they show considerable wear. However, in many modern induction-drive motors, brushes have been eliminated, thus removing a source of dust that causes motor failure.

Because centrifuges generate heat, the temperature in the chamber in many centrifuge models may increase by as much as 5 °C after a single run. When the material to be centrifuged has a labile temperature, a refrigerated centrifuge should be used. In the simplest form, a refrigerator unit is mounted beside the centrifuge, and cold air is blown into the rotor chamber. This approach is usually inadequate to stabilize the low temperature. With more sophisticated centrifuges, refrigeration coils around the chamber make it possible to maintain a preset temperature within ± 1 °C. The temperature of a refrigerated centrifuge should be measured at least once every 6 months under reproducible conditions and should be within 2 °C of the expected temperature.

Gravimetry

Gravimetry is the process used to measure the mass of a substance. Weight is a function of mass under the influence of gravity, a relationship expressed by

$$\text{Weight} = \text{mass} \times \text{gravity}$$

Two substances of equal weight and subject to the same gravitational force have equal masses. The determination of mass is made using a balance to compare the mass of an unknown with that of a known mass. This comparison is called weighing, and the absolute standards with which masses are compared are called weights. In practice, the terms mass and weight are used synonymously.

The classic form of a balance is a beam poised on an agate knife-edge fulcrum, with a pan hanging from each end of the beam and a rigid pointer hanging from the beam at the poised point.

Principles of Weighing

In practice, two modes of weighing are used: (1) Analytical weights are added to equal the weight of the object being weighed, or (2) the material to be weighed is added to a balance pan to achieve equilibrium with a preset weight. This is second mode is used more commonly in clinical laboratories, where the major necessity is to weigh a fixed quantity of chemical so that a calibrator or reagent solution of known concentration may be prepared. Before a sample of the chemical is weighed, the weight of the container must be determined to subsequently allow for deducting the weight of the container from the gross weight of the container plus sample to obtain the net weight of the sample. This is is called taring. When taring is impractical, the weight of the empty container must be subtracted from the combined weight of the container and the material to obtain the weight of the material alone.

Types of Balances

Double- and single-pan and electronic balances are frequently used in the clinical laboratory.

Double-Pan Balance

A double-pan balance conforms to the classic design, consisting of a single beam with arms of equal length. Standard weights are usually added by hand to the right-side pan to counterbalance the weight of the object on the other, but in some models, a dial or a vernier with chain is used to make fine adjustments to the mass associated with the right-side pan. In single-pan balances, the arms are of unequal length. The object to be weighed is placed on the pan attached to the shorter arm. A restoring force is applied mechanically or electronically to the other arm to return the beam to its null position. Double- and triple-beam balances are forms of the unequal-arm balance.

Single-Pan Balance

The single-pan balance is a commonly used balance in the clinical laboratory. It is most often electronically operated and self-balancing. Such a balance may be coupled directly to a computer or recording device. In the electronic single-pan balance, a load on the pan causes the beam to tilt downward. A null detector senses the position of the beam and indicates when the beam has deviated from the equilibrium point.

Electronic Balance

In an electronic balance, an electromagnetic force is applied to return the balance beam to its null position. This is force is proportionate to the weight on the pan. Most electronic balances have a built-in provision for taring, so that the mass of the container is subtracted easily from the total mass measured. In addition, in many modern balances, a built-in computer compensates for changes in temperature and provides both automatic zero tracking and calibration.

Analytical Weights. Analytical weights are used to counterbalance the weight of objects weighed on two-pan balances and to verify the performance of both single- and two-pan balances. The NIST recognizes five classes of analytical weights. Class S

weights are used for calibrating balances. In the clinical laboratory, balances should be calibrated at least monthly and before very accurate analytical work is conducted. These weights are typically made from brass or stainless steel and are lacquered or plated for protection. The fractional weights of a set of class S standards are usually made of platinum or aluminum. Tolerances of the different weights have been defined by the NIST. For class S weights from 1 to 5 g, the tolerance is ±0.054 mg, from 100 to 500 mg it is ±0.025 mg, and from 1 to 50 mg it is ±0.014 mg.

Thermometry

In the clinical chemistry laboratory, measurements of temperature are made primarily to verify that devices measure within their prescribed temperature limits. Water baths and heated cells where reactions take place are examples of such devices, as are refrigerators, whose temperatures must be measured and recorded daily to meet laboratory regulatory requirements.

The two most popular types of thermometers in the chemistry laboratory are liquid-in-glass thermometers and thermistor probes.

All thermometers must be verified against a certified thermometer before they are placed into use. For example, the NIST SRM 934 is a mercury-in-glass thermometer with calibration points at 0 °C, 25 °C, 30 °C, and 37 °C. Some manufacturers supply liquid-in-glass thermometers that have ranges greater than the SRM thermometer and are verified to have been calibrated against the NIST thermometers. Details of verification of the calibration of a thermometer have been described.[6] The NIST also supplies several materials that melt at a known temperature, including gallium (SRM 1968), which melts at 29.7723 °C, and rubidium (SRM 1969), which melts at 39.3 °C.

Control of Hydrogen Ion Concentration

In the laboratory, hydrogen ion concentration is controlled with buffers. Buffers are defined as a solution containing either a weak acid and its salt or a weak base and its salt, which is resistant to changes in the **pH** of a system. All weak acids or bases, in the presence of their salts, form buffer systems. The action of buffers and their role in maintaining the pH of a solution are explained with the aid of the Henderson-Hasselbalch equation, which is derived as follows.

Chemically, the ionization of a weak acid, HA, and of a salt of that acid, BA, is represented as:

$$HA \underset{\rightarrow}{\leftarrow} H^+ + A^-$$

$$BA \overset{\leftarrow}{\rightarrow} B^+ + A^-$$

The dissociation constant for a weak acid (K_a) may be calculated from the following equation:

$$K_a = \frac{[H^+]\ [A^-]}{[HA]}$$

Thus

$$[H^+] = K_a \times \frac{[HA]}{[A^-]}$$

or

$$\log[H^+] = \log K_a + \log \frac{[HA]}{[A^-]}$$

where brackets indicate the concentration of the compound contained within. Now multiplying throughout by −1:

$$-\log[H^+] = -\log K_a - \log \frac{[HA]}{[A^-]}$$

By definition, $pH = -\log [H^+]$, and $pK_a = -\log K_a$, therefore

$$pH = pK_a + \log \frac{[A^-]}{[HA]}$$

This equation is known as the Henderson-Hasselbalch equation. Because A^- is derived principally from the salt, the equation also is written as:

$$pH = pK_a + \log \frac{[salt]}{[undissociated\ acid]}$$

or simply as:

$$pH = pK_a + \log \frac{[salt]}{[acid]}$$

where [salt] = $[A^-]$ = concentration of dissociated salt and [acid] = [HA] = concentration of undissociated acid.

This derivation demonstrates that the pH of the system is determined by the pK_a of the acid and the ratio of $[A^-]$ to [HA]. The buffer has its greatest buffer capacity at its pK_a, that is, that pH at which $[A^-]$ = [HA].

The capacity of the buffer decreases as the ratio deviates from 1. In general, buffers should not be used at a pH greater than 1 unit from their pK_a. If the ratio is beyond 50:1 or 1:50, the system is considered to have lost its buffering capacity. This is point is approximately 1.7 pH units to either side of the pK_a of the acid because

$$pH = pK_a \pm 1.7$$

Use of Procedures for Processing Solutions

Several procedures are routinely used to process solutions in the clinical laboratory, including those for (1) diluting, (2) evaporating (3) lyophilizing, and (4) filtering solutions.

Dilution

Dilution is the process by which the concentration or activity of a given solution is decreased by the addition of solvent. In laboratory practice, most dilutions are made by transferring an exact volume of a concentrated solution into an appropriate flask and then adding water or another diluent to the required volume, with appropriate mixing to ensure homogeneity. A serial dilution is a sequential set of dilutions done in mathematical sequence. A given dilution is expressed as the amount, either volume or weight, of a solute (analyte) in a specified

volume. For example, a 1:5 volume-to-volume (vol/vol) dilution contains one volume in a total of five volumes (one volume plus four volumes).

To prevent errors that arise when two liquids of very different composition are mixed, the technique of diluting to volume is used. Instead of adding 90 mL of water to 10 mL of concentrated solution, the 10 mL of concentrated solution should be pipetted into a 100-mL volumetric flask. Water is added to bring the volume to the 100-mL mark on the neck of the flask with its contents mixed.

When a dilution is performed, the following equation is used to determine the volume (V_2) necessary to dilute a given volume (V_1) of solution of a known concentration (C_1) to the desired lesser concentration (C_2):

$$C_1 \times V_1 = C_2 \times V_2$$

or

$$V_2 = \frac{C_1 \times V_1}{C_2}$$

Likewise, the equation is used to calculate the concentration of the diluted solution when a given volume is added to the starting solution.

Evaporation

Evaporation is a process used to convert a liquid or a volatile solid into vapor. It is used in the clinical laboratory to remove liquid from a sample, thereby increasing the concentrations of analyte(s) left behind.

Note: Evaporation is also an analytical problem when a sample remains in its cup for too long a time. When this occurs, the concentration of a nonvolatile analyte increases and subsequent measurement yields an inaccurate result.

Lyophilization

Lyophilization (also known as "freeze drying") is used in laboratory medicine for the preparation of (1) calibrators, (2) control materials, (3) reagents, and (4) individual specimens for analysis. Lyophilization first entails freezing a material at −40 °C or less and then subjecting it to a high vacuum. Very low temperatures cause the ice to sublimate to a vapor state. The solid nonsublimable material remains behind in a dried state.

Filtration

Filtration is defined as the passage of liquid through a filter and is accomplished by (1) gravity, (2) pressure, or (3) vacuum. Filtrate is the liquid that has passed through the filter. The purpose of filtration is to remove particulate matter from the liquid. Many filtrations in the clinical laboratory are carried out with filter paper and with plastic membranes of controlled pore size.

Membrane filters have been incorporated into certain disposable tips for use with semiautomatic pipettes. These filters minimize the exchange of aerosol droplets between the tips and the pipette. This is of particular importance for DNA amplification and microbiological procedures. Other membrane filters are designed for ultrafiltration and are available in a variety of pore sizes for selective filtration. Ultrafiltration is a technique by which dissolved particles are removed with the use of an extremely fine filter. It is used to concentrate macromolecules, such as proteins, because smaller dissolved molecules pass through the filter.

Safety

In the United States, the Federal Occupational Safety and Health Act of 1970 marked the beginning of formal regulatory oversight of employee safety. Since 1970 the Occupational Safety and Health Administration (**OSHA**) and the Centers for Disease Control and Prevention (CDC) have published numerous safety standards that apply to clinical laboratories. Each year, as The Joint Commission (TJC), formerly known as the Joint Commission on Accreditation of Healthcare Organizations (JCAHO), and the College of American Pathologists (CAP) revise their guidelines, more attention is devoted to safety. Consideration for the health and responsibility for the safety of employees are now accepted as obligations of all employers and laboratory directors. In May of 1988, OSHA expanded the Hazard Communication Standard to apply to hospital workers. Part of this standard is frequently referred to as the "Lab Right to Know Standard."

The safe operation of a clinical laboratory comprises many aspects. Key elements to ensure safety in the clinical laboratory include the following:

1. A formal safety program
2. Documented policies and effective use of mandated plans and/or programs in the areas of (a) chemical hygiene, (b) control of exposure to bloodborne pathogens, (c) tuberculosis control, and (d) ergonomics
3. Identification of significant occupational hazards, such as (a) biological, (b) chemical, (c) fire, and (d) electrical hazards, and clear identification and documentation of policies for employees to deal with each type of hazard (e.g., packaging and shipping of diagnostic specimens and infectious substances)
4. Recognition that additional important and relevant safety areas of concern must be addressed. These areas include effective (a) waste management, (b) bioterrorism, and (c) chemical terrorism response plans in the event of potential threats or casualties involving these types of agents.

Safety Program

Every clinical laboratory must have a comprehensive and effective formal safety program. Regardless of the size of the clinical laboratory, a specific individual should be designated as "Safety Officer" or "Chair of the Safety Committee" and given the responsibility to implement and maintain a safety program. Safety is each employee's responsibility, but responsibility for the entire program begins with the laboratory leadership (directors, administrative directors, supervisors, managers, etc.) and is delegated through the leadership to the safety officer or the safety committee. This individual or committee then has the duties of providing guidance to laboratory leadership on matters related to the provision of a safe workplace for all employees. Although a small institution may have

one individual who deals with all safety-related matters for all departments, including the laboratory, OSHA mandates that the laboratory specifically have a chemical hygiene officer who is designated on the basis of training or experience to provide technical guidance in the development of the chemical hygiene plan (CHP) discussed later.

An integral part of the laboratory safety program is the education and motivation of all laboratory employees in all matters related to safety. All new employees should be given a copy of the general laboratory safety manual as part of their orientation. The continuing education program of the laboratory should include periodic talks on safety. Several audiovisual resources are available from a variety of sources to support the continuing education part of the safety program.[3,5]

Another important part of the laboratory safety program relates to ensuring that the laboratory environment meets accepted safety standards. This effort would include, but not be limited to, attention to such items as (1) proper labeling of chemicals, (2) types and locations of fire extinguishers, (3) hoods that are in good working order, (4) proper grounding of electrical equipment, (5) ergonomic issues (which include attention to equipment, such as pipetting devices and laboratory furniture, and prevention of musculoskeletal disorders),[12] and (6) means for the proper handling and disposal of biohazardous materials, including all patient specimens.[4]

Safety Equipment

OSHA requires that institutions provide employees with all necessary personal protective equipment (PPE). Key important safety items include (1) clothing (such as laboratory coats, gowns, and/or scrubs), (2) gloves, and (3) eye protection. These safety items should be used in areas where they are appropriate. Eye washers or face washers should be available in every chemistry laboratory. Many types are available, and some simply connect to existing plumbing. A handheld eye and/or face safety spray is a requisite safety device and is typically placed in a position next to each sink using only a few inches of space. Safety showers, strategically located in the laboratory, must be available and should be tested on a regular basis.

Heat-resistant (nonasbestos) gloves should be available for handling hot glassware and dry ice. Eye safety devices such as (1) safety goggles, (2) glasses, and (4) visors, including some that will fit conveniently over regular eyeglasses, are available in many sizes and shapes. Personnel wearing contact lenses should be aware of the danger of irritants getting under a lens, making it difficult to irrigate the eye properly. Shatterproof safety shields should be used in front of systems posing a potential danger because of implosion (vacuum collapse) or pressure explosions. Desiccator guards should be used with vacuum desiccators. Hot beakers should be handled with tongs. Inexpensive polyethylene pumps are available to pump acids from large bottles. Spill kits for acids, caustic materials, or flammable solvents are available in various sizes. Such kits and other appropriate safety materials should be located at convenient and appropriate sites in the laboratory.

A chemical fume hood is a necessity for every clinical chemistry laboratory. The fume hood is used to (1) open any container of a material that gives off harmful vapors, (2) prepare reagents that produce fumes, and (3) heat flammable solvents. In the event of an explosion or a fire in the hood, closing its window contains the fire.

Safety Inspections

It is good laboratory practice to organize a safety inspection team from the laboratory staff. This team is responsible for conducting periodic and scheduled safety inspections of the laboratory.[5]

In the United States, several (1) regulatory, (2) private accreditation, (3) state, and (4) federal organizations may conduct a safety inspection of the laboratory. Some of these safety inspections may occur unannounced. From an external perspective, OSHA inspectors have the authority to enter a clinical laboratory unannounced and, on presentation of credentials, inspect it. The inspection may be regular or may occur as the result of a complaint. In addition, the Commission on Inspection and Accreditation of the CAP inspects clinical laboratories and uses various safety checklists (available to the laboratory before inspection) when evaluating a laboratory for accreditation. Although the TJC will accept CAP accreditation of a laboratory, it still may conduct a safety inspection of the laboratory when it inspects the hospital. The TJC and the CAP conduct their accreditation inspections, which may include a full laboratory or laboratory safety component, unannounced.

Depending on the group designated as responsible for accrediting a particular laboratory, selected laboratories may be subject to inspection for the purposes of accreditation and/or safety only by state agencies or local Center for Medicare & Medicaid Services (CMS) groups. Inspections may be made on a regular basis by state or local health departments or by local fire departments to determine conformance to their particular safety requirements. Currently a laboratory that meets federal or state OSHA requirements is likely to satisfy the standards of any other inspecting agency.

Mandated Plans

In 1991 OSHA mandated that all clinical laboratories in the United States must have a **CHP** and an **exposure control plan**. OSHA has since updated its requirements for the exposure control plan to provide new examples of engineering controls and to place significantly greater responsibility on employers to minimize and manage employee occupational exposure to bloodborne pathogens.[14] Also, the CAP and other groups require that an accredited laboratory have a documented tuberculosis exposure control plan that conforms with biosafety guidelines published by the CDC.[1] In addition, it is now recognized that the workplace setting of a clinical laboratory exposes employees to the occupational risk of developing various musculoskeletal disorders. As a result, the focus of OSHA on laboratories having an effective ergonomics program has caused federal, state, and private accreditation groups to address this area of occupational safety. However, considerable controversy has surrounded this issue, and a final ergonomics rule was published and then withdrawn in 2001.[8]

Chemical Hygiene Plan

Major elements of a CHP include listing of responsibilities for (1) employers, (2) employees, and (3) a chemical hygiene officer. Also, every laboratory must have a complete chemical inventory that is updated annually. A copy of the **Material Safety Data Sheet (MSDS)**, which defines each chemical as (1) toxic, (2) carcinogenic, or (3) dangerous, must be on file and readily accessible and available to all employees 24 hours a day, 7 days a week. The MSDS contains important information for the benefit of laboratory employees. The chemical manufacturer's information as supplied on the MSDS is used to ascertain whether a certain chemical is hazardous. Each MSDS must give the product's identity as it appears on the container label and the chemical and common names of its hazardous components. The MSDS also provides physical data on the product, such as (1) boiling point, (2) vapor pressure, and (3) specific gravity. Easily recognized characteristics of the chemical are listed on the line for "appearance and odor." Information about hazardous properties is given in detail on the MSDS; this includes fire and explosion hazard data and health-related data, including the threshold limit value (TLV), exposure limits, and toxicity values. The TLV is the exposure allowable for an employee during one 8-hour day. It also notes effects of overexposure and provides first aid procedures. Each MSDS also provides information on spill and disposal procedures and on protective personal gear and equipment requirements.

Exposure Control Plan

OSHA regulations require that each laboratory develop, implement, and adhere to a plan that ensures the protection of laboratory workers against potential exposure to bloodborne pathogens[3,5,11,14] and ensures that the medical wastes produced by the laboratory are managed and handled in a safe and effective manner.[3,5,11,14] OSHA regulations also place responsibility on employers (1) to implement new developments in exposure control technology; (2) to solicit the input of employees directly involved in patient care in the identification, evaluation, and selection of these work practice controls; and, in certain instances, (3) to maintain a log for employee percutaneous injuries from sharp devices, such as syringe needles.[14] Organizationally, the plan should include sections on (1) purpose, (2) scope, (3) applicable references, (4) applicable definitions, (5) definitions of responsibilities, and (6) detailed procedural steps.

When implementing the plan, each laboratory employee must be placed into one of three groups. The three classifications are as follows:

Group I: A job classification in which all employees have occupational exposure to blood or other potentially infectious materials

Group II: A job classification in which some employees have occupational exposure to blood or other potentially infectious materials

Group III: A job classification in which employees do not have any occupational exposure to blood or other potentially infectious materials

Tuberculosis Control Plan

The purpose of the tuberculosis control plan is to prevent the transmission of tuberculosis (TB), which occurs when an individual inhales a droplet that contains Mycobacterium tuberculosis. M. tuberculosis is aerosolized when an infected individual sneezes, speaks, or coughs. Transmission of TB and exposure to TB are greatly diminished by (1) early identification and isolation of patients at risk, (2) environmental controls, (3) appropriate use of respiratory protection equipment, (4) education of laboratory employees, and (5) early initiation of therapy.

An effective tuberculosis control plan will include determination of exposure at regular intervals for all employees who are at occupational risk. Engineering and work practice controls are particularly important in laboratory areas, such as surgical pathology and microbiology. But a risk of exposure from specimens of patients with suspected or confirmed tuberculosis is clearly present in every section of the laboratory, including chemistry.

Ergonomics Program

Several areas of occupational risk for development of musculoskeletal disorders are present in the clinical laboratory. These include (1) routine laboratory activity, (2) functionality of the workspace (including laboratory floor matting, bright lighting, and noise generation), and (3) equipment design (computer keyboards and displays, workstations, and chairs). One particular laboratory function, pipetting and related pipette design, has received considerable attention. As depicted in Figure 8-2, pipettes are being designed with the goal of reducing an employee's risk of developing cumulative stress disorders caused by awkward posture, repetitive motion, and the repeated use of force.

The CAP requires accredited laboratories to have a comprehensive and defined ergonomics program that is designed to prevent work-related musculoskeletal disorders through prevention and engineering controls. The documented ergonomics plan should include (1) elements of employee training regarding areas of risk, (2) engineering controls designed to minimize or eliminate risks, and (3) an assessment process for use in identifying problematic issues for documentation and remediation.

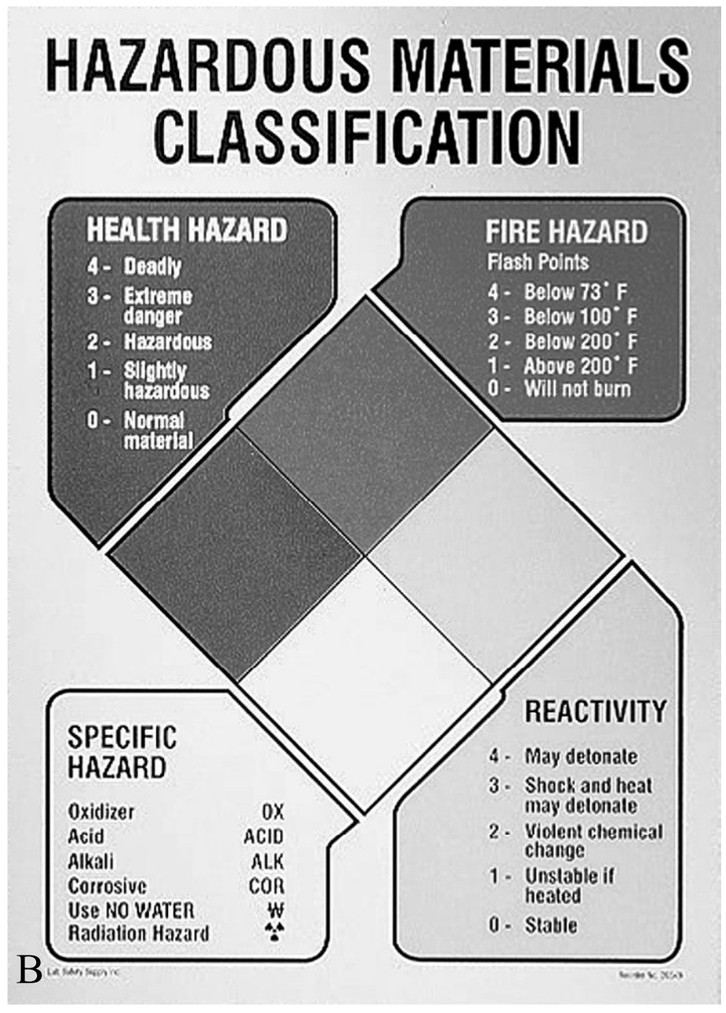
Hazards in the Laboratory

Various types of hazards are encountered in the operation of a clinical laboratory. These hazards must be identified and labeled, and work practices developed for dealing with them. The major categories of hazards encountered include (1) biological, (2) chemical, (3) electrical, and (4) fire hazards.

Identification of Hazards

Clinical laboratories deal with each of the nine classes of hazardous materials. These are classified by the United Nations (UN) as (1) explosives, (2) compressed gases, (3) flammable liquids, (4) flammable solids, (5) oxidizer materials, (6) toxic materials, (7) radioactive materials, (8) corrosive materials, and (9) miscellaneous materials not elsewhere classified.

Shipping and handling of class 6 toxic materials, specifically, biological and potentially infectious materials, has received considerable attention. In 2002 the U.S. Department of Transportation (DOT) released a revised rule with standards for infectious substance hazardous material handling. The impact and requirements of these regulations are described in the section on biological hazards.



Warning labels aid in the identification of chemical hazards during shipment. Under regulations of the DOT, chemicals that are transported in the United States must carry labels based on the UN classification. DOT placards or labels are diamond shaped with a digit imprinted on the bottom corner that identifies the UN hazard class (1 to 9). The hazard is identified more specifically in printed words placed along the horizontal axis of the diamond. Color coding and a pictorial art description of the hazard supplement the identification of hazardous material on the label; the artwork appears in the top corner of the diamond (Figure 8-5, A).

This system is used by the DOT for shipping hazardous materials; however, when the hazardous material reaches its destination and is removed from the shipping container, this identification is lost. The laboratory must then label each individual container. Usually the information necessary to classify the contents of the container appropriately is contained on the shipping label and should be noted. Important first aid information is usually provided on this label as well.

In practice, OSHA prescribes the use of labels or other appropriate warnings for hazardous chemicals used in clinical laboratories. Appropriate hazard warnings include any (1) words, (2) pictures, (3) symbols, or (4) combinations that convey the health or physical hazards of the container's contents and must be specific as to the effect of the chemical and the specific target organs involved. The National Fire Protection Association (NFPA) has developed the 704-M Identification System, which classifies hazardous material from 0 to 4 (most hazardous) according to flammability and reactivity (instability). This system uses diamond-shaped labels (Figure 8-5, B), which are available from most companies that sell laboratory safety equipment. The labels are color-coded and are divided into quadrants. Three of the quadrants have a characteristic color and represent a particular type of hazard. A number in the quadrant indicates the degree of the hazard. The fourth (lower) quadrant contains information of special interest to firemen.

Biological Hazards

It is essential to minimize the exposure of laboratory workers to infectious agents, such as the hepatitis viruses and human immunodeficiency virus (HIV). Exposure to infectious agents results from (1) accidental puncture with needles, (2) spraying of infectious materials by a syringe or spilling and splattering of these materials on bench tops or floors, (3) centrifuge accidents, and (4) cuts or scratches from contaminated vessels. Any unfixed tissue, including blood slides, must also be treated as potentially infectious material.

OSHA has mandated that all U.S. laboratories have an exposure control plan. In addition, the National Institute for Occupational Safety and Health (NIOSH), a functional unit of the CDC, has prepared and widely distributed a document entitled **Universal Precautions** that specifies how U.S. clinical laboratories should handle infectious agents.[11] In general it mandates that clinical laboratories treat all human blood and other potentially infectious materials as if they were known to contain infectious agents, such as (1) hepatitis B virus (HBV), (2) HIV, and (3) other bloodborne pathogens. These requirements apply to all specimens of (1) blood, (2) serum, (3) plasma, (4) blood products, (5) vaginal secretions, (6) semen, (7) cerebrospinal fluid, (8) synovial fluid, and (9) concentrated HBV or HIV viruses. In addition, any specimen of any type that contains visible traces of blood should be handled using these Universal Precautions.

Universal Precautions also specify that barrier protection must be used by laboratory workers to prevent skin and mucous membrane contamination from specimens. These barriers, also known as personal protective equipment (PPE), include (1) gloves, (2) gowns, (3) laboratory coats, (4) face shields or mask and eye protection, (5) mouthpieces, (6) resuscitation bags, (7) pocket masks, and (8) other ventilator devices. With

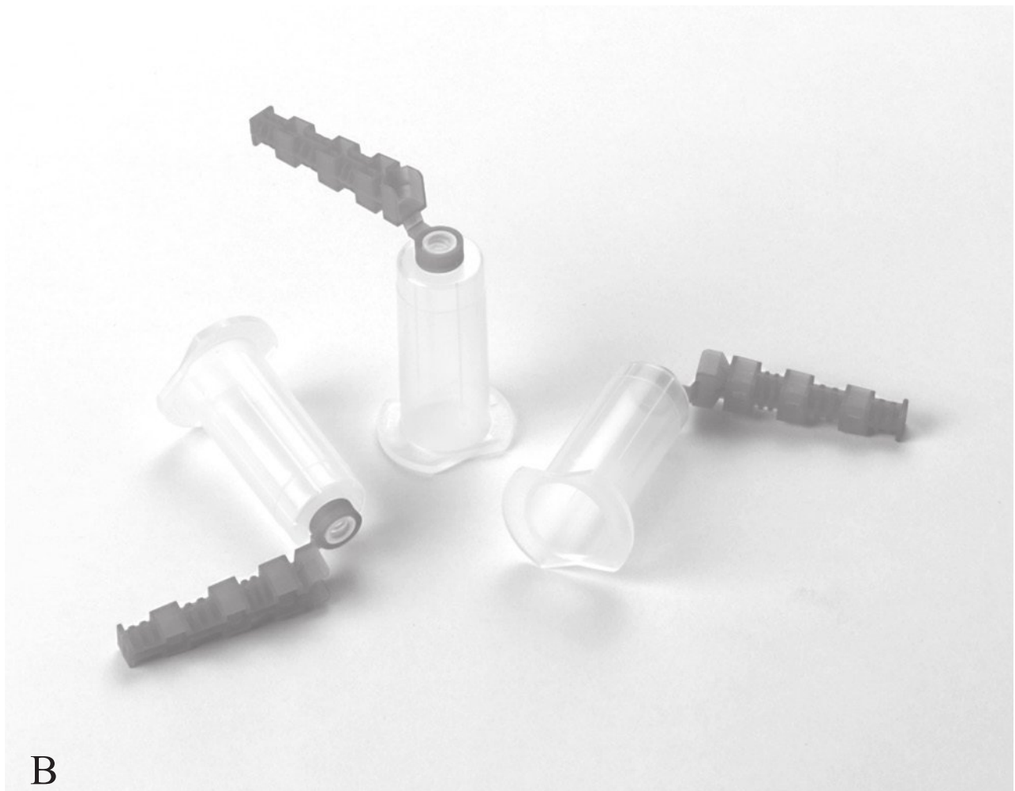
some individuals, latex allergy is a problem when latex gloves are used for barrier protection. For such individuals, medical grade nonlatex gloves made of materials such as vinyl, nitrile, neoprene, or thermoplastic elastomer are available. If latex gloves are to be used, they should be made of powder-free, low-allergen latex.

New products for improving employee protection against needle sticks include an array of novel containers for sharps (e.g., needles, scalpels, glass) and biological safety disposal bags and needle sheaths that may be closed after venipuncture without physically touching the needle or the sheath.

The CLSI has published a similar set of recommendations,[4,5] several of which are specified as requirements in the OSHA exposure control plan. They include the following:

1. Never perform mouth pipetting and never blow out pipettes that contain potentially infectious material.
2. Do not mix potentially infectious material by bubbling air through the liquid.
3. Use barrier protection, such as gloves, masks, and protective eyewear and gowns, when drawing blood from a patient and when handling all patient specimens. This includes the removal of stoppers from tubes. Gloves must be made of disposable, nonsterile latex or another material that provides adequate barrier protection. Phlebotomists must change gloves and must adequately dispose of them between sessions of drawing blood from different patients.
4. Wash hands whenever gloves are changed.
5. Use facial barrier protection if there is significant potential for the spattering of blood or body fluids.
6. Avoid using syringes whenever possible, and dispose of needles in rigid containers (Figure 8-6, A) without handling them (Figure 8-6, B).
7. Dispose of all sharps appropriately.
8. Wear protective clothing, which serves as an effective barrier against potentially infective materials. When leaving the laboratory, remove protective clothing.
9. Strive to prevent accidental injuries.
10. Encourage frequent hand washing in the laboratory; employees must wash their hands whenever they leave the laboratory.
11. Make a habit of keeping your hands away from your mouth, nose, eyes, and any other mucous membranes. This reduces the possibility of self-inoculation.
12. Minimize spills and spatters.
13. Decontaminate all surfaces and reusable devices after use with appropriate U.S. Environmental Protection Agency (EPA)-registered hospital disinfectants. Sterilization, disinfection, and decontamination are discussed in detail in CLSI publication M29-A3.[3] Do not use warning labels on patient specimens because all should be treated as potentially hazardous.
15. Use biosafety level 2 procedures whenever appropriate.
16. Before centrifuging tubes, inspect them for cracks. Inspect the inside of the trunnion cup for signs of erosion or adhering matter. Be sure that rubber cushions are free from all bits of glass.
17. Use biohazard disposal techniques (e.g., "Red Bag").

A



B

Figure 8-6 A, Convenient needle disposal system for sharps. B, Needle sheathing devices for prevention of body contact with needle. (B, Courtesy MarketLab Inc.)

18. Never leave a discarded tube or an infected material unattended or unlabeled.
19. Periodically, clean out the freezer and dry-ice chests to remove broken ampules and tubes of biological specimens. Use rubber gloves and respiratory protection during this cleaning.
20. OSHA requires that hepatitis B vaccine be offered to all employees at risk of potential exposure as a regular or occasional part of their duties. CDC's Advisory Committee on Immunization Practices (ACIP) recommends that (1) medical technologists, (2) phlebotomists, and (3) pathologists be vaccinated with hepatitis B vaccine. It is a regulatory mandate that all of the above laboratory employees at a minimum be given the option to receive free hepatitis B vaccine.

Investigation of tragic air accidents in the late 1990s by the U.S. National Transportation Safety Board (NTSB) led to the development of revised and strict requirements for the shipping and handling of hazardous materials by DOT, in cooperation with the International Air Transport Association (IATA) and the International Civil Aviation Organization (ICAO).[4] With continued awareness of the necessity for Universal Precautions, the risk of bloodborne pathogens, and the potentially adverse consequences of serious infection, the shipping and handling of class 6 toxic materials—biological materials—is a critical safety issue.

Federal shipping and packaging guidelines divide potentially infectious specimens or substances into four risk groups that range from low to high risk.

These regulations place particular emphasis on the hazardous material (HAZMAT) training that must be given to laboratory employees for shipping and handling infectious substances. Elements include (1) general awareness and familiarization, (2) function-specific training, and (3) safety training. Proper training, particularly in the areas of package labeling and documentation (including a shipper's declaration of contents for dangerous goods), is mandatory, and documented certification is required from employers that the relevant employees have completed appropriate training programs. Although the adverse impact of improper training can be reflected most by potential human morbidity and mortality, identified violations of these regulations also carry large financial fines and penalties for both the infringing individual and the employer or institution.

Chemical Hazards

Proper storage and use of chemicals is necessary to prevent dangers, such as (1) burns, (2) explosions, (3) fires, and (4) toxic fumes. Thus knowledge of the properties of the chemicals in use and of proper handling procedures greatly reduces dangerous situations. Bottles of chemicals and solutions should also be handled carefully, and a cart should be used to transport heavy or multiple numbers of containers from one area to another. Glass containers with chemicals should be transported in rubber or plastic containers that protect them from breakage and, in the event of breakage, contain the spill. Appropriate spill kits should be available in strategic locations. A general spill kit, such as the Sasco Solidifier Spill Response Kit (http://www.sascochemical.com; accessed July 22, 2013), should contain specific materials to be used with spills of acid or of caustic or organic materials. Directions for use of these materials are contained in the kit.

Spattering from acids, caustic materials, and strong oxidizing agents is a hazard to clothing and eyes and is a potential source of chemical burns. A bottle should never be held by its neck but instead should be held firmly around its body with one or both hands, depending on the size of the bottle. Acids must be diluted by slowly adding them to water while mixing; water should never be added to concentrated acid. When one is working with acid or alkali solutions, safety glasses should be worn. Acids, caustic materials, and strong oxidizing agents should be mixed in the sink. This provides water for cooling and for confinement of the reagent in the event that the flask or the bottle breaks.

All bottles that contain reagents must be properly labeled. It is good practice to label the container before adding the reagent, thus preventing the possibility of an unlabeled reagent. The label should bear (1) the name and concentration of the reagent, (2) the initials of the person who made up the reagent, and (3) the date on which the reagent was prepared. When appropriate, the expiration date should also be included. Labels should be color-coded or another label added to designate specific storage instructions, such as the requirement for refrigeration or special storage related to a potential hazard. All reagents found in unlabeled bottles should be disposed of in accordance with appropriate procedures and precautions.

Hazardous chemicals such as (1) strong acids, (2) caustic materials, and (3) strong oxidizing agents should be dispensed by a commercially available automatic dispensing device. Under no circumstances is mouth pipetting permitted.

In some instances, all waste materials are not collected in the same container. With certain pieces of equipment, strong acids or other hazardous materials are pumped directly into the drain. This is should always be accompanied by a steady flow of water from the faucet. Safety glasses should be used by instrument operators when acids are pumped under pressure.

Perchloric acid, because it is potentially explosive in contact with organic materials, requires careful handling. Perchloric acid should not be used on wooden bench tops, and bottles of this acid should be stored on a glass tray. Disposal may be accomplished by adding the acid dropwise (using a splatter shield) to at least 100 volumes of cold water and pouring the diluted acid down the drain with large amounts of additional cold water. Special perchloric acid hoods, with special washdown facilities, should be installed if large amounts of this acid are used.

Special care is necessary when one is dealing with mercury. Even small drops of mercury on bench tops and floors may poison the atmosphere in a poorly ventilated room. The element's ability to amalgamate with a number of metals is well known. After an accidental spillage of mercury, the spill area should be cleaned carefully until no droplets remain. All containers of mercury should be kept well stoppered. Because it is highly hazardous, most recommend that **no** mercury be used in the laboratory.

The EPA controls the disposal of nonradioactive hazardous wastes. The Resource Conservation and Recovery Act of 1976 (RCRA) states that disposal of materials classifiable within any of the nine UN hazardous materials classes is enforced in such a way that health and safety professionals involved in the disposal of such materials are personally liable for each individual violation.

A CLSI publication[4] covers hazardous waste disposal; however, many municipalities and states have their own regulations. These agencies should be contacted by the laboratory for specifics.

Volatile chemicals and compressed gases pose specific hazards.

Hazards from Volatiles

Use of organic solvents in a clinical laboratory represents a potential fire hazard and hazards to health from inhalation of toxic vapors or skin contact. These solvents should be used in a fume hood. Storage of organic solvents is regulated by rules set down by OSHA. However, some local fire department rules are more stringent. Solvents should be stored in an OSHA-approved metal storage cabinet that is properly vented. The maximum working volume of flammable solvents allowed outside storage cabinets is 5 gallons per room. No more than 60 gallons of type I and II solvents may be stored in a single cabinet. No more than three cabinets may be located in each 5000 square feet of laboratory space.

Vaporization is a major problem in the ignition and spread of fires. Vapors from flammable and combustible liquids and solids form a flammable mixture with air. They are characterized by their flash point, where the flash point is defined as the lowest temperature at which a solvent gives off flammable vapors in the close vicinity of its surface. The mixture at its flash point ignites when exposed to a source of ignition. At temperatures below the flash point, the vapor given off is considered too lean for ignition.

Disposal of flammable solvents in storm sewers or sanitary sewers generally is not allowed. Exceptions include small amounts of those materials that are miscible with water, but even disposal of these should be followed by large amounts of cold water. Other solvents should be collected in safety cans. Separate cans should be used for ether and for chlorinated solvents; all other solvents may be combined in a third can. The cans should be stored, in keeping with storage quantity rules, in a safety cabinet until pickup by a waste disposal firm. A more economical approach is to transfer the solvents to larger cans or drums in an outside storage facility so that pickup is less frequent. Some large institutions have their own in-house disposal facilities.

Hazards from Compressed Gases

DOT regulations cover the labeling of cylinders of compressed gases that are transported by interstate carriers. The diamond-shaped labels described previously are used on all large cylinders and on any boxes containing small cylinders. Some general rules for handling large cylinders of compressed gas follow here:

1. Always transport cylinders using a hand truck to which the cylinder is secured.
2. Leave the valve cap on a cylinder until the cylinder is ready for use, at which time the cylinder should have been secured by a support around the upper one-third of its body. Disconnect the hose or regulator, shut off the valve, and replace the cap before the cylinder is completely empty to prevent the possibility of the development of negative pressure. Place an "empty" sign or label on the cylinder.
3. Chain or secure cylinders at all times even when empty.
4. Always check cylinders for the composition of their contents before connection.
5. Never force threads; if a regulator does not thread readily, something is wrong.

The precautions cited for large refillable gas cylinders also apply to small cylinders that are not refillable. Propane cylinders and cylinders of calibrating gases for blood gas equipment are examples of disposable cylinders. Cylinders in floor-standing base supports require the additional security of a chain or a strap attached to a wall or a fixed piece of furniture. Local fire department regulations (which vary considerably from place to place) govern the disposal of exhausted cylinders.

Electrical Hazards

Electrical wires or connections are potential shock or fire hazards. Worn wires on all electrical equipment should be replaced immediately, and all equipment should be grounded with the use of three-prong plugs. OSHA regulations stipulate that the requirements for grounding of electrical equipment of the National Electrical Code (published by NFPA) must be met. If grounded receptacles are not available, a licensed electrician should be consulted for proper alternative grounding techniques. Some local codes are more stringent than OSHA requirements and do not allow for two-pole mating receptacles with adapters for a three-pole plug.

Use of extension cords is prohibited. This is standard is more stringent than any other existing regulation. In some instances, an extension cord may have to be used temporarily. In such cases, the cord should (1) be less than 12 feet long, (2) consist of at least 16 American Wire Gauge (AWG) wire, (3) be approved by the Underwriters Laboratory (UL), and (4) have only one outlet at the end. If several outlets are necessary in an area, a power strip with its own fuse or circuit breaker may be installed at least 3 inches above bench top level. Several manufacturers now sell devices to check for high resistance in neutral or ground wiring or excess voltage in neutral wiring.

Electrical equipment and connections should not be handled with wet hands, nor should electrical equipment be used after liquid has been spilled on it. The equipment must be turned off immediately and dried thoroughly. In the case of a wet or malfunctioning electrical instrument that is used by several people, the plug should be pulled, and a note cautioning coworkers against use should be left on the instrument.

Fire Hazards

NFPA and OSHA publish standards covering subjects from emergency exits (including means of egress) to safety and firefighting equipment. NFPA also publishes the National Fire Codes. Many state and local agencies have adopted these codes (some of which are more stringent than OSHA requirements) and thus make them legally enforceable.

Every laboratory should have the necessary equipment to extinguish or confine a fire in the laboratory and to extinguish a fire on the clothing of an individual. Easy access to safety showers is essential. A safety shower should have a pull chain attached to the wall at a convenient height or hanging down from the shower head; the chain should have a large ring attached, so that the shower may be easily activated, even with eyes closed. Fire blankets for smothering fire on clothing should be available in an easily accessible wall-mounted case. The blanket is unrolled from the case and rolled around the body by taking hold of the rope that is attached to the blanket

TABLE 8-8 Classification of Fires and Fire Extinguisher Requirements

Type of Hazard	Class of Fire	Recommended Extinguisher Agents
Ordinary combustibles: wood, cloth, paper	A	Water, dry chemical foam, loaded steam
Flammable liquids and gases: solvents and greases, natural or manufactured gases	B	Dry chemical, carbon dioxide, loaded steam, Halon 1211 or 1301 foam
Electrical equipment: any energized electrical equipment. If electricity is turned off at source, this reverts to a Class A or B	C	Dry chemical, carbon dioxide, Halon 1211 or 1301 foam
Combinations of ordinary combustibles and flammable liquids and gases	A&B	Dry chemical, loaded steam, foam
Combinations of ordinary combustibles and electrical equipment	A&C	Dry chemical
Combinations of flammable liquids and gases and electrical equipment	B&C	Dry chemical, carbon dioxide, Halon 1211 or 1301 foam
Combinations of ordinary combustibles, flammable liquids and gases, and electrical equipment	A, B, &C	Triplex dry chemical

and turning the body around. The location of this equipment and the locations of fire alarms and maps of evacuation routes are dictated by the local fire marshal.

Various types of fire extinguishers are available. The type that should be used depends on the type of fire. Because it is impractical to have several types of fire extinguishers present in every area, dry-chemical fire extinguishers are among the preferred all-purpose extinguishers for laboratory areas. An extinguisher should be provided near every laboratory door and, in a large laboratory, at the end of the room opposite to the door. Everyone in the laboratory should be instructed in the use of these extinguishers and any other firefighting equipment. All fire extinguishers should be tested by qualified personnel at intervals specified by the manufacturer. The three classes of fires and the type of fire extinguisher to be used for each are listed in Table 8-8. Every fire extinguisher is labeled as to the type of fire it should be used to extinguish.

Two additional types of fires, designated "D" and "E," should be handled only by trained personnel. Type "D" fires include those involving powdered metal materials (e.g., magnesium). A special powder is used to fight this hazard. A type "E" fire is one that cannot be put out or is liable to result in a detonation (such as an arsenal fire). A type "E" fire is usually allowed to burn out while nearby materials are appropriately protected.

Many clinical laboratories now have a computer that is housed in a temperature- and humidity-controlled room. The most popular automatic fire control system used in these rooms is Halon 1301 (bromotrifluoromethane). Although this is the least toxic of the halons, NFPA regulations require a warning sign at the entrance to the room and availability of self-contained breathing equipment.

Review Questions

1. One aspect of universal precautions and an OSHA requirement involves the provision of personal protective equipment (PPE) to laboratory employees. PPE includes (but is not limited to) which of the following?
   a. Gloves only
   b. Gloves and a lab coat only
   c. Gloves, eye protection, and a lab coat
   d. Gloves, eye protection, a lab coat, and special footwear
2. The formula for determining how much of a concentrated solution is required to make a specific volume of a less concentrated solution is:
   a. $C_1V_1 = C_2V_2$.
   b. number of moles of solute/number of kilograms of solvent.
   c. mg/L divided by mg molecular mass.
   d. mass in grams/gram molecular weight in grams.
3. The organization that develops and implements standards and guidelines for laboratories in addition to setting certain safety guidelines is:
   a. CAP.
   b. CLSI.
   c. EPA.
   d. DOT.
4. The process by which the concentration or activity of a given solution is decreased by the addition of solvent is referred to as:
   a. solution.
   b. evaporation.
   c. lyophilization.
   d. dilution.
5. The formula used to determine the molarity of a solution is which of the following?
   a. $C_1V_1 = C_2V_2$.
   b. number of moles of solute/number of liters of solution.
   c. mg/L divided by mg molecular mass.
   d. mass in grams/gram molecular weight in grams.
6. The universal coding system for reporting laboratory and other clinical observations to facilitate electronic transmission of laboratory data within and between institutions is referred to as the system.
   a. OSHA
   b. CLIA
   c. LOINC
   d. CLSI
7. Which of the following statements regarding water type is incorrect?
   a. Type I water is acceptable for analytical purposes.
   b. Testing that requires minimal interference (such as iron or enzyme analysis) requires the use of type I water.

c. Type I water is distilled water that is acceptable for glassware-washing purposes.
d. Type I water results from ion exchange purification.

8. The two chemical grades that are suitable for use in a clinical chemistry laboratory are:
   a. technical and analytical reagent grades.
   b. ultrapure and technical grades.
   c. technical and National Formulary grades.
   d. ultrapure and analytical reagent grades.
9. RCF is measured in which of the following units?
   a. Gravities (g)
   b. Centimeters (cm)
   c. RPMs
   d. Forces (f)
10. Protection of laboratory workers against potential exposure to bloodborne pathogens and assurance that medical waste is handled safely are OSHA requirements that are part of which of the following plans?
    a. Chemical hygiene plan
    b. Exposure control plan
    c. Tuberculosis control plan
    d. Fire safety plan

CHAPTER 9

Optical Techniques*

L.J. Kricka, D.Phil., F.A.C.B., C.Chem., F.R.S.C., F.R.C.Path., and Jason Y. Park, M.D., Ph.D.

Objectives

1. Define the following terms:
   - Absorbance
   - Atomic absorption
   - Beer's law
   - Electromagnetic radiation
   - Flame emission spectrophotometry
   - Fluorescence
   - Fluorescence polarization
   - Light
   - Nephelometry
   - Percent transmittance
   - Phosphorimetry
   - Photometry
   - Spectral/Natural bandwidth
   - Spectrophotometry
   - Stokes shift
   - Transmittance
   - Turbidimetry
   - Visible/Ultraviolet/Infrared spectrum
   - Wavelength
2. Describe the relationship between the light transmitted and the light absorbed by a solution of a compound; state this relationship as a mathematical formula.
3. Express Beer's law mathematically, and define each of the components of the formula; calculate the concentration of a substance in solution using Beer's law.
4. Explain how Beer's law is used to create a calibration curve, and list five conditions that must be met before Beer's law can be applied to a measurement.
5. List the basic components of generic single-beam and double-beam spectrophotometers and state the purpose of each of the components; provide and describe two examples, if appropriate, of each component.
6. State the principle of reflectance photometry and the clinical laboratory applications of this technique.
7. State the principle of atomic absorption spectrophotometry; list the clinical laboratory applications of this technique.
8. List the components of an atomic absorption spectrophotometer and the role each component plays in measurement.
9. Describe and give examples of spectral and nonspectral interferences that might limit measurements made using atomic absorption.
10. State the principle of fluorescence; list the clinical laboratory applications of this technique.
11. Express as an equation the derivation of the Beer-Lambert law in relation to fluorescence intensity and concentration, and define each of the components of this equation.
12. Compare the sensitivity of fluorescence intensity measurements with that of absorbance measurements, and list three reasons why fluorescence measurements are more sensitive.
13. Describe fluorescence polarization and its use in the clinical laboratory.
14. List the components of a generic fluorometer; list and describe four types of fluorometers, including their use in the clinical laboratory.
15. List and describe six possible interferences that influence fluorescence measurements.
16. Explain the basic concepts of chemiluminescence, bioluminescence, and electrochemiluminescence; list the clinical laboratory applications of these techniques.
17. Explain the basic concepts of light scattering, including six factors that affect light scattering.
18. Compare nephelometry and turbidimetry, and list the clinical laboratory applications of these techniques; describe a turbidimeter and a nephelometer.
19. List and describe two possible interferences that might limit light-scattering measurements.

*The authors gratefully acknowledge the original contributions by Dr. Merle A. Evenson and Dr. Thomas O. Tiffany, upon which portions of this chapter are based.

Key Words and Definitions

Absorbance (A) The amount of light absorbed as incident light passes through a sample, which is equivalent to log (1/T) or −log (T), where T is transmittance.

Absorptivity (a) A proportionality constant for a compound that is the measure of the absorption of radiant energy at a given wavelength as it passes through a solution of that compound at a concentration of 1 g/L; expressed mathematically as absorbance divided by the product of the concentration of a substance in g/L and the sample path length in centimeters (a = A/bc).

Atomic absorption (AA) spectrophotometry An emission technique in which an element in a sample is dissociated from its chemical bonds (atomized) and placed in an unexcited or ground state (neutral atom); the atom at low energy is able to absorb radiation and the radiant energy given off as the element returns to its ground state is measured.

Bandpass The range of wavelengths passed by a filter or a monochromator at one-half the peak transmittance of that filter.

Beer's law A mathematical equation that states that the concentration of a substance is directly proportional to the amount of light absorbed or is inversely proportional to the logarithm of the transmitted light; mathematically expressed as A= abc.

Bioluminescence The emission of light when an electron returns from an excited or higher energy level to a lower energy level in which the excitation event is caused by a biochemical reaction and not by photo illumination; a special form of chemiluminescence in which an enzyme or a photoprotein increases the efficiency of the light emission.

Blank A solution used in photometry/spectrophotometry that is identical to calibrating or unknown solutions except for the substance to be measured.

Chemiluminescence The emission of light when an electron returns from an excited or higher energy level to a lower energy level, in which the excitation event is caused by a chemical reaction and not by photo illumination; the excitation event is caused by the oxidation of an organic compound.

Electrochemiluminescence The emission of light when an electron returns from an excited or higher energy level to a lower energy level, in which the excitation event is a reaction generated electrochemically on the surface of an electrode.

Flow cytometry The measurement of a physical or chemical characteristic of cells or particles made while the cells or particles pass singly through a measuring apparatus in a fowing fuid stream.

Fluorescence The emission of electromagnetic radiation that occurs when a molecule absorbs light at one wavelength and reemits light at a longer wavelength, when it returns to ground state with the excitation event being caused by photo illumination.

Fluorometry The measurement of emitted fuorescence light that occurs when a molecule absorbs light at one wavelength and reemits light at a longer wavelength.

Light Energy transmitted via electromagnetic waves that are characterized by frequency and wavelength; light is composed of photons whose energy is inversely proportional to the wavelength.

Light scattering A physical phenomenon that results from the interaction of light with particles in solution.

Molar absorptivity (ε) A proportionality constant for a compound that is the measure of the absorption of radiant energy at a given wavelength as it passes through a solution of that compound at a concentration of 1 mol/L; expressed mathematically as absorbance divided by the product of the concentration of a substance in mol/L and the sample path length in centimeters (ε = A/bc).

Nephelometry The detection and measurement of light energy scattered or refected toward a detector that is not in the direct path of the transmitted light; common nephelometers measure scattered light at right angles to the incident light, and some are designed to measure scattered light at an angle other than 90°.

Photometry/Spectrophotometry The measurement of the luminous intensity of light or the amount of luminous light falling on a surface from such a source; spectrophotometry is the measurement of the intensity of light at selected wavelengths.

Reflectance photometry A spectrophotometric technique in which diffused light illuminates a reaction mixture in a carrier containing a substance of interest, and the intensity of the refected light is measured and compared with a reference; the refected light is nonlinear in relation to the concentration of the substance and must be converted to a linear format.

Spectral bandwith The width in nanometers of the spectral transmittance curve at a point equal to one-half of the peak transmittance; used to describe the spectral purity of a filter or other monochromator.

Transmittance The intensity of a transmitted light beam divided by the intensity of an incident (incoming) light beam passed through a square cell containing a solution of a compound that absorbs light at a specific wavelength stated as $T = I/I_0$; when compared with a reference cell, the transmitted light is divided by the incident light ($T = I/I_R$). A reference cell is used to set an arbitrary value of 100 which corresponds to 100% transmittance.

Turbidimetry The detection and measurement of a decrease in intensity of an incident beam of light as it passes through a solution of particles.

Wavelength A characteristic of electromagnetic radiation; the distance between two wave crests that is measured in nanometers.

Many determinations made in the clinical laboratory are based on measurements of radiant energy (1) emitted, (2) transmitted, (3) absorbed, (4) scattered, or (5) reflected under controlled conditions (Table 9-1). The principles involved in such measurements are considered in this chapter.

Photometry and Spectrophotometry

Photometry[5] is the measurement of the luminous intensity of **light** or the amount of luminous light falling on a surface from such a source. **Spectrophotometry** is the measurement of the intensity of light at selected wavelengths. The term photometric measurement was defined originally as the process used to measure light intensity independent of wavelength. Modern instruments, however, isolate a narrow wavelength range of the spectrum for measurements. Those that use filters for this purpose are referred to as *filter photometers*, whereas those that use prisms or gratings are called spectrophotometers. The primary analytical utility of filter photometry or spectrophotometry is the isolation and use of discrete portions of the spectrum for purposes of measurement.

Basic Concepts

Energy is transmitted via electromagnetic waves that are characterized by their frequency and **wavelength.** Analytically, the term wavelength describes a position within a spectrum. Electromagnetic radiation includes radiant energy that extends from cosmic rays with wavelengths as short as 10^{-9} nm up to radio waves longer than 1000 km. However, in this chapter, the term light is used to describe radiant energy from the ultraviolet to the visible light portions of the spectrum (290 to 750 nm).

In addition to possessing wavelength characteristics, light behaves as if it is composed of discrete energy packets called photons, whose energy is inversely proportional to the wavelength. For example, ultraviolet (UV) radiation at 200 nm possesses greater energy than infrared (IR) radiation at 750 nm.

Table 9-2 shows the approximate relationships between wavelengths and color characteristics for the UV, visible, and short IR portions of the spectrum.

Relationship Between Transmittance and Absorbance

When an incident light beam with intensity I_0 passes through a square cell containing a solution of a compound that absorbs light of a specific wavelength, λ (Figure 9-1), given that the intensity of the transmitted light beam is I, the **transmittance** of light is defined as

$$T = \frac{I}{I_0} \qquad (1)$$

Some of the incident light, however, may be reflected by the surface of the cell or absorbed by the cell wall or solvent. These factors are eliminated by using a reference cell identical to the sample cell, except that the compound of interest is

Table 9-1 Scope of Optical Methods

Type	Example
Absorption	Atomic absorption, densitometry, Fourier transform infrared spectroscopy, photometry, spectrophotometry, reflectance photometry, x-ray spectroscopy
Emission	Fluorescence correlation spectroscopy (FCS), fluorescence energy transfer spectroscopy (FRET), fluorometry, luminometry (light emission from a bioluminescent, chemiluminescent, or electrochemiluminescent reaction), phosphorimetry, time-resolved fluorimetry
Polarization	Fluorescence polarization spectroscopy, polarimetry
Scattering	Nephelometry, turbidimetry

Table 9-2 Ultraviolet, Visible, and Short Infrared Spectrum Characteristics Colors

Wavelength, nm	Region Name	Observed*
<380	Ultraviolet†	Invisible
380-440	Visible	Violet
440-500	Visible	Blue
500-580	Visible	Green
580-600	Visible	Yellow
600-620	Visible	Orange
620-750	Visible	Red
750-2500	Near-infrared	Not visible
2500-15,000	Mid-infrared	Not visible
15,000-1,000,000	Far-infrared	Not visible

*Owing to the subjective nature of color, the wavelength intervals shown are only approximations.
†The ultraviolet (UV) portion of the spectrum is sometimes further divided into "near" UV (220 to 380 nm) and "far" UV (<220 nm). This arbitrary distinction has a practical basis because cuvets made from silica transmit light effectively at wavelengths ≥220 nm.

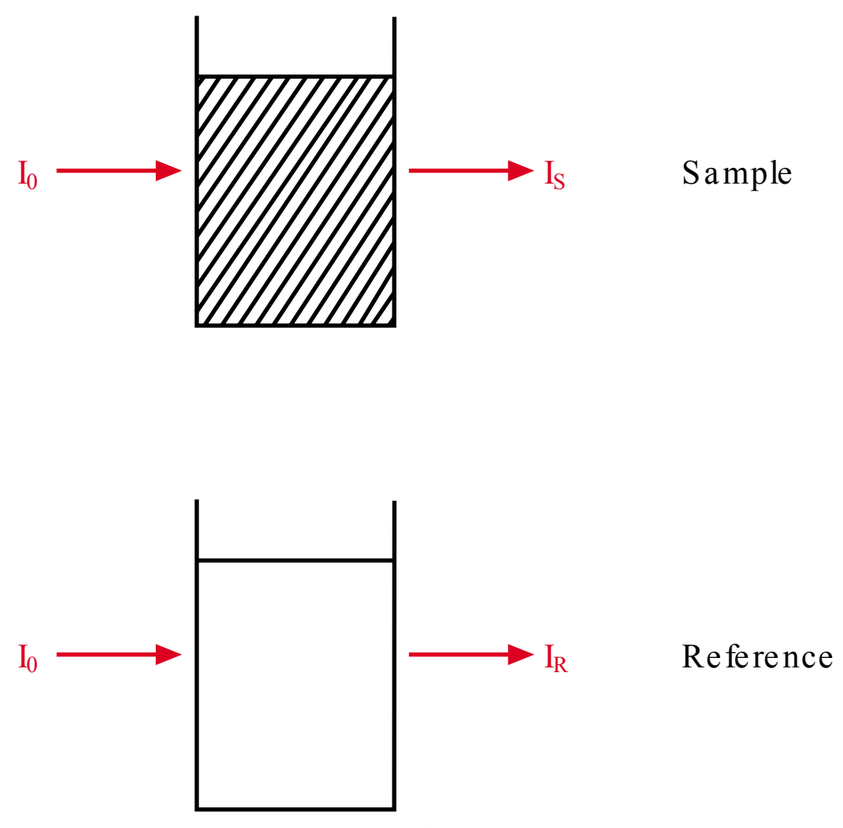

Figure 9-1 Transmittance of light through sample and reference cells. Transmittance of sample versus reference = I/I_R. I_0 = intensity of incident light; I = intensity of transmitted light for compound in solution; I_R = intensity of transmitted light through the reference cell.

omitted from the solvent in the reference cell. The transmittance (T) through this reference cell is I_R divided by I_0; the transmittance for the compound in solution then is defined as I divided by I_R. In practice the reference cell is inserted and the instrument adjusted to an arbitrary scale reading of 100 (corresponding to 100% transmittance), after which the percent transmittance reading is made on the sample. The amount of light absorbed (A) as the incident light passes through the sample is equivalent to

$$A = -\log\frac{I}{I_R} = -\log T \tag{2}$$

Beer's Law

Beer's law states that the concentration of a substance is directly proportional to the amount of light absorbed or is inversely proportional to the logarithm of the transmitted light (Figure 9-2). Mathematically, Beer's law is expressed as

$$A = abc \tag{3}$$

where

A = absorbance;
a = proportionality constant defined as **absorptivity**;
b = light path in centimeters; and
c = concentration of the absorbing compound, usually expressed in grams per liter.

This equation forms the basis of quantitative analysis by absorption photometry. **Absorbance (A)** values have no units; hence, the units for a are the reciprocal of those for b and c. When b is 1 cm and c is expressed in moles per liter, the symbol ε (epsilon) is substituted for the constant a. The value for ε is a constant for a given compound at a given wavelength under prescribed conditions of solvent, temperature, pH, etc., and is called the **molar absorptivity (ε)**. The nomenclature of spectrophotometry is summarized in Table 9-3.

Application of Beer's Law

In practice, the direct proportionality between absorbance and concentration must be established experimentally for a given instrument under specified conditions. Frequently, a linear relationship exists up to a certain concentration or absorbance. When this relationship occurs, the solution is said to obey Beer's law up to this point. Within this limitation, a calibration constant (K) may be derived and used to calculate the concentration of an unknown solution by comparison with a calibrating solution. From Equation (3),

$$a = \frac{A}{bc} \tag{4}$$

Therefore,

$$\frac{A_1}{b_1c_1} = \frac{A_2}{b_2c_2} \tag{5}$$

where subscripts 1 and 2 indicate the absorbance (A), path length (b), and concentration (c) of calibrating and unknown solutions, respectively.

Because the light path (b) remains constant in a given method of analysis with a fixed cuvet size, $b_1 = b_2$, Equation (5) then becomes

$$\frac{A_1}{c_1} = \frac{A_2}{c_2} \text{ or } \frac{A_c}{c_c} = \frac{A_u}{c_u} \tag{6}$$

where c and u represent calibrator and unknown, respectively.

Solving for the concentration of unknown,

$$c_u = \frac{A_u}{A_c} \times c_c \tag{7}$$

or the equivalent expression,

$$c_u = A_u \times \frac{c_c}{A_c} = A_u \times K \tag{8}$$

where $K = c_C/A_C$. The value of the constant K is obtained through measurement of the absorbance (A_C) of a calibrator of known concentration (c_C).

Certain precautions must be observed with the use of such calibration constants. Under no circumstances should the constant be used when the calibrator or unknown readings exceed the linear portion of the calibration curve (i.e., when the curve no longer obeys Beer's law). At least two or preferably more

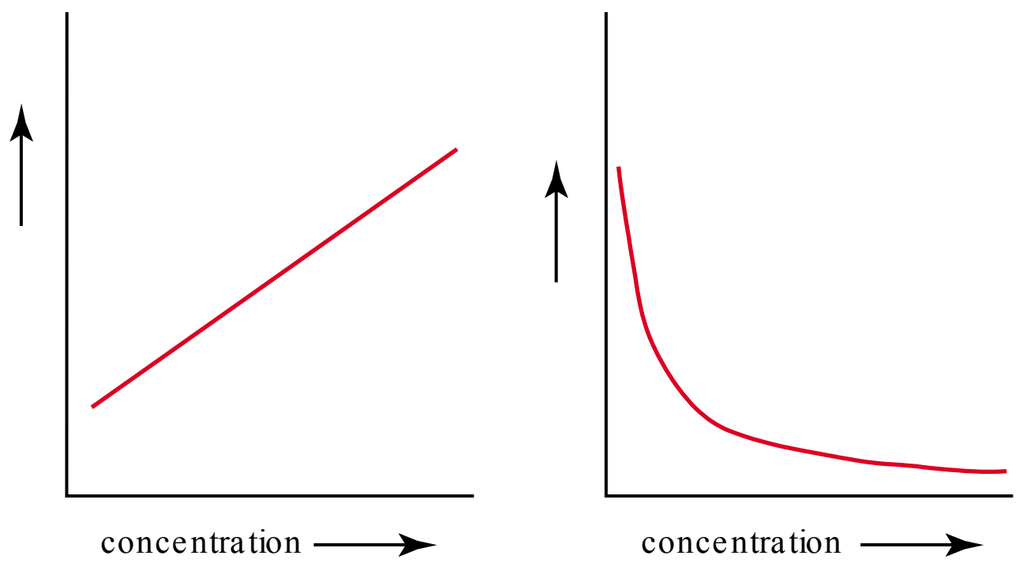

Figure 9-2 Absorbance and %T relationship.

Table 9-3 Spectrophotometry Nomenclature

Name	Symbol	Definition
Absorbance	A	$\log T$ or $\log I_0/I$
Absorptivity	a	A/bc (c in g/L)
Molar absorptivity	ε	A/bc (c in mol/L)
Path length	b	Internal cell or sample length, in cm
Transmittance	T	I/I_0*
Wavelength unit	nm	10^{-9} m
Absorption maximum	λmax	Wavelength at which maximum absorption occurs

*I/I_0 is the ratio of the intensity of transmitted light to incident light.

calibrators should be included in the generation of a calibration curve. A nonlinear calibration curve may be used if a sufficient number of calibrators of varying concentrations are included to cover the entire range encountered for readings on unknowns.

In some cases, a pure reference material may not be readily available, and constants may be provided that were obtained on pure materials and reported in the literature. In general, published constants should be used only if the method is followed in detail and measurements are made on a spectrophotometer capable of providing light of high spectral purity at a verified wavelength. Use of broader-band light sources usually leads to some decrease in absorbance. The absorbance of reduced nicotinamide adenine dinucleotide (NADH) at 340 nm, for example, frequently is used as a reference for the determination of enzyme activity, based on a molar absorptivity of 6.22×10^3 (see Chapter 19). This value is acceptable only under the carefully controlled conditions previously described and should not be used unless these conditions are met. Published values for molar absorptivities and absorption coefficients should be used only as guidelines until they are verified by readings on pure reference materials for a given instrument. In addition, Beer's law is followed only if the following conditions are met:

- Incident radiation on the substance of interest is monochromatic.
- The solvent absorption is insignificant, compared with the solute absorbance.
- The solute concentration is within given limits.
- An optical interferant is not present.
- A chemical reaction does not occur between the molecule of interest and another solute or solvent molecule.

Measurement Errors

With most photometers, the response of the detector to a signal of transmitted light is such that any uncertainty in %T is constant over the entire %T scale. The uncertainty derives from electrical and mechanical imperfections in the instrument and individual variations in the use of the instrument.

A fixed distance on the linear scale (e.g., 1% T) represents a greater change in absorbance for low values of %T than for high values of %T. For this reason, the absolute concentration error or uncertainty is greater when readings are taken at high absorbance. However, the relative concentration error is greater for readings at both low and high absorbances. Studies have shown that the relative error is minimal at an absorbance of 0.434 (36.8% T). Consequently, methods should be designed within an absorbance interval of approximately 0.1 and 0.7 (20% and 80% T).

Instrumentation

Modern instruments isolate a narrow wavelength range of the spectrum for measurements. Those that use filters for this purpose are referred to as *filter* photometers; those that use prisms or gratings are called spectrophotometers. Spectrophotometers are classified as single- or double-beam.

The major components of a single-beam spectrophotometer are shown schematically in Figure 9-3. With such an instrument, a beam of light is passed through a monochromator that isolates the desired region of the spectrum to be used for measurements. Slits are used to isolate a narrow beam of the light and improve its chromatic purity. The light next passes through an absorption cell (cuvet), where a portion of the radiant energy is absorbed, depending on the nature and concentration of the substance in the solution. Any light not absorbed is transmitted to a detector (photocell or phototube), which converts light energy to electrical energy that is registered on a meter or recorder or digitally displayed.

In manual operation, an opaque block is substituted for the cuvet, so that no light reaches the photocell, and the meter is adjusted to read 0% T. Next, a cuvet containing a reagent **blank** is inserted, and the meter is adjusted to read 100% T (zero absorbance). The composition of the reagent blank should be identical to that of calibrating or unknown solutions except for the absorbing substance to be measured. Calibrating solutions containing various known concentrations of the substance are inserted, and readings are recorded. Finally, a reading is made of the unknown solution, and its concentration is determined by comparison with readings obtained on the calibrators. With most spectrophotometers, digital hardware and software are integral components and perform these functions automatically.

Figure 9-4 illustrates schematically a typical double-beam-in-space system in which all components are duplicated except the light source. Another approach is a double-beam-in-time instrument that uses a light-beam chopper (a rotating wheel with alternate silvered sections and cutout sections) inserted after the exit slit (Figure 9-5). A system of mirrors passes the portions of light reflected off the chopper alternately through the sample and a reference cuvet onto a common detector. The chopped-beam approach, using one detector, compensates for light source variation and for sensitivity changes of the detector.

Components

The basic components of a spectrophotometer include (1) a light source, (2) a means to isolate light of a desired wavelength, (3) fiber optics, (4) cuvets, (5) a photodetector, (6) a readout device, (7) a computer, and (8) a recorder.

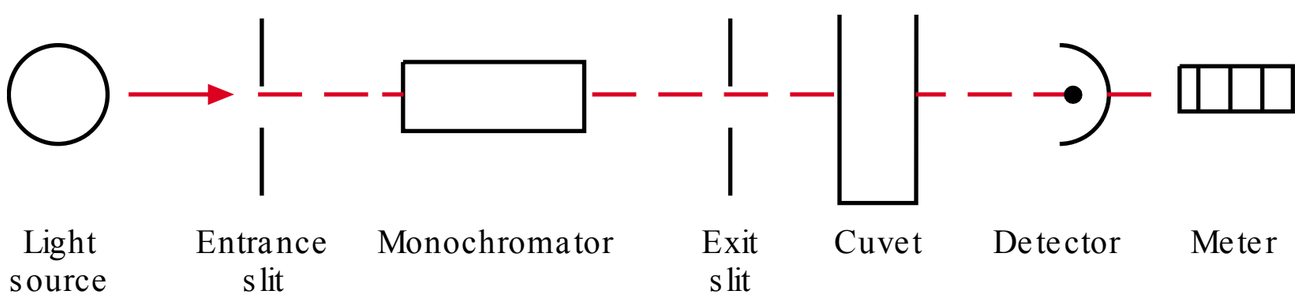

Figure 9-3 Major components of a single-beam spectrophotometer.

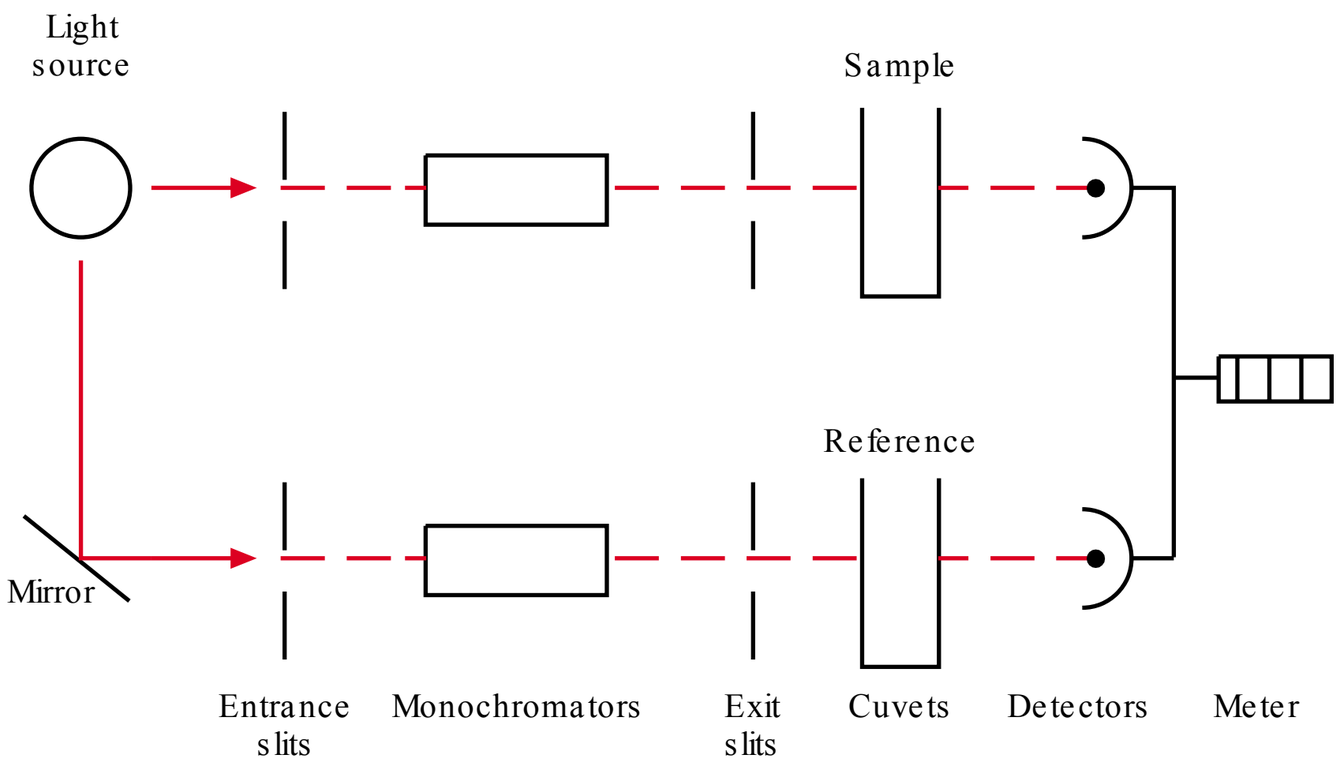

Figure 9-4 Double-beam-in-space spectrophotometer.

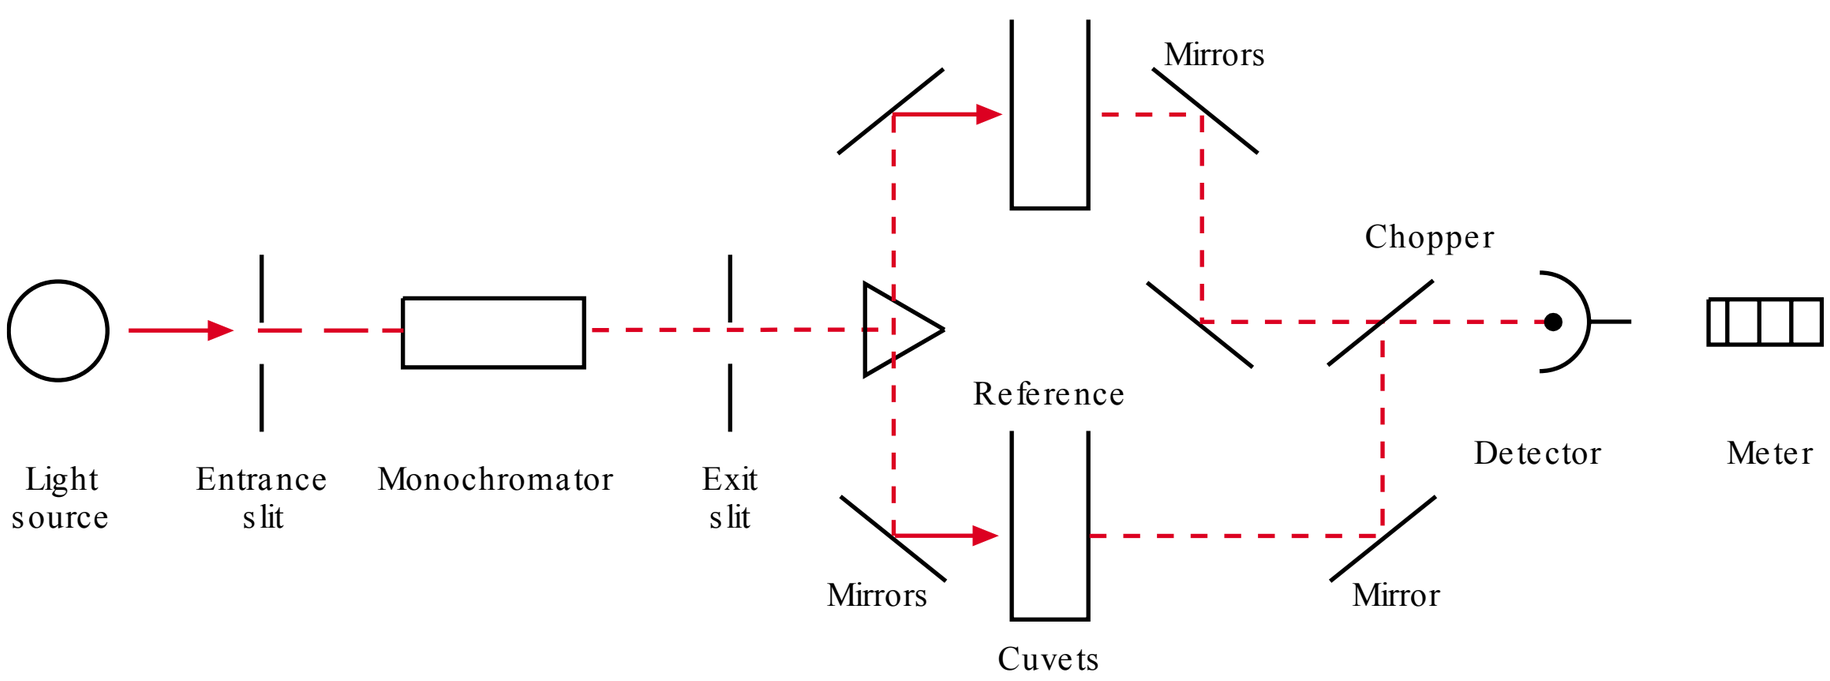

Figure 9-5 Double-beam-in-time spectrophotometer.

Light Sources

Types of light sources used in spectrophotometers include incandescent lamps and lasers.

Incandescent Lamps

T e light source for measurements in the visible portion of the spectrum is usually a tungsten light bulb. T e lifetime of a tungsten filament is greatly increased by the presence of a low pressure of iodine or bromine vapor within the lamp. An example is the quartz-halogen lamp, which has a fused-silica envelope, and which provides high-intensity light over a wide spectrum and for extended operating periods.

A tungsten light source does not supply suf cient radiant energy for measurements below 320 nm. In the UV region of the spectrum, a low-pressure mercury vapor lamp that emits a discontinuous or line spectrum is useful for calibration purposes but is not practical for absorbance measurements because it is used only at certain wavelengths. Hydrogen and deuterium lamps provide sources of continuous spectra in the UV region with some sharp emission lines, as do high-pressure mercury and xenon arc lamps. T ese sources are more commonly used in UV absorption measurements. A deuterium lamp is more stable and has a longer life than a hydrogen lamp.

A widely used photometer employed as a high-pressure liquid chromatographic (HPLC) detector uses the intense 254-nm resonance line produced by a mercury arc lamp (see Chapter 12). Others employ a miniature hollow cathode lamp as a very-narrow-wavelength intense source. For example, a zinc hollow cathode lamp gives a line at 214 nm that is adequately close to the maximum wavelength of peptide bond absorption (206 nm) and has been used to measure peptides and proteins. Details on the hollow cathode lamp are found in the section on Atomic Absorption Spectrophotometry.

Laser Sources

A laser (light amplification by stimulated emission of radiation) is a device that also is used as a light source in spectrophotometers. T ese devices transform light of various frequencies into an extremely intense, focused, and nearly nondivergent beam of monochromatic light. T rough selection of different materials, different wavelengths of light emitted by the laser are obtained (Table 9-4).

Spectral Isolation

A system for isolating radiant energy of a desired wavelength and excluding that of other wavelengths is called a monochromator. Devices used for spectral isolation include (1) filters,

Table 9-4 Various Types of Lasers and the Wavelengths at Which They Operate

Laser	Wavelength, nm
Argon fluoride	193
Argon fluoride	248
Helium-cadmium	325 or 442
Nitrogen	337
Argon (blue)	488
Argon (green)	514
Helium-neon (green)	543
Light-emitting diode—GaP	550 or 700
Rhodamine 6G dye (tunable)	570-650
Laser diode (AlGaInP, GaAlAs)	634-1660
Helium-neon (red)	633
Ruby ($CrAlO_3$) (red)	694
Light-emitting diode—GaAs	880
Light-emitting diode—Si	1100

Carbon dioxide	9300, 9600, 10,300, or 10,600

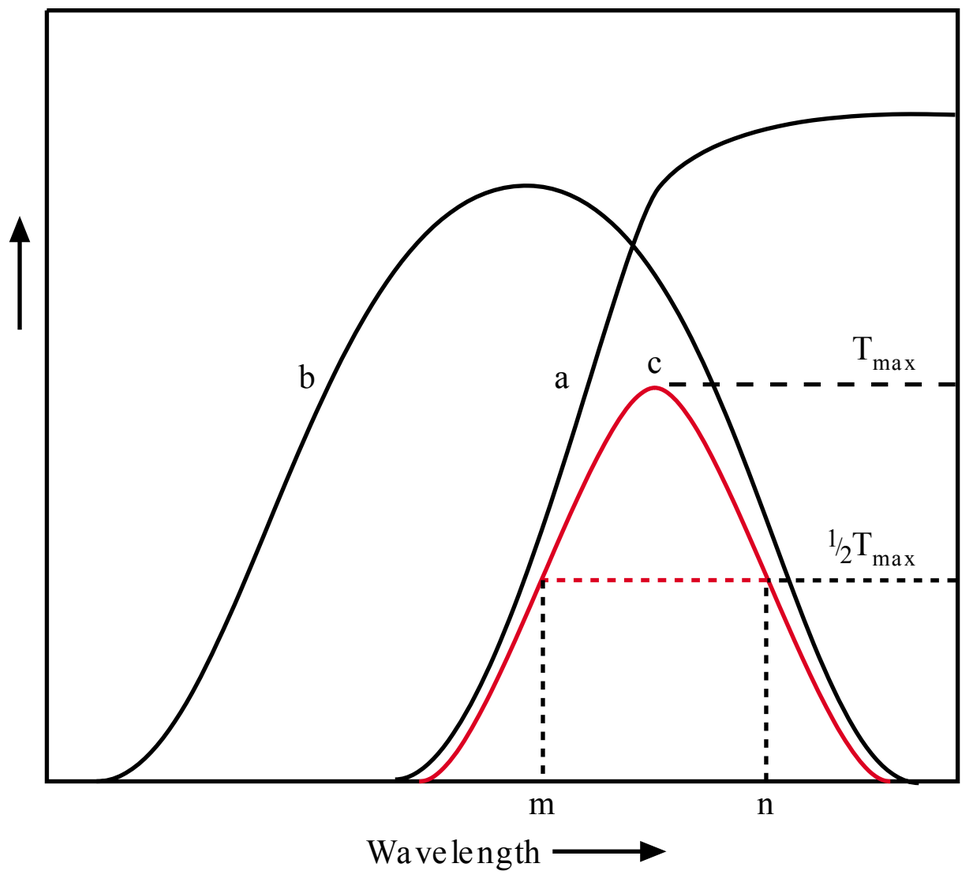

Figure 9-6 Spectral characteristics of a sharp-cutoff filter (a) and a wide-bandpass filter (b). The narrow-bandpass filter (c) is obtained by combining filters a and b. The spectral bandwidth of filter c (distance n-m) is defined as the width in nanometers of the spectral transmittance curve at a point equal to one-half of maximum transmittance.

(2) prisms, and (3) diffraction gratings. In addition, combinations of lenses and slits are often inserted before or after the monochromatic device to render light rays parallel or to isolate narrow portions of the light beam. Variable slits also are used to permit adjustments in total radiant energy reaching the photocell.

Filters

The simplest type of filter is a thin layer of colored glass. Strictly speaking, a glass filter is not a true monochromator because it transmits light over a relatively wide range of wavelengths. The spectral purity of a filter or other monochromator is usually described in terms of its **spectral bandwidth**. This is defined as the width, in nanometers, of the spectral transmittance curve at a point equal to one-half the peak transmittance (Figure 9-6). Commonly used glass filters have spectral bandwidths of approximately 50 nm and are referred to as wide-**bandpass** *filters*.

Other glass filters include the narrow-bandpass and sharp-cutoff types (see Figure 9-6). As shown, a cutoff filter typically shows a sharp rise in transmittance over a narrow portion of the spectrum and is used to eliminate light below a given wavelength. Narrow-bandpass filters are constructed by combining two or more sharp-cutoff filters or regular filters.

Interference filters are also used as monochromators. These filters have narrow spectral bandwidths, usually from 5 to 15 nm. Because they also transmit harmonics, or multiples, of the desired wavelength, accessory glass filters are required to eliminate these undesired wavelengths. Thus an interference filter designed for 620 nm will also transmit some radiation at 310 and 1240 nm unless accessory cutoff filters are provided to absorb this undesired stray light.

Prisms and Gratings

Prisms and diffraction gratings are also widely used as monochromators. A prism separates white light into a continuous spectrum by refraction with shorter wavelengths that are being bent, or refracted, to a greater extent than longer wavelengths as they pass through the prism. A *diffraction* grating is prepared by depositing a thin layer of aluminum-copper alloy on the surface of a flat glass plate; then, many small parallel grooves are made in the metal coating. Diffraction gratings (1) are extremely accurate, (2) have low light scatter, and (3) are widely used in the spectrophotometers used in analytical instruments. For example, most UV-visible spectrophotometers and virtually all IR spectrophotometers use reflective gratings. In addition, HPLC detectors frequently use a concave holographic reflective grating in their optical system.

Each groove of the grating, when illuminated, gives rise to a tiny spectrum. Wave fronts are formed that reinforce those wavelengths in phase and cancel those not in phase. The net result is a uniform linear spectrum. Some instruments contain diffraction gratings that produce spectral bandwidths of 20 nm or more; higher-priced instruments may have a resolution of 0.5 nm or less.

A grating may also be ruled at a specified angle, so that a maximum fraction of the radiant energy is directed into wavelengths diffracted at a selected angle. This type of grating is called an echelette and is said to have been given a blaze at a particular angle or to have been blazed at a certain wavelength (e.g., 250 nm).

Selection of a Monochromator

The type of monochromator chosen depends on the analytical purpose for which it is to be used. For example, narrow spectral bandwidths are required in spectrophotometers for resolving and identifying sharp absorption peaks that are closely adjacent. Lack of agreement with Beer's law will occur when a part of the spectral energy transmitted by the monochromator

is not absorbed by the substance being measured. T is is more commonly observed with wide-bandpass instruments.

Some increase in absorbance and improved linearity with concentration are usually observed with instruments that operate at narrower bandwidths of light. T is is especially true for substances that exhibit a sharp peak of absorption. Spectral absorbance curves for a solution of coproporphyrin I (Figure 9-7) demonstrate a notable decrease in maximum absorbance as the spectral bandwidth is increased from 1 to 20 nm. T e natural bandwidth of an absorbing substance is defined as "the bandwidth of the spectral absorbance curve at a point equal to one-half of the maximum absorbance." Curve a in Figure 9-7, scanned at a spectral bandwidth of 1 nm, shows a natural bandwidth of approximately 10 nm. As a general rule, for peak absorbance readings to be within 99.5% of true values, the spectral bandwidth should not exceed 10% of the natural bandwidth. For example, many chemistry procedures used in the clinical laboratory produce an absorbing species for which the natural bandwidth ranges from 40 to greater than 200 nm. T e natural bandwidth of NADH is 58 nm (λmax = 339 nm). T erefore, for accurate measurements of this compound, an instrument should be used that has a spectral bandwidth of 6 nm or less.

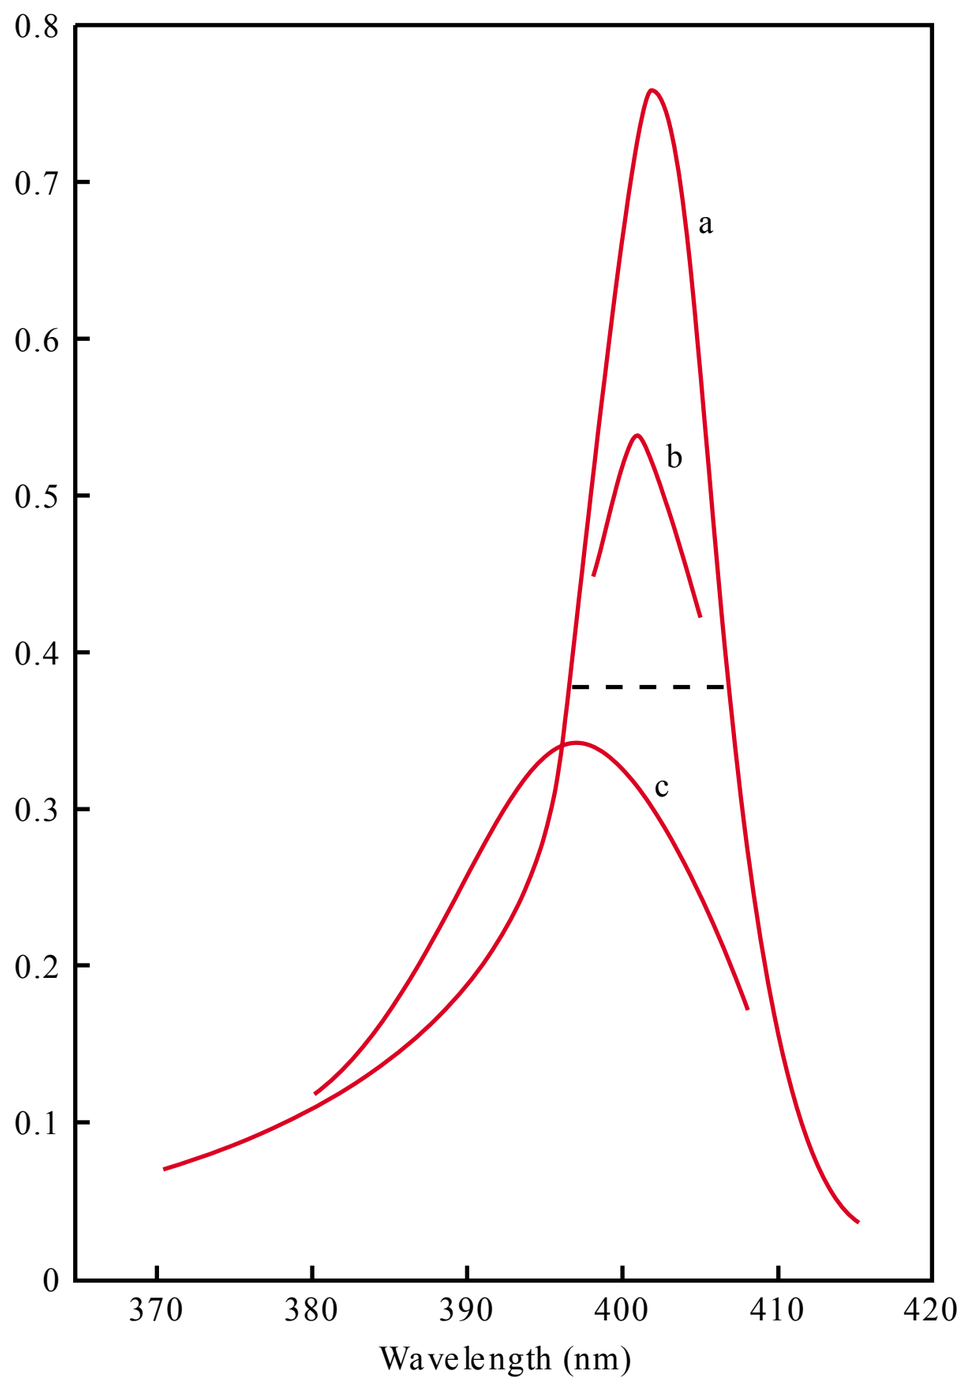

Figure 9-7 Effect of spectral bandwidth (SBW) on the absorption spectrum of coproporphyrin I. Nominal concentration, 1 µg/mL in HCl, 0.1 mol/L. SBW: curve a, 1 nm; curve b, 10 nm; and curve c, 20 nm. The dotted horizontal line shows a natural bandwidth of 10 nm for coproporphyrin I when scanned at a spectral bandwidth of 1 nm. The shift of A_{max} to lower wavelengths as SBW is increased is related to skewness of the absorption spectrum to the left.

In practice, the wavelength selected is usually at the peak of maximum absorbance to achieve maximum sensitivity; however, it may be desirable to choose another wavelength to minimize interfering substances. For example, **turbidity** readings on a spectrophotometer are greater in the blue region than in the red region of the spectrum, but the latter region is chosen for turbidity measurements to avoid absorption of light by bilirubin (460 nm) or hemoglobin (417 and 575 nm). In addition, measurements should not be taken on the steep slope of an absorption curve because a slight error in wavelength adjustment will introduce a significant error in absorbance readings.

Fiber Optics

In the single- and double-beam spectrophotometers shown diagrammatically in Figures 9-4 and 9-5, the positioning of the individual components dictates the path that the light beam must follow as it travels from the source to the detector. T is approach places certain restrictions on the (1) design, (2) size, and (3) cost of such instruments. To overcome these restrictions, fiber optics are now integrated into the optical design of spectrophotometers. Fiber optics, also known as light pipes, are bundles of thin, transparent fibers of glass, quartz, or plastic that are enclosed in material of a lower index of refraction and that transmit light throughout their lengths by internal reflections. T e use of fiber optics in spectrophotometers offers the advantage of better directional control of the beam of light within the geometrical confines of an instrument. T is allows for the design and manufacture of miniature and inexpensive optical subsystems for use in automated instruments. For example, a single light source is multiplexed with multiple detectors by fiber optics for optimal positioning of the source and detectors in an automated system. Disadvantages of fiber optics include (1) greater amounts of stray light; (2) refractive index changes in the glass, quartz, or plastic rods; and (3) loss of transmitted energy after continued use in the UV region of the spectrum. T is loss of energy is known as solarization and results in a decrease in the optical performance of an instrument.

Cuvets

A cuvet (also often termed a cuvette) is a small vessel used to hold a liquid sample to be analyzed in the light path of a spectrometer. Cuvets may be (1) round, (2) square, or 3) rectangular and are constructed from (1) glass, (2) silica (quartz), or (3) plastic. Square or rectangular cuvets have plane-parallel optical surfaces and a constant light path. Most have a 1.0-cm light path, held to close tolerances. Ordinary borosilicate glass cuvets are suitable for measurements in the visible portion of the spectrum. For readings below 340 nm, however, quartz cells are usually required. Some plastic cells have good clarity in both visible and UV ranges but often present problems related to (1) tolerance, (2) cleaning, (4) etching by solvents, and (4) temperature deformation. Many plastic cuvets are designed for disposable, single-use applications.

Cuvets must be clean and optically clear because etching or deposits on the surface affect absorbance values. Cuvets used in the visible range are cleaned by copious rinsing with tap water and distilled water. Alkaline solutions should not be left standing in cuvets for prolonged periods because alkali slowly dissolves glass and produces etching. Cuvets may be cleaned in mild detergent or soaked in a mixture of concentrated HCl/water/ethanol (1:3:4). Cuvets should never be soaked in dichromate cleaning solution because the solution is hazardous and tends to adsorb onto and discolor the glass.

Cuvets used for measurements in the UV region should be handled with special care. Invisible scratches, fingerprints, or residual traces of previously measured substances may be present and may absorb significantly. A good practice is to fill all such cuvets with distilled water and measure the absorbance for each against a reference blank over the wavelengths to be used. T is value should be essentially zero.

Photodetectors

Photodetectors are devices that convert light into an electrical signal that is proportional to the number of photons striking its photosensitive surface. T e photomultiplier tube (PMT) is a photodetector that is commonly to measure light intensity in UV and visible regions of the spectrum. PMTs (1) have extremely rapid response times, (2) are very sensitive, and (3) are slow to fatigue.

Photodiodes also are used as photodetectors. T ey are solid-state devices that are fabricated from photosensitive semiconductor materials, such as (1) silicon, (2) gallium arsenide, (3) indium antimonide, (4) indium arsenide, (5) lead selenide, and (6) lead sulfide. T ese materials absorb light over a characteristic wavelength range (e.g., 250 nm to 1100 nm for silicon). T eir development and use as detectors in spectrophotometers have resulted in instruments capable of measuring light at a multitude of wavelengths. When a photodetector consists of two-dimensional arrays of diodes, each of which responds to a specific wavelength, it is known as a photodiode array. For example, photodiode arrays have been designed to have a 2-nm resolution per diode from 200 to 340 nm, and a 1-nm resolution per diode from 340 to 800 nm.

Readout Devices

Electrical energy from a detector is displayed on some type of meter or readout system. Historically, analog devices were widely used as readout devices in spectrophotometers. However, they have been replaced by digital readout devices that provide a visual numerical display of absorbance or converted values of concentrations. T ese operate on the principle of selective illumination of portions of a bank of light-emitting diodes (LEDs), controlled by the voltage signal generated. Visible LEDs incorporate gallium as the major component, and at present, $GaAs_XP_X$ diodes that emit red light are most widely used. Compared with meters, digital readout devices have faster response and are easier to read.

Digital Hardware and Software Computers

Various types of digital hardware, with resident software and processors, are incorporated and integrated into both photometers and spectrophotometers. For example, with a resident computer and software, (1) output from a calibrator is digitally stored, (2) digital signals from blanks are subtracted from calibrators and unknowns, and (3) the concentration of unknowns is automatically calculated. Data from multiple calibrators often are used to (1) store a complete calibration curve, (2) display or print out the curve for visible inspection, and (3) calculate results of unknowns based on the curve or some mathematical transformation of the data. Computers and their resident software also are used to convert kinetic data into concentration or enzyme activity.

Recorders

Historically, spectrophotometers were equipped with recorders in addition to or instead of a digital display. T ese were synchronized to provide line traces of transmittance or absorbance as a function of time or wavelength. When a continuous tracing of absorbance versus wavelength is recorded, the resultant figure is called an absorption spectrum. If a substance absorbs light, distinct peaks of absorbance will be observed. Measuring the absorption spectra of an unknown sample and comparing them with spectra from known compounds is very useful for qualitative purposes. For example, this type of procedure is especially useful for identification of drugs that absorb in the UV region. Several criteria are used, including (1) determination of those wavelengths showing maximum and minimum absorbance in both dilute acid and alkaline solutions; (2) absorptivity at the wavelength of maximum absorbance; and (3) ratios of absorbance at two wavelengths. Finally, the entire spectrum is compared with that of a known sample of the suspected drug.

Performance Parameters

In most spectrophotometric analytical procedures, the absorbance of an unknown is compared directly with that of a calibrator or a series of calibrators. Under these circumstances, (1) minor errors in wavelength calibration, (2) variations in spectral bandwidths, and (3) the presence of stray light are compensated for and do not usually contribute to serious errors. Use of a series of calibrators covering a wide range of concentrations also provides a measure of linearity and validation of agreement with Beer's law for a given procedure and instrument. However, when calculations are based on published or previously determined values for molar absorptivities or absorption coef cients, the spectrophotometer must be checked more rigorously.

T e National Institute of Standards and Technology (NIST) provides several standard reference materials (SRMs) for spectrophotometry that are useful in the calibration or verification of the performance of photometers or spectrophotometers (e.g., SRM 930e is used for the verification and calibration of the transmittance and absorbance scales of visible absorption spectrometers) (http://www.nist.gov; accessed July 21, 2013). T e Institute for Reference Materials and Measurements

(IRMM), a metrology institute that belongs to the European Commission, also provides reference materials for verification of the performance of photometers or spectrophotometers (http://www.irmm.jrc.be; accessed July 21, 2013).

Reflectance Photometry

In **reflectance photometry,** diffused light illuminates a reaction mixture in a carrier, and the reflected light is measured.[4] Alternatively, the carrier is illuminated and the reaction mixture generates a diffuse reflected light, which is measured. The intensity of the reflected light from the reagent carrier is compared with the intensity of light reflected from a reference surface. Because the intensity of reflected light is nonlinear in relation to the concentration of the analyte, the Kubelka-Munk equation or the Clapper-Williams transformation is commonly used to convert the data into a linear format. The electro-optical components used in reflectance photometry are essentially the same as those required for absorbance photometry. Reflectance photometry is used as the measurement method with dry-film chemistry systems.

Atomic Absorption Spectrophotometry

Atomic absorption (AA) spectrophotometry is used widely in clinical laboratories to measure elements including (1) aluminum, (2) calcium, (3) copper, (4) lead, (5) lithium, (6) magnesium, and (7) zinc.

Basic Concepts

AA is an optical technique in which an element in the sample is excited and the radiant energy produced is measured as the element returns to its lower energy level. However, the element is not appreciably excited in the flame but is merely dissociated from its chemical bonds (atomized) and placed in an unexcited or ground state (neutral atom). Thus, the atom is at a low energy level, at which it is capable of absorbing radiation at a very narrow bandwidth corresponding to its own line spectrum. A hollow-cathode lamp with the cathode made of the material to be analyzed is used to produce a wavelength of light specific for the material. Thus, if the cathode was made of calcium, calcium light at predominantly 423 nm would be emitted by the lamp. When the light from the hollow-cathode lamp enters the flame, some of it is absorbed by the ground-state atoms in the flame, resulting in a net decrease in the intensity of the beam from the lamp. This process is referred to as atomic absorption. Owing to the unique specificity of the wavelength from the hollow-cathode lamp, these methods are highly specific for the element being measured.

Instrumentation

The components of an AA spectrophotometer are shown in Figure 9-8. A hollow-cathode lamp serves as the light source for an AA spectrophotometer. Such lamps are made of the metal of the substance to be analyzed; this is different for each metal analysis. When an alloy is used to make the cathode, the result is a multielement lamp.

With *flameless* AA techniques (carbon rod or "graphite furnace"), the sample is placed in a depression on a carbon rod in an enclosed chamber. Strips of tantalum or platinum metal are used as sample cups. In successive steps, the temperature of the rod is raised to dry, char, and finally atomize the sample in the chamber. The atomized element then absorbs energy from the corresponding hollow-cathode lamp. This approach is very sensitive and permits determination of trace metals in small samples of blood or tissue.

With flameless AA, a novel approach called the Zeeman correction has been used to correct for background absorption.[10] With Zeeman background correction, the analyte is placed in a strong magnetic field. The intense magnetic field splits the degenerate (i.e., of equal energy) atomic energy levels of equal energy into two components that are polarized parallel and perpendicular to the magnetic field, respectively. The parallel component is at the resonance line of the source, whereas the two perpendicular components are shifted to different wavelengths. The two components interact differently with polarized light. A polarizer is placed between the source and the atomizer, and two absorption measurements are taken at different polarizer settings. One measures both analyte and background absorptions (A_t), the other only background absorption (A_{bc}). The difference between the two absorption readings is the corrected absorbance.

The major advantage of the Zeeman correction method is that the same light source at the same wavelength is used to measure total and background absorption. Implementation is complex and expensive, and the strength of the magnetic field needs to be optimized for every element, but the method gives more accurate results at higher background levels than are associated with other correction techniques.

Limitations of Atomic Absorption Spectrophotometry

Spectral and nonspectral interferences are limitations of AA spectroscopy.

Spectral Interferences

Spectral interferences include (1) absorption by other closely absorbing atomic species, (2) absorption by molecular species, (3) scattering by nonvolatile salt particles or oxides, and

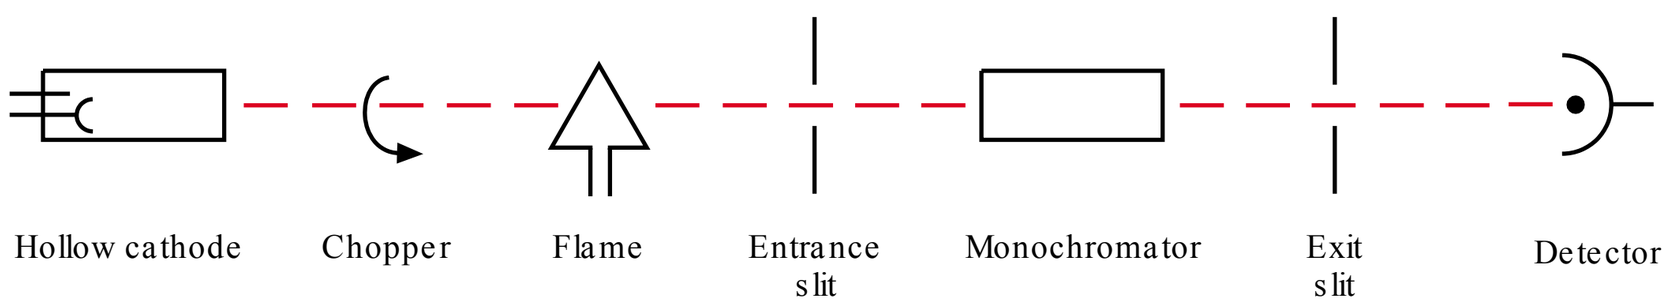

Figure 9-8 Basic components of an atomic absorption spectrophotometer.

(4) background emission (which is corrected for by electronic filtering). Absorption by other atomic species usually is not a problem because of the extremely narrow bandwidth (0.01 nm) used in absorption measurements. Absorption and scattering by molecular species are particularly problematic in lower atomizing temperatures.

Nonspectral Interferences

Nonspectral interferences may be nonspecific or specific. Nonspecific interferences affect nebulization by altering the (1) viscosity, (2) surface tension, or (3) density of the analyte solution, and consequently the sample flow rate. Specific interferences (chemical interferences) are analyte dependent. Solute volatilization interference refers to the situation in which the contaminant forms nonvolatile species with the analyte. An example is seen in phosphate interference in the determination of calcium that is caused by the formation of calcium-phosphate complexes. The phosphate interference is eliminated by adding a cation, usually lanthanum or strontium that competes with calcium for the phosphate. Enhancement effects are also observed, in which the addition of contaminants increases the volatilization efficiency. Such is the case with aluminum, which normally forms nonvolatile oxides but in the presence of hydrofluoric acid forms more volatile aluminum fluoride. Dissociation interferences affect the degree of dissociation of the analyte. Analytes that form oxides or hydroxides are especially susceptible to dissociation interferences. Ionization interference occurs when the presence of an easily ionized element, such as K, affects the degree of ionization of the analyte, which leads to changes in the analyte signal. In cases of excitation interference, the analyte atoms are excited in the atomizer, with subsequent emission at the absorption wavelength. This type of interference is more pronounced at higher temperatures.

Fluorometry

Fluorescence occurs when a molecule absorbs light at one wavelength and reemits light at a longer wavelength. An atom or molecule that fluoresces is termed a *fluorophore*. **Fluorometry** is defined as the measurement of emitted fluorescence light. Fluorometric analysis is a very sensitive and widely used method of quantitative analysis in the chemical and biological sciences.[5]

Basic Concepts

The relationship between (1) absorption, (2) fluorescence, and (3) phosphorescence is shown in Figure 9-9. As indicated, each molecule contains a series of closely spaced energy levels. Absorption of a quantum of light energy by a molecule causes the transition of an electron from the singlet ground state to one of a number of possible vibrational levels of its first singlet state. The actual number of molecules in the excited state under typical reaction conditions and excited with a typical 150-W light source is very small and is estimated to be about 10^{-13} mole per mole of fluorophore. Once the molecule is in an excited state, it returns to its original energy state by different mechanisms. These include (1) radiation-less vibrational equilibration, (2) the fluorescence process, (3) quenching of the excited singlet state, (4) radiation-less crossover to a triplet state, (5) quenching of the first triplet state, and (6) the phosphorescence process.

As shown in Figure 9-9, vibrational equilibration before fluorescence results in some loss of excitation energy. The emitted fluorescence light is therefore of less energy or has a longer wavelength than the excitation light. The difference between the maximum wavelength of the excitation light and the maximum wavelength of the emitted fluorescence light is a constant referred to as the Stokes shift. This constant is a measure of energy lost during the lifetime of the excited state (radiation-less vibrational deactivation) before return to the ground singlet level (fluorescence emission).

Time Relationships of Fluorescence Emission

The time required for a molecule to absorb radiant energy and to be promoted to an excited state is approximately 10^{-15} s. The length of time needed for vibrational equilibration to occur to the lowest excited state is of the order of 10^{-14} to 10^{-12} s. The length of time required for fluorescence emission to occur is of the order of 10^{-8} to 10^{-7} s. Relatively speaking, there is a considerable time delay between (1) absorption of light energy, (2) return to the lowest excited state, and (3) emission of fluorescence light. This time relationship is shown in Figure 9-10. Phase I represents the time period between absorbance of light energy and radiation-less loss of energy during vibrational rearrangement to the lowest excited energy state. This is time period is represented by the up and down arrows in the diagram. Phase II shows the emission and decay of a short-lived (b) and a longer-lived (a) fluorophore. If the fluorescence emission is measured over time following a pulse of light from an excitation source, such as a xenon lamp or laser, the intensity of the emitted light decays as a first-order process similar to radioactive decay. The time required for the emitted light to

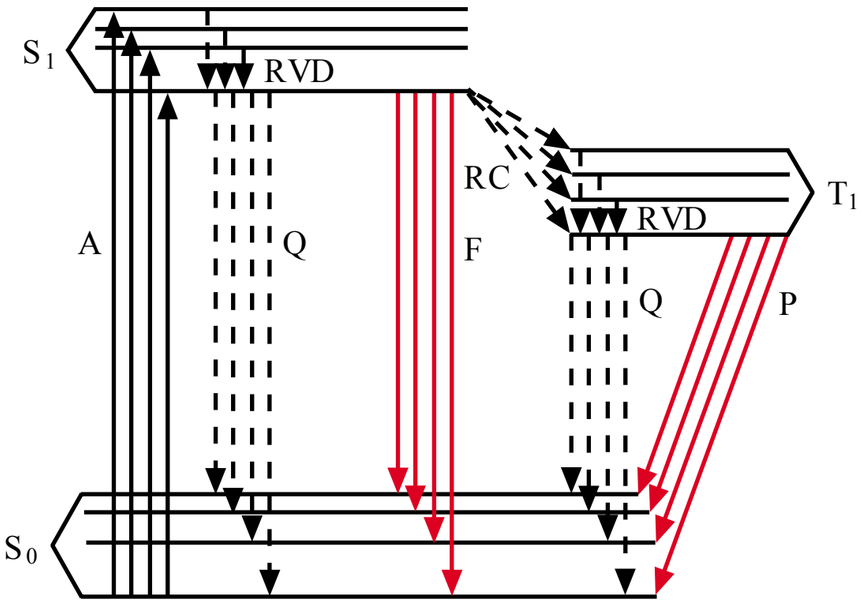

Figure 9-9 Luminescence energy-level diagram of typical organic molecule. S_0 is the ground level singlet state; S_1 is the first excited singlet state; A is the absorption process; T_1 is the first excited triplet state; and RVD is the radiation-less vibrational deactivation. Q is quenching of the excited singlet or triplet state. F is the fuorescence process from the first excited singlet state. P is the phosphorescence process from the first excited triplet state. RC is the radiation-less crossover from the first excited singlet state to the first excited triplet state.

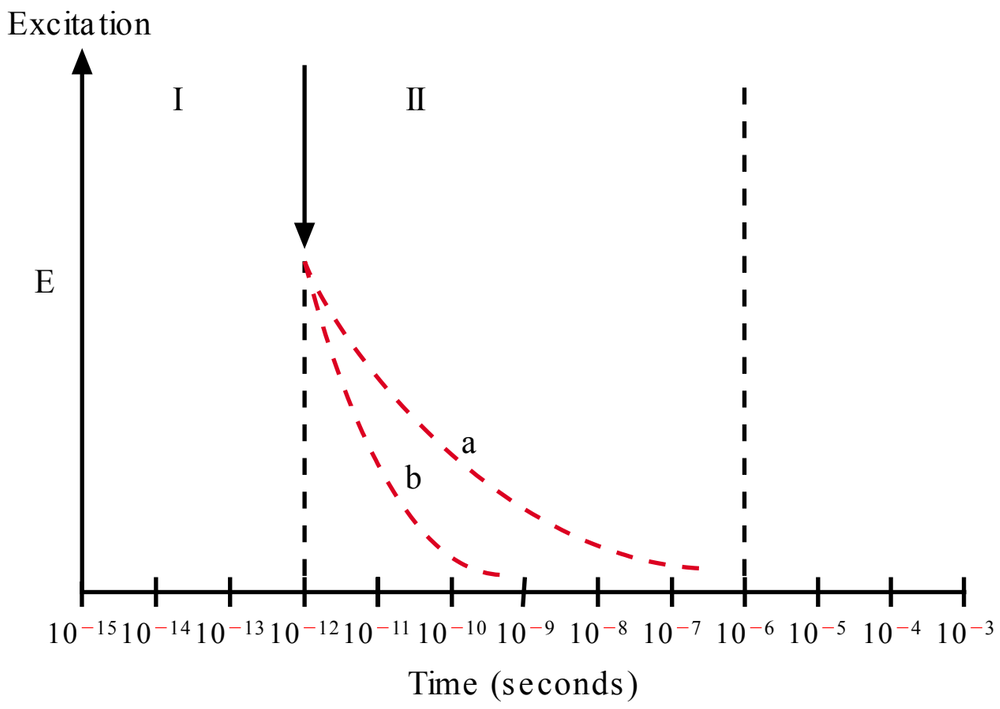

Figure 9-10 Fluorescence decay process: E is the absorption of energy; I is the vibrational deactivation time phase; II is the fuorescence emission time phase; a is long fuorescence decay time; and b is short fuorescence decay time.

reach 1/e of its initial intensity, where e is the Naperian base 2.718, is called the average lifetime of the excited state of the molecule, or the fluorescence decay time.

The time delay between absorption of quanta of energy and fluorescence used in fluorescence instrumentation is called a time-resolved fluorometer. Advantages of a time-resolved fluorometer include the elimination of background light scattering and background from short-lived fluorescence. This results in a consequent dramatic increase in the signal-to-noise ratio and detection sensitivity.

Depending on how the fluorescence emission response is measured, time-resolved fluorometry[3] is categorized as pulse or phase fluorometry. In pulse fluorometry, the sample is illuminated with an intense brief pulse of light, and the intensity of the resulting fluorescence emission is measured as a function of time with a fast detector system. In phase fluorometry, a continuous-wave laser illuminates the sample, and the fluorescence emission response is monitored for impulse and frequency response.[6]

Relationship of Concentration and Fluorescence Intensity

The relationship of concentration to the intensity of fluorescence emission is derived from Beer's law and is expressed as:

$$F = \Phi I_0 abc \tag{9}$$

where

F = relative intensity;
Φ = fluorescence efficiency (i.e., the ratio between quanta of light emitted and quanta of light absorbed);
I_0 = initial excitation intensity;
a = molar absorptivity;
b = volume element defined by geometry of the excitation and emission slits; and
c = the concentration in mol/L.

Equation (9) indicates that fluorescence intensity is directly proportionate to the concentration of the fluorophore and the intensity of the excitation. This relationship holds only for dilute solutions in which absorbance is less than 2% of the exciting radiation. Above 2%, the fluorescence intensity becomes nonlinear. This phenomenon is called the inner filter effect, and it is discussed in greater detail in a later section. Other factors influencing the measurement of fluorescence intensity are the sensitivity of the detector and the degree of background light scatter seen by the detector.

Fluorescence intensity measurements are more sensitive than absorbance measurements. The magnitude of absorbance of a chromophore in solution is determined by its concentration and the path length of the cuvet. The magnitude of the fluorescence intensity of a fluorophore is determined by (1) its concentration, (2) the path length, and (3) the intensity of the light source. Comparatively, fluorescence measurements are 100 to 1000 times more sensitive than absorbance measurements. This is due to the use of (1) more intense light sources, (2) digital signal filtering techniques, and (3) sensitive emission photometers.

Frequently, fluorescence measurements are expressed in relative intensity units. The word relative is used because the intensity measured is not an absolute quantity. It is a small part of the total fluorescence emission, and its magnitude is defined by (1) instrument slit width, (2) detector sensitivity, (3) monochromator efficiency, and (4) excitation intensity. Because these are instrument-related variables, establishing an absolute intensity unit for a given concentration of a fluorophore that is valid from instrument to instrument is difficult, if not impossible.

Fluorescence Polarization

Light is composed of electrical and magnetic waves at right angles to each other. Light waves produced by standard excitation sources have their electrical vectors oriented randomly. Light waves passed through certain crystalline materials (polarizers) have their electrical vectors oriented in a single plane and are said to be plane-polarized. Fluorophores absorb light most efficiently in the plane of their electronic energy levels. If their rotational relaxation (Brownian movement) is slower than their fluorescence decay time, as is the case for large fluorescent-labeled molecules, the emitted fluorescence light will be polarized. Because small molecules have rotational relaxation times that are much shorter than their fluorescence decay time, their emitted fluorescence light is depolarized. However, if the small fluorescent molecule is attached to a macromolecule, or if it is placed in a viscous solution, the small molecule will emit polarized light. Fluorescence polarization, P, is defined by the following equation:

$$P = \frac{I_v - I_h}{I_v + I_h} \tag{10}$$

where
I_v = intensity of emitted fluorescence light in the vertical plane; and
I_h = intensity of emitted fluorescence light in the horizontal plane.

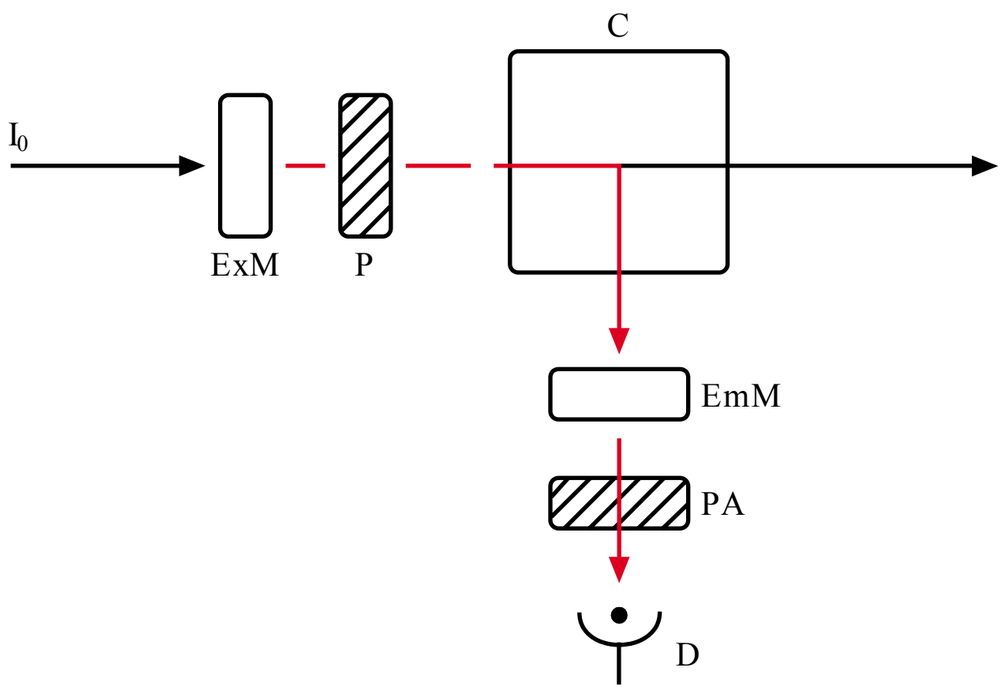

Figure 9-11 Schematic diagram of a fuorescence polarization analyzer. I_0 is the intensity of excitation light. P is the polarizer to provide polarized excitation light. PA is the polarizer analyzer, which is rotated to provide the measurement of parallel and perpendicular polarized fuorescence-emission intensity. ExM is the excitation monochromator, EmM is the emission monochromator, D is the detector, and C is the reaction cell or cuvet.

As indicated, P is the difference between the two observed intensities divided by their sum. Fluorescence polarization is measured by placing a mechanically or electrically driven polarizer between the sample cuvet and the detector. A diagram of a fluorescence polarization measurement system is shown in Figure 9-11. In the normal instrumentation mode, the sample is excited with polarized light to obtain maximum sensitivity. First, the polarization analyzer is positioned to measure the intensity of emitted fluorescence light in the vertical plane (I_v), and then the polarization analyzer is rotated 90° to measure emitted fluorescence light intensity in the horizontal plane (I_h). P is then calculated manually or automatically by using Equation (10).

Fluorescence polarization is used to quantitate analytes by using the change in fluorescence depolarization following immunologic reactions (see Chapter 15). Quantitation is accomplished by adding a known quantity of fluorescent-labeled analyte molecules to a reaction solution containing an antibody specific to the analyte. The labeled analyte binds to the antibody, resulting in a change in its rotational relaxation time and fluorescence polarization. The addition of a nonlabeled analyte, such as an unknown quantity of a therapeutic drug in a serum specimen, will result in competition for binding to the antibody with the fluorescent-labeled analyte. This change in binding of the fluorophore-labeled analyte causes a change in fluorescence polarization that is inversely proportional to the amount of analyte contained in a given sample. Because the change in fluorescence polarization is a direct response to the reaction mixture, the bound fluorophore need not be separated from free fluorophore. Thus fluorescence polarization is applicable to homogeneous assays of low-molecular-weight analytes, such as therapeutic drugs.[7]

Instrumentation

Fluorometers and spectrofluorometers are used to measure fluorescence. Operationally, a fluorometer uses interference

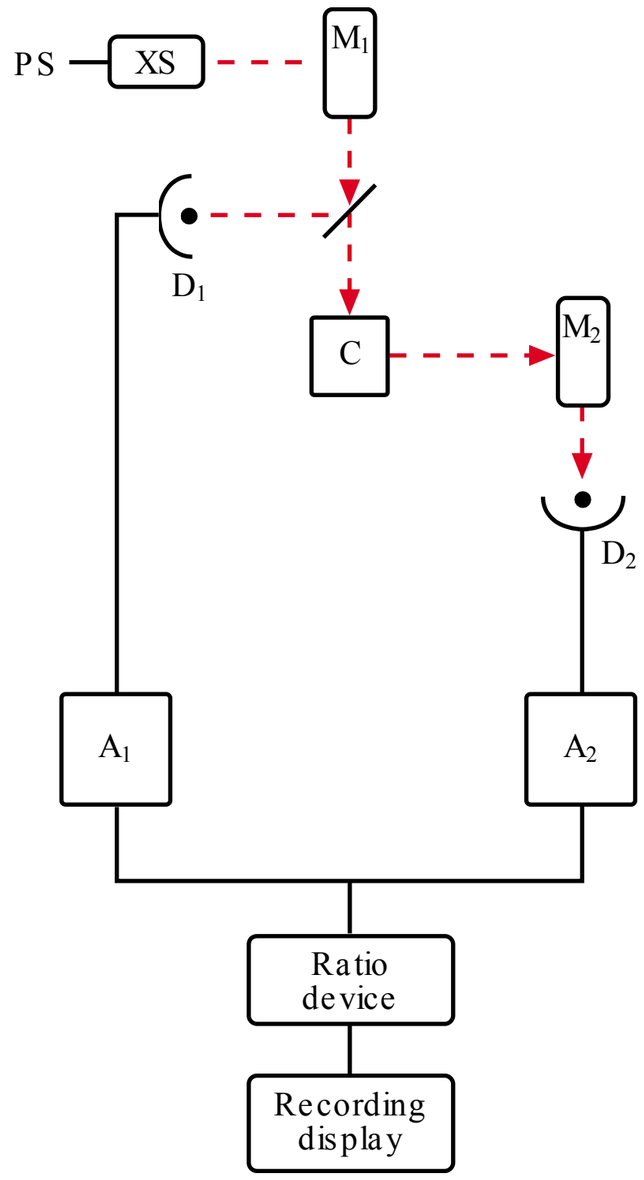

Figure 9-12 Block diagram of a typical spectrofuorometer: XS is the xenon source; PS is the power supply; M_1 is the excitation monochromator; C is the sample cell; M_2 is the emission monochromator. D_1 and D_2 are detectors; D_1 monitors the variation in excitation intensity, and D_2 measures fuorescence emission intensity. A_1 and A_2 are excitation signal and emission signal amplifiers, respectively.

filters or glass filters to produce monochromatic light for sample excitation and for isolation of fluorescence emission, whereas a spectrofluorometer uses a grating or prism monochromator.

Components

Basic components of fluorometers and spectrofluorometers include (1) an excitation source, (2) an excitation monochromator, (3) a cuvet, (4) an emission monochromator, and (5) a detector. In Figure 9-12, these components are shown as they would be configured in a 90° optical system.

With fluorometers and spectrofluorometers, placement of the cuvet and the excitation beam relative to the photodetector is critical in establishing the optical geometry for fluorescence measurements. As fluorescence light is emitted in all directions from a molecule, several excitation/emission geometries are used to measure fluorescence (Figure 9-13). Most commercial spectrofluorometers and fluorometers use the right angle detector approach because it minimizes the background signal that limits analytical detection. The end-on approach allows the adaptation of a fluorescence detector to existing 180° absorption instruments. Its limit of detection is restricted by (1) the quality of the excitation and/or emission interference filter pair, (2) the excitation and/or emission spectral band overlap, and (3) the inner filter effect that is discussed later. The front surface approach provides the greatest linearity over a broad range of concentration because it minimizes the

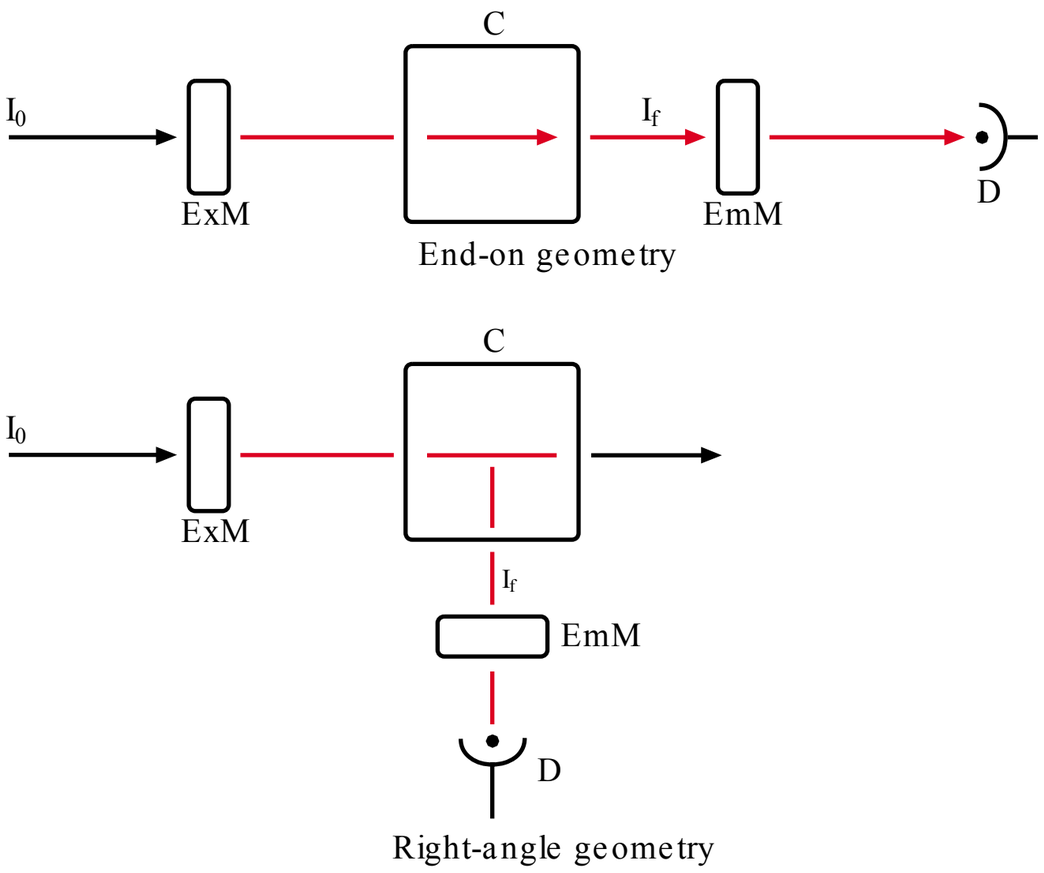

Figure 9-13 Fluorescence excitation/emission geometries: I_0 is the initial excitation energy; ExM is the excitation monochromator; C is the sample cuvet; I_f is the fuorescence intensity; EmM is the emission monochromator; and D is the detector.

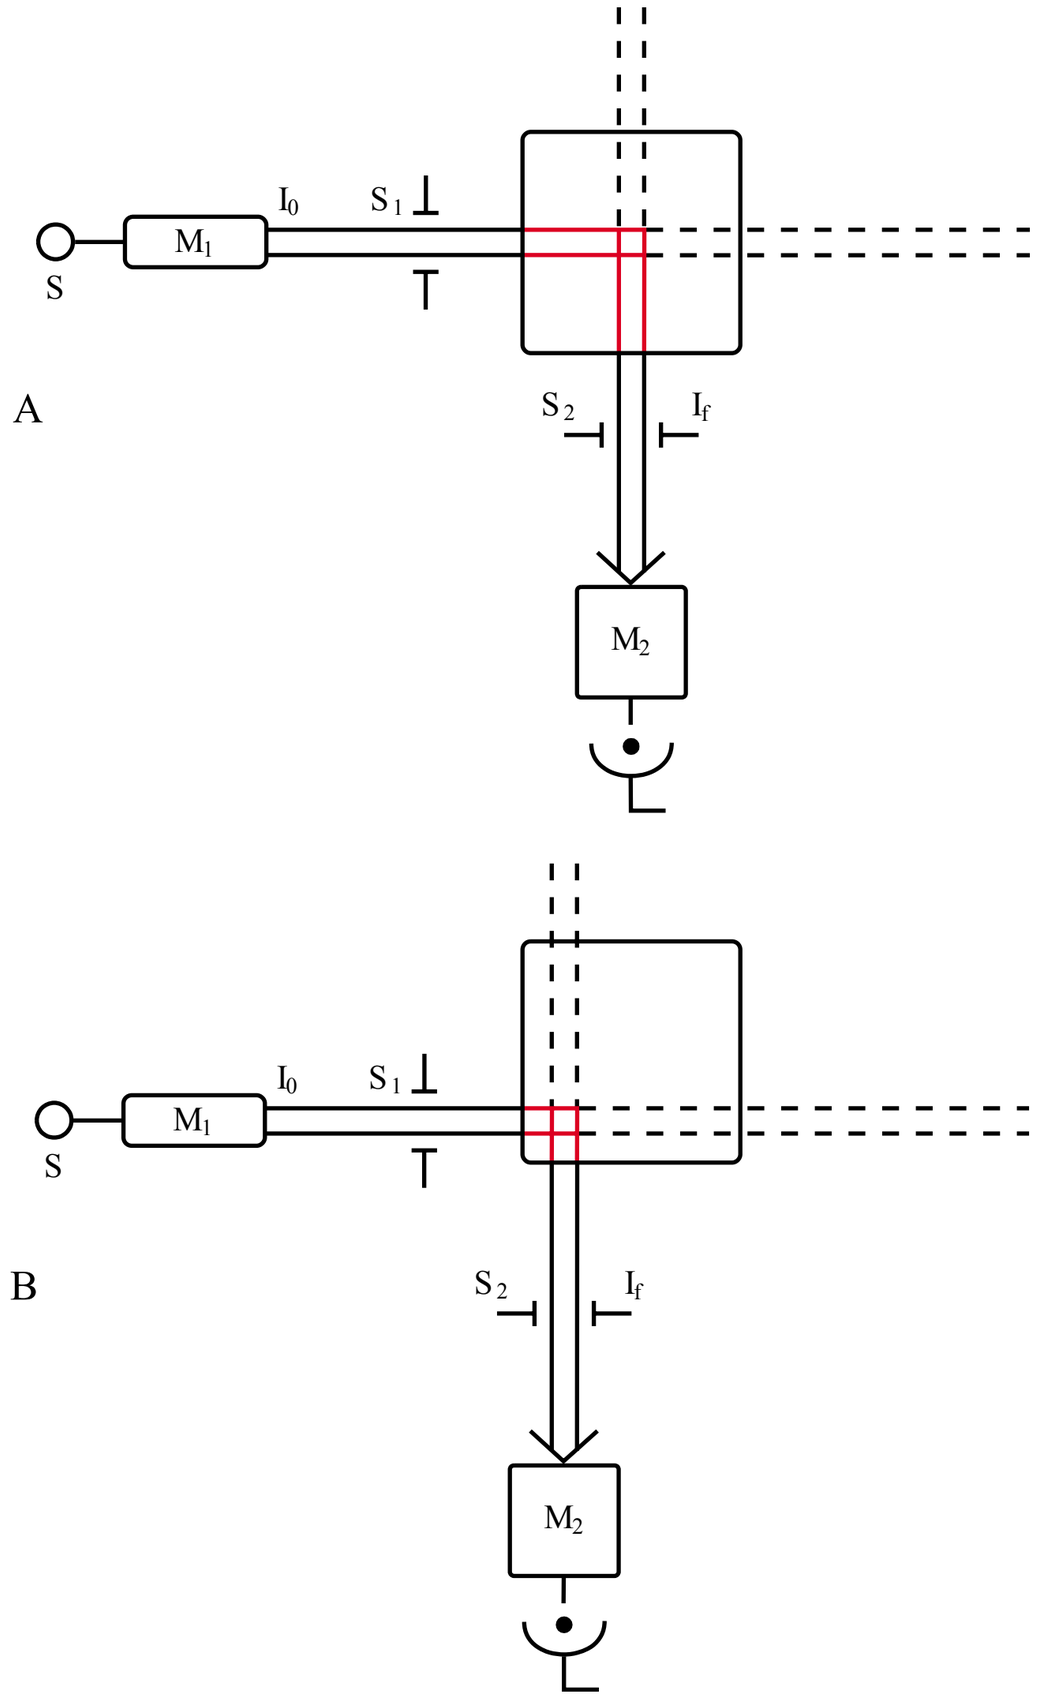

Figure 9-14 Two right-angle fuorescence sample cuvet positions. A shows the standard 90° configuration. B shows the offset positioning of the cuvet to minimize the inner filter effect.

inner filter effect. T e front surface approach has a comparable limit of detection to right angle detectors but is more susceptible to background light scatter. Front surface fluorometry has been widely applied to heterogeneous solid phase fluorescence immunoassay systems.

To accommodate these different geometries, the sample cell is oriented at different angles in relation to the excitation source and the detector. Major concerns related to the geometry of the sample cell are (1) light scattering, (2) the inner filter effect, and (3) the sample volume element seen by the detector. Figure 9-14 shows the sample cell and slit arrangement for a conventional fluorescence spectrophotometer with excitation and emission slits oriented at a right angle. S_1 and S_2 designate the excitation and emission slits, respectively. T e position of the emission slit and the width of the slit are important. If the emission slit is located near the front edge of the sample cell, as shown in Figure 9-14, B, the inner filter effect is minimized. If the emission slit width is increased, the detector will be more sensitive, but specificity may decrease.

Performance Verification

As with spectrophotometers, NIST provides a number of SRMs for use in calibration or verification of the performance of fluorometers or fluorospectrophotometers. T ese include SRM 936a (quinine sulfate dihydrate) for calibrating such instruments and SRM 1932 (fluorescein) for establishing a reference scale for fluorescence measurements (see http://www.nist.gov; accessed July 21, 2013).

Types of Fluorometers and Spectrofuorometers

Fluorometers and fluorescence spectrophotometers are available that offer a variety of features. T ese features include (1) ratio referencing, (2) computer-controlled excitation and emission monochromators, (3) pulsed xenon light sources, (4) photon counting, (5) a rhodamine cell for corrected spectra, (6) polarizers, (7) flow cells, (8) front surface viewing adapters, (9) multiple cell holders, and (10) computer-based data reduction systems.

In addition to the basic spectrofluorometer discussed earlier (see Figure 9-12), other types of fluorometric instruments include (1) a ratio-referencing spectrofluorometer, (2) a time-resolved fluorometer, (3) a flow cytometer, and (4) a hematofluorometer.

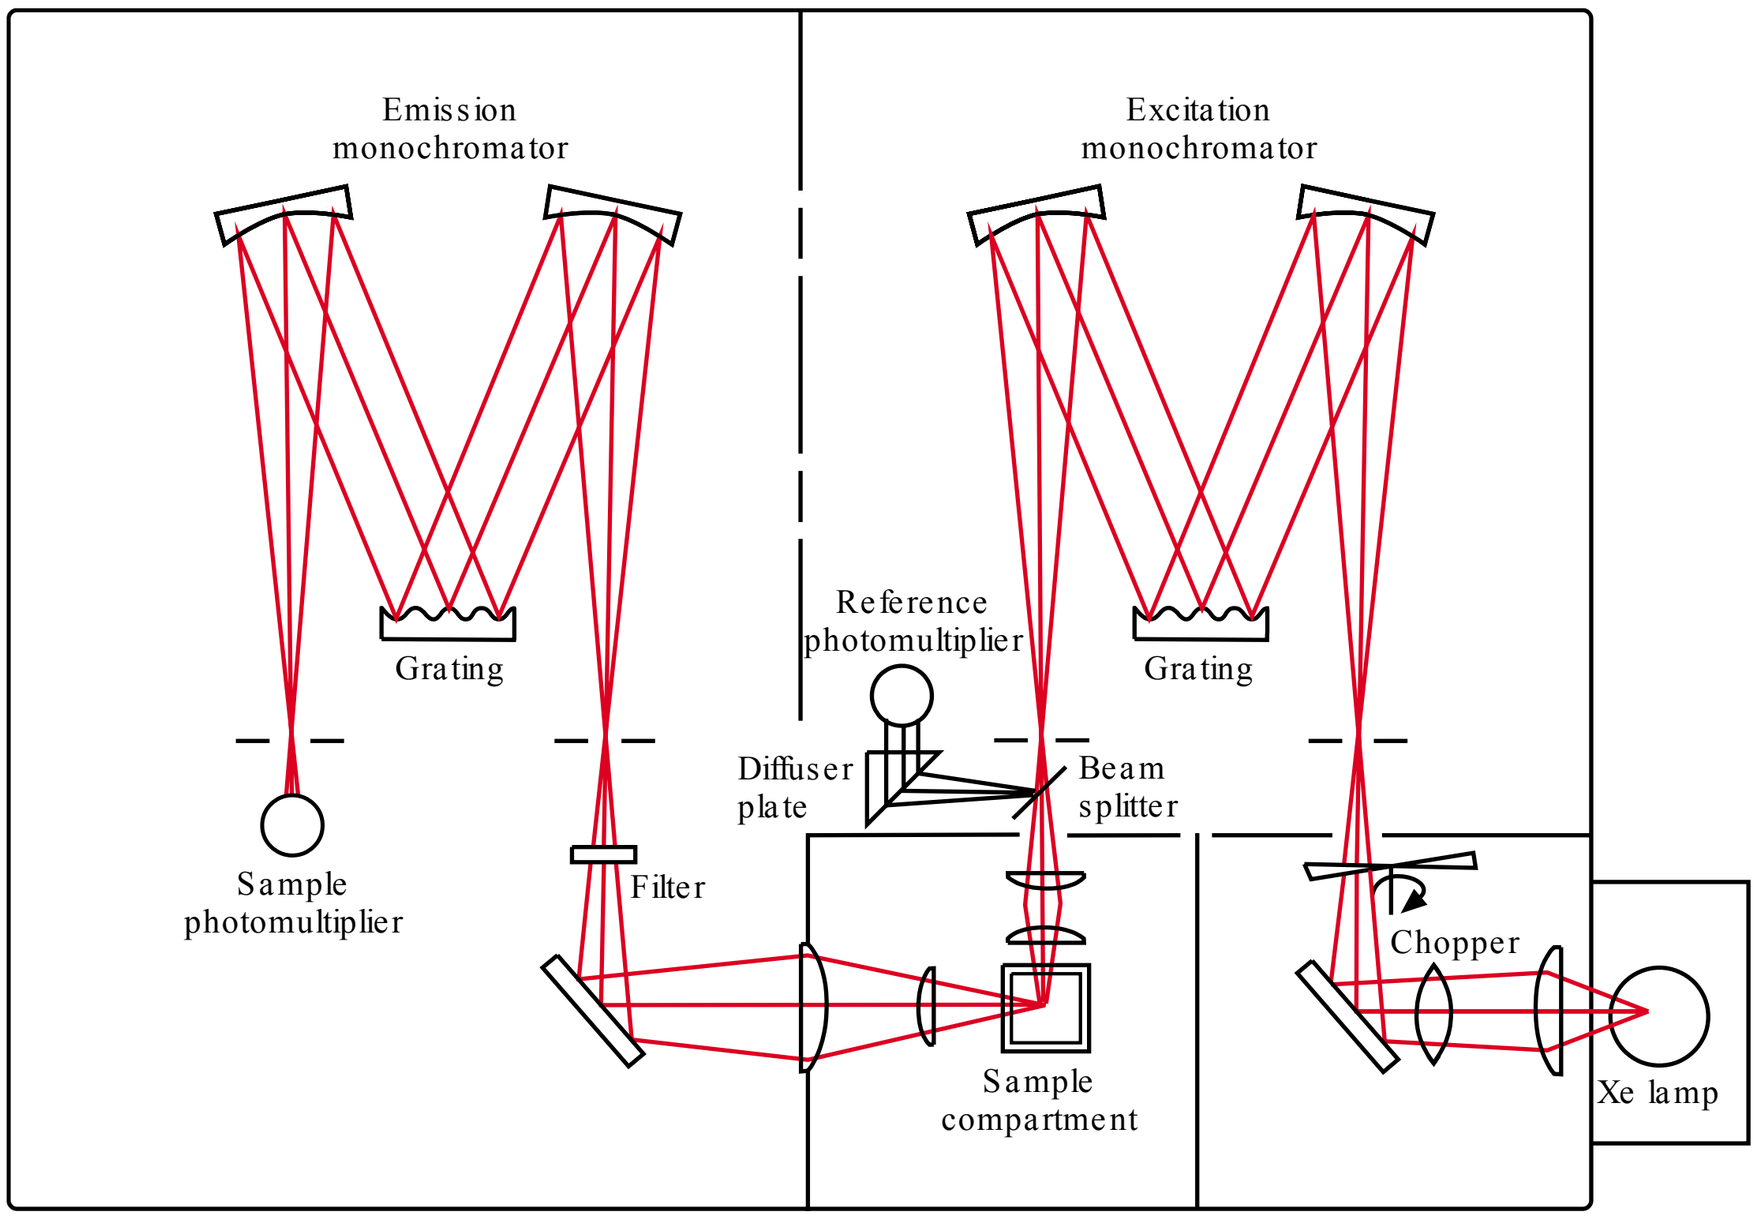

Figure 9-15 Diagram of a typical ratio-referencing spectrofuorometer.

Ratio-Referencing Spectrofuorometer

A typical ratio-referencing spectrofluorometer is illustrated in Figure 9-15. Basically, this is a simple right-angle instrument that uses two monochromators (M1 and M2), two PMT detectors (D1 and D2, the reference and sample PMTs), and a xenon lamp source. T e light from the exciter monochromator (M1) is split, and a small portion (10%) is directed to the reference PMT (D1) for ratio-referencing purposes. T e remaining excitation light is focused into the sample cuvet (C). Emission optics are positioned at a right angle to the excitation optics. An emission monochromator (M2) is used to select or scan the desired portion of the emission spectra, which is directed to the sample PMT (D2) for measurement of emission intensity. T e output signals from the reference and from the sample PMTs are amplified (A1 and A2), and a ratio of the sample to the reference signal is provided by a digital display or a chart recorder. T e operational mode of a ratio fluorometer is similar to that of a spectrofluorometer; however, only discrete excitation and emission wavelengths are available, and the use of this type of instrument is precluded from scanning fluorophores to obtain emission and excitation spectra. T e ratio filter fluorometer is most useful for obtaining concentration measurements at defined excitation and emission wavelengths.

T e ratio-referencing spectrofluorometer is operated at fixed excitation and emission wavelength settings for concentration measurements, or it is used to measure the excitation or emission spectrum of a given compound. Measurement of the concentration of unknowns is accomplished in a similar manner as with a single-beam fluorometer. A blank solution and a calibrating solution are first measured, and then the unknown samples are measured. T e ratio-referencing spectrofluorometer in Figure 9-15 provides two advantages over single-beam spectrofluorometers. First, it eliminates short- and long-term xenon lamp energy fluctuations (i.e., arc flicker and lamp decay), thus minimizing the need for frequent calibration of the instrument during analysis. Second, it provides "essentially" corrected excitation spectra by compensating for wavelength-dependent energy fluctuations.

Time-Resolved Fluorometers

T e time-resolved fluorometer was introduced in the mid-1970s, when Weider developed a pulsed nitrogen laser fluorometer in conjunction with a lanthanide-based immunoassay system. T is instrument measured fluorescence decay of lanthanide chelates as a means of eliminating background interferences from light scatter and short decay time fluorescence compounds. T e time-resolved fluorometer[3] is similar to the ratio-referencing fluorometer, with the exception that the light source is pulsed[9] and the detector monitors, in a fast photon-counting mode, the exponential decay of the fluorescence signal after excitation. Time-resolved fluorometry requires the use of long-lived fluorophores, such as the lanthanide (rare earth) metal ions europium (Eu^{3+}) and samarium (Sm^{3+}). Whereas most fluorescence compounds have decay times of 5 to 100 ns, europium chelates decay in 0.6 to 100 s. T us time-resolved fluorescence assays take advantage of the difference in the lifetimes of fluorophore and background fluorescence by measuring the decaying fluorescence signal. T is eliminates background interferences and at

the same time averages the signal to improve the precision of measurement. Detection limits of approximately 10^{-13} mol/L have been achieved with time-resolved fluorometry, for an improvement of about four orders of magnitude compared with conventional fluorometric measurements. For example, Eu^{3+}-labeled nanoparticles in combination with time-resolved fluorometry have been used to develop a highly sensitive immunoassay for free and total prostate-specific antigen with a functional sensitivity of 0.5 ng/L.[11]

Flow Cytometer

Cytometry refers to the measurement of physical and/or chemical characteristics of cells or particles. **Flow cytometry** is a process in which such measurements are made while cells or particles pass, preferably in single file, through the measuring apparatus in a fluid stream. Flow sorting extends flow cytometry by using electrical or mechanical means to divert and collect cells with one or more measured characteristics falling within a range or a ranges of values set by the user.[8,9]

Operationally, flow cytometry combines laser-induced fluorometry and particle light-scattering analysis that allow different populations of (1) molecules, (2) cells, or (3) particles to be differentiated by size and shape using low-light and right-angle light scattering. The use of a laser is ideally suited for low-angle light scattering. These cells, molecules, or particles are labeled with different specific fluorescent labels, such as (1) β-phycoerythrin, (2) fluorescein isothiocyanate, (3) rhodamine-6G, and (4) dye-labeled antibodies. As these elements flow through the flow cell, simultaneous fluorescence and light-scattering measurements are automatically performed by the flow cytometer. Most flow cytometers incorporate two or more fluorescence emission detection systems so that multiple fluorescent labels are able to be used. In this manner, molecules, cells, and particles are classified by (1) size, (2) shape, and (3) type according to their light-scattering and fluorescent properties. A schematic diagram of a flow cytometer is shown in Figure 9-16.

Flow cytometers are able to measure multiple parameters, including (1) cell size (forward scatter), (2) granularity (90° scatter), (3) DNA and RNA content, (4) DNA (AT)/(GC) nucleotide ratios, (5) chromatin structure, (6) antigens, (7) total protein content, (8) cell receptors, (9) membrane potential, and (10) calcium ion concentration as a function of pH. Of particular note have been the development and use of particle-based flow cytometric assays. With this technology, a flow cytometer is combined with microspheres that are used as the solid support for conventional immunoassay, affinity assay, or DNA hybridization assay.[14] The resultant system is very flexible and has led to the development of multiplexed assays that simultaneously measure many different analytes in a small sample volume.

Hematofluorometer

The hematofluorometer is a single-channel front surface photofluorometer dedicated to the analysis of zinc protoporphyrin in whole blood (see Chapter 29). A typical hematofluorometer uses a quartz-tungsten lamp, a narrow-bandpass excitation filter (420 nm), front surface optics, a narrow-bandpass filter (594 nm), and a PMT. A drop of whole blood is placed on a small rectangular glass slide that serves as a cuvet.

Limitations of Fluorescence Measurements

Factors that influence fluorescence measurements include (1) concentration effects (e.g., inner filter effect, concentration quenching), (2) background effects (due to Rayleigh and Raman scattering), (3) solvent effects (e.g., interfering nonspecific fluorescence, quenching from the solvent), (4) sample effects (e.g., light scattering, interfering fluorescence, sample adsorption), (5) temperature effects, and (6) photodecomposition (bleaching) of the sample.

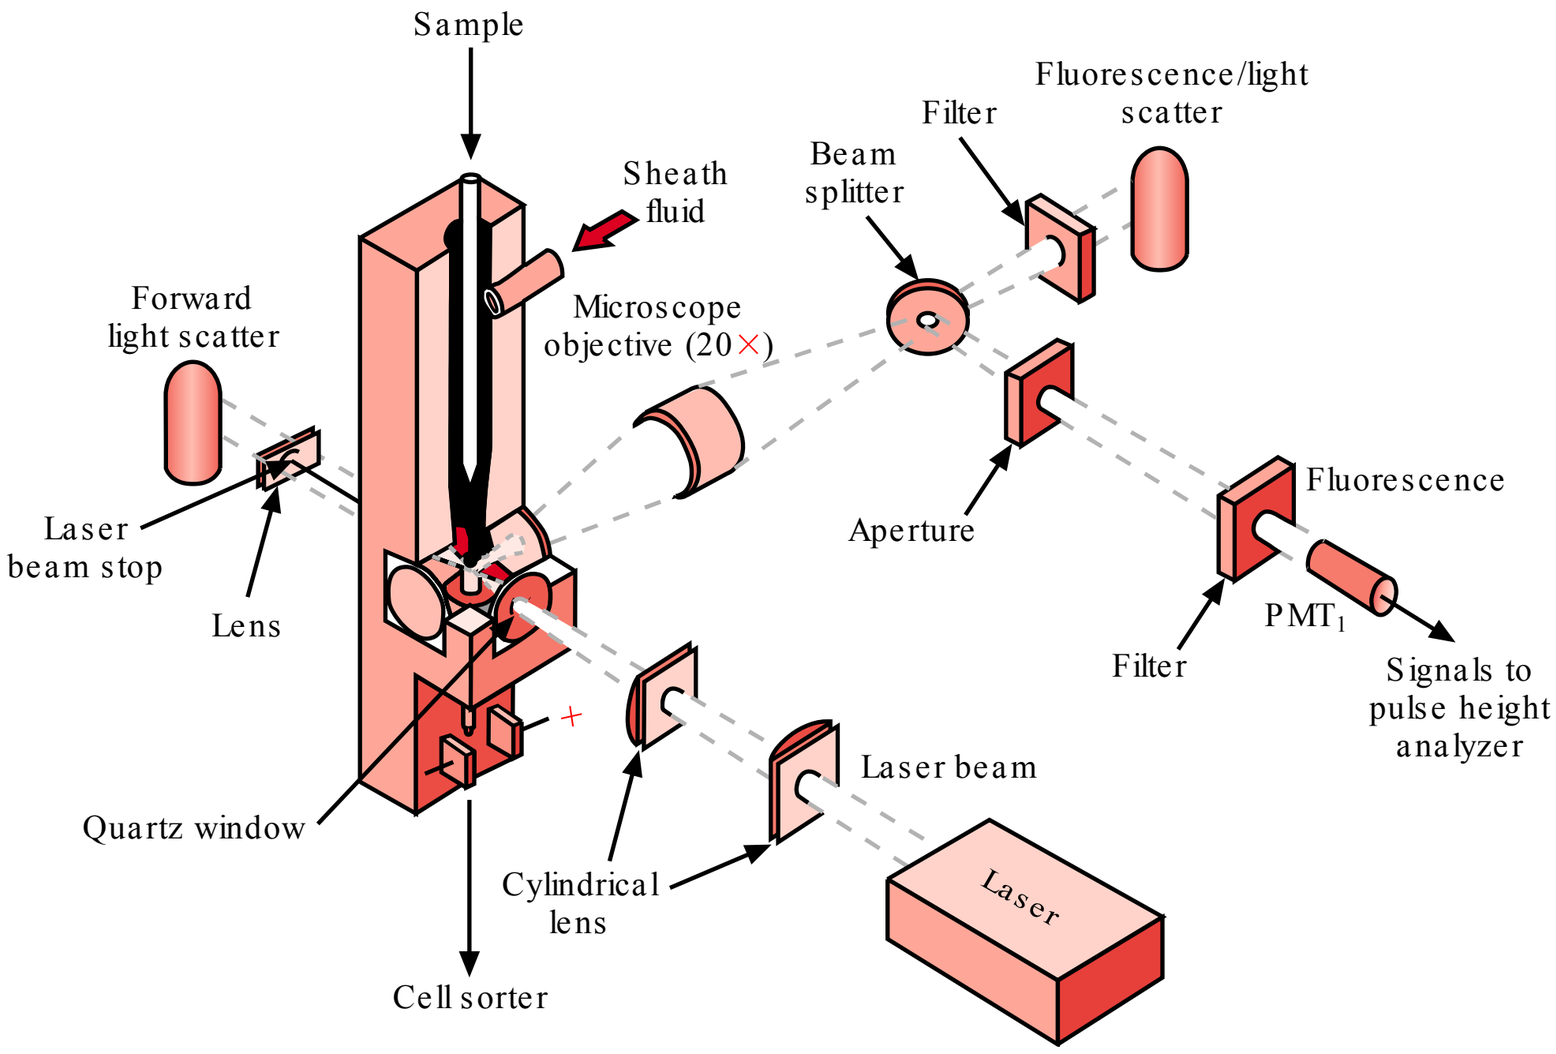

Figure 9-16 Schematic diagram of a fow cytometer.

Inner Filter Effect

The linear relationship between concentration and fluorescence emission (Equation 9) is valid when solutions absorb less than 2% of the exciting light. As the absorbance of the solution increases above this amount, the relationship becomes nonlinear—a phenomenon known as the inner *filter effect*. It is caused by loss of excitation intensity across the cuvet path length as excitation light is absorbed by the fluorophore. Thus, as the fluorophore becomes more concentrated, absorbance of excitation intensity increases, and loss of excitation light as it travels through the cuvet increases. This effect is most often encountered with a right-angle fluorescence instrument, in which the emission slits are set to monitor the center of the sample cell, where absorbance of excitation light is greater than at the front surface of the cuvet. Therefore it is less problematic if a front surface fluorescence instrument is used. However, most fluorescence measurements are made on very dilute solutions, and the inner filter effect therefore is not a problem.

Concentration Quenching

Another related phenomenon that results in a lower quantum yield than expected is called concentration quenching. This occurs when a macromolecule, such as an antibody, is heavily labeled with a fluorophore, such as fluorescein isothiocyanate. When this compound is excited, the fluorescence labels are in such close proximity that a radiation-less energy transfer occurs. Thus the resulting fluorescence is much lower than expected for the concentration of the label. This is a common problem in flow cytometry and in laser-induced fluorescence when attempts are made to enhance detection sensitivity by increasing the density of the fluorescing label.

Light Scattering

Light scattering—Rayleigh and Raman—limits the use of fluorescence measurements. Rayleigh scattering occurs with no change in wavelength. For fluorophores with small Stokes shifts, the excitation and emission spectra overlap and are particularly susceptible to loss of detection caused by background light scatter. Rayleigh scatter is controlled by the use of well-defined emission and excitation interference filters or by appropriate monochromator settings and the use of polarizers.

Raman scattering occurs with lengthening of wavelength. This type of light scattering is independent of excitation wavelength and is a property of the solvent. Because Raman light scattering appears at longer wavelengths than the exciting radiation, it is a difficult interference to eliminate when working at very low fluorophore concentrations.

Cuvet Material and Solvent Effects

Certain quartz glass and plastic materials that contain ultraviolet absorbers will fluoresce. Some solvents, such as ethanol, are also known to cause appreciable fluorescence. It is therefore important when developing a fluorescence assay to assess the background fluorescence of all components of the reaction mixture. Fluorescence grade solvents and cuvets with minimum fluorescence emission, which minimize these types of fluorescence background problems, are commercially available.

Sample Matrix Effects

A serum or urine sample contains many compounds that fluoresce. Thus the sample matrix is a potential source of unwanted background fluorescence and must be examined when new methods are developed. The most serious contributors to unwanted fluorescence are proteins and bilirubin. However, because protein excitation maxima are in the spectral region of 260 to 290 nm, their contribution to overall background fluorescence is minor when excitation occurs above 300 nm.

Light scattering of proteins and other macromolecules in the sample matrix has been known to cause unwanted background fluorescence. Lipemic samples, for example, are noted for their intense light scattering, and the relative contribution of lipids to the background signal of a fluorescence measurement should be investigated when a new method is developed.

In addition to background interferences, dilute solutions of some fluorophores in the concentration range of 10^{-9} mol/L and below will absorb to the walls of glass cuvets and other reaction vessels. Also, dilute solutions of fluorophores, when excited over long periods, are susceptible to photodecomposition by intense excitation light. Operationally, these problems are prevented by (1) selecting proper reaction vessels, (2) adding wetting agents, and (3) minimizing the length of time a sample is exposed to the excitation light.

Temperature Effects

The fluorescence quantum efficiency of many compounds is sensitive to temperature fluctuations. Therefore the temperature of the reaction must be regulated to within ±0.1 °C. In general, fluorescence intensity decreases with increasing temperature by approximately 1% to 5% per degree Celsius. Furthermore, collisional quenching decreases with increasing viscosity, thereby reducing the quenching of fluorescence. Operationally, fluorescence intensity is enhanced by increasing reaction viscosity or lowering solvent temperature. Temperature effects are minimized by controlling reaction temperature and warming samples or reagents, or both, if they have been refrigerated.

Photodecomposition

In conventional **fluorometry**, excitation of weakly fluorescing or dilute solutions with intense light sources will cause photochemical decomposition of the analyte (photobleaching).

The following steps help to minimize photodecomposition effects:

1. Always use the longest feasible wavelength for excitation that does not introduce light-scattering effects.
2. Decrease the duration of excitation of the sample by measuring the fluorescence intensity immediately after excitation.
3. Protect unstable solutions from ambient light by storing them in dark bottles.
4. Remove dissolved oxygen from the solution.

In addition, highly intense laser light sources with energy output greater than 5 to 10 mW will rapidly photodecompose some fluorescence analytes. T is decomposition introduces nonlinear response curves and loss of most of the sample fluorescence. Fluorescence-based assays for analytes at ultralow concentrations require optimization of laser intensity and use of a sensitive detector. Assays with high energy, photodecomposing light sources include (1) flow cytometry, (2) fluorescence microscopy, and (3) laser-induced fluorescence measurements.T is decomposition introduces nonlinear response curves and loss of sample fluorescence. Fluorescence-based assays for analytes at ultralow concentrations require optimization of laser intensity and use of a sensitive detector.

Phosphorimetry

Phosphorimetry is the measurement of phosphorescence, a type of luminescence produced by certain substances after radiant energy or other types of energy are absorbed. Phosphorescence is distinguished from fluorescence in that it continues even after the radiation causing it has ceased. T e decay time of emission of phosphorescence light is longer (10^{-4} to 10^{-2} s) than the decay time of fluorescence emission. Decay times are expressed in a time range of several orders of magnitude and vary with the molecule and its solution environment. Phosphorescence shows a larger shift in emitted light wavelength than does fluorescence.

Luminometry

Chemiluminescence, **bioluminescence**, and **electrochemiluminescence** are types of luminescence in which the excitation event is caused by a chemical, biochemical, or electrochemical reaction, and not by photo illumination. Instruments for measuring this type of light emission are known generically as luminometers.

Basic Concepts

T e physical event of light emission in (1) chemiluminescence, (2) bioluminescence, and (3) electrochemiluminescence is similar to fluorescence in that it occurs from an excited singlet state, and the light is emitted when the electron returns to the ground state.

Chemiluminescence and Bioluminescence

Chemiluminescence is the emission of light when an electron returns from an excited or higher energy level to a lower energy level. T e excitation event is caused by a chemical reaction with compound such as (1) luminol, (2) isoluminol, (3) acridinium esters, (4) luciferin, (5) hydrogen peroxide, (6) hypochlorite, and (7) oxygen. Light is emitted from the excited product formed in the oxidation reaction. T ese reactions occur in the presence of catalysts such as (1) enzymes (e.g., alkaline phosphatase, horseradish peroxidase, microperoxidase), (2) metal ions or metal complexes (e.g., Cu^{2+} and Fe^{3+} phthalocyanine complex), and (3) hemin.[2,15]

Bioluminescence is a special form of chemiluminescence found in biological systems. In bioluminescence, an enzyme or a photoprotein increases the ef ciency of the luminescence reaction. Luciferase and aequorin are two examples of these biological catalysts. T e quantum yield (e.g., total photons emitted per total molecules reacting) is approximately 0.1% to 10% for chemiluminescence and 10% to 30% for bioluminescence.

Chemiluminescence assays are ultrasensitive (attomole-to-zeptomole detection limits) and have wide dynamic ranges. T ey are now widely used in automated immunoassay and DNA probe assay systems such as (1) acridinium ester and acridinium sulfonamide labels, (2) 1,2-dioxetane substrates for alkaline phosphatase labels, and (3) the enhanced luminol reaction for horseradish peroxidase labels.

Electrochemiluminescence

Electrochemiluminescence differs from chemiluminescence in that the reactive species that produce the chemiluminescent reaction are electrochemically generated from stable precursors at the surface of an electrode.[1] A ruthenium (Ru^{2+}), tris(bipyridyl) chelate is the most commonly used electrochemiluminescence label, and electrochemiluminescence is generated at an electrode via an oxidation reduction type of reaction with tripropylamine. T is chelate is very stable and relatively small and has been used to label haptens or large molecules (e.g., proteins, oligonucleotides). T e electrochemiluminescence process has been used in both immunoassays and nucleic acid assays. Advantages of this process include (1) improved reagent stability, (2) simple reagent preparation, and (3) enhanced sensitivity. With its use, detection limits of 200 fmol/L and a dynamic range extending over six orders of magnitude have been obtained.

Instrumentation

T e basic components of a luminometer include (1) the sample cell housed in a light-tight chamber, (2) the injection system for adding reagents to the sample cell, and (3) the detector.[2,15] T e detector is usually a PMT. However, (1) a charged coupled detector (CCD—multichannel device), (2) x-ray film, or (3) photographic film has been used to image bioluminescence or chemiluminescence reactions on a membrane or in the wells of a microplate. For electrochemiluminescence, the reaction vessel incorporates an electrode at which the electrochemiluminescence is generated.

Limitations of Chemiluminescence, Bioluminescence, and Electrochemiluminescence Measurements

Factors that commonly degrade the analytical performance of luminescence measurements include (1) light leaks, (2) light piping, (3) and high background luminescence from assay reagents and reaction vessels (e.g., plastic tubes exposed to light). T e ultrasensitive nature of chemiluminescence assays requires stringent controls on the purity of reagents and the solvents (e.g., water) used to prepare reagent solutions. Ef - cient capture of the light emission from reactions that produce

a flash of light requires an efficient injector that provides adequate mixing when the triggering reagent is added to the reaction vessel. Bioluminescence, chemiluminescence, and electrochemiluminescence assays have a wide linear range, usually including several orders of magnitude, but very high-intensity light emission has led to pulse pileup in PMT tubes, and this may lead to a serious underestimation of the true light emission intensity.

Nephelometry and Turbidimetry

Light scattering is a physical phenomenon that results from the interaction of light with particles in solution. **Nephelometry** and **turbidimetry** are analytical techniques that are used to measure scattered light. Light-scattering measurements have been applied to immunoassays of specific proteins and haptens.

Basic Concepts

Light scattering occurs when radiant energy passing through a solution encounters a molecule in an elastic collision, which results in scattering of light in all directions. Unlike fluorescence emission, the wavelength of the scattered light is the same as that of the incident light.

Factors that influence light scattering include (1) effect of particle size, (2) wavelength dependence, (3) distance of observation, (4) effect of polarization of incident light, (5) concentration of the particles, and (6) molecular weight of the particles.

Particle Size

The Rayleigh scattering Equation (11) presented below applies to the scattering of light from small particles with much smaller dimensions than the wavelength of incident light (e.g., particle size < $\lambda/10$). When the dimensions of the particles are much smaller than the wavelength of the incident light, each particle is subjected to the same electrical field strength at the same time. The reradiated or scattered light waves from the small particle are in phase and reinforce each other. As the particles become larger than the incident light wave, the radiated light waves are no longer all in phase. Reinforcement of radiation occurs in some directions, and destructive interference occurs in others. The scattering patterns from these large particles are characteristic of the size and shape of the particle.

Wavelength Dependence of Light Scattering

In 1871 Lord Rayleigh derived the following equation, which demonstrates the relationship of the intensity (I_S) of scattered light to the intensity (I_0) of incident light:

$$\frac{I_s}{I_0} = \frac{16\pi^2 a \sin^2\theta}{\lambda^4 r^2} \qquad (11)$$

where

I_S = intensity of scattered light;
I_0 = intensity of excitation light;
a = polarizability of the small particle;
θ = angle of observation;
λ = wavelength of incident light; and
r = distance from light scattering to the detector.

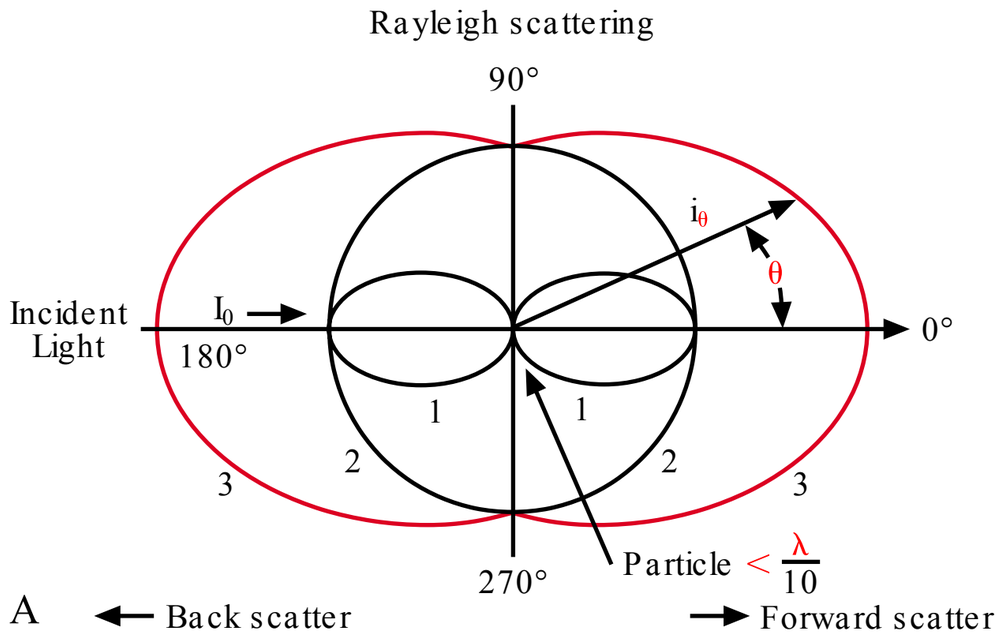
As indicated, the intensity of light scattering increases by the fourth power of the wavelength as the wavelength of the incident light is decreased. Another useful observation from Equation (11) is the fact that light intensity decreases by the square of the distance r from the light-scattering particles to the detector. Thus the detector should be located close to the analytical cell by combining the cell and the detector or by using good collection optics.

Concentration and Molecular Weight Factors in Light Scattering

The direct relationship of light scattering to the concentration of the particles and to the molecular weight of the particles is derived from Equation (11), showing that:

$$\frac{I}{I_0} = \frac{4\pi^2 (dn/dc)^2 Mc \sin^2\theta}{N_a \lambda^4 r^2} \qquad (12)$$

where



I = intensity of scattered light from small particles excited by polarized light;
I_0 = incident intensity;
dn/dc = change in refractive index of the solvent with respect to change in solute concentration;
M = molecular weight (g/mol);
c = concentration (g/mL) of the particles;
θ = angle of observation;
N_a = Avogadro's number;
λ = wavelength of the incident light; and
r = distance from light scattering to the detector.

As indicated in Equation (12), there is a direct relationship of light scattering to the concentrations of particles and to their molecular weight.[13]

The Effect of Polarized Light on Light Scattering

Equations (11) and (12) are different forms of the Rayleigh expression for light scattering from small particles if excited by polarized light. Figure 9-17, A, shows the effects of polarized and nonpolarized light on light-scattering intensity from small particles as a function of the scattering angle. Curve 2 shows a spherically symmetrical intensity diagram as predicted by Equation (11). Curve 3 is the resultant intensity diagram when Curves 1 and 2 are summed and is the scattering angular intensity diagram obtained when light scatters from small particles excited with nonpolarized light. Curves 1 and 2 represent intensity diagrams from vertically and horizontally polarized light components that are considered to comprise nonpolarized light. The Rayleigh light-scattering expression for small particles excited by nonpolarized light is given by Equation (13):

$$\frac{I}{I_0} = \frac{2\pi^2 (dn/dc)^2 Mc (1 + \cos\theta)}{N_a \lambda^4 r^2} \qquad (13)$$

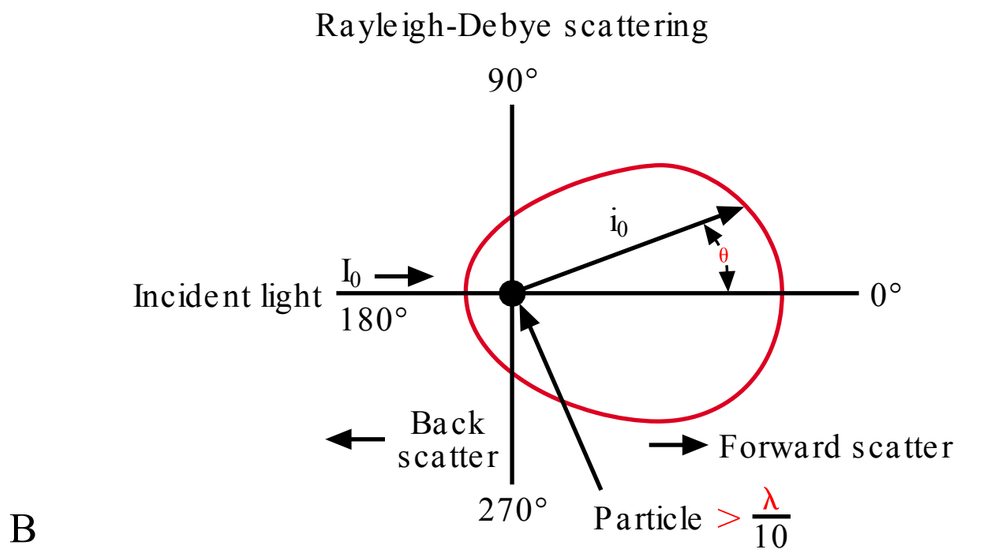


Figure 9-17 The angular dependence of light-scattering intensity with nonpolarized and polarized incident light for small particles (A) and the angular dependence of light scattering with nonpolarized light for larger particles (B).

The Angular Dependence of Light Scattering

The angular dependence of light scattering from small particles (less than λ/10) is represented by Figure 9-17, A. As shown in Curve 3, the light scatter intensity for forward scatter and back scatter (I_0 at 0° and 180°) from small particles excited by nonpolarized light is equal. However, light scatter intensity at 90° is much less. As particles become larger (e.g., greater than λ/10), the angular dependence of light scatter takes on the dissymmetrical relationship shown in Figure 9-17, B. In this situation, the light-scattering intensities at forward and back angles are not equal, and the forward-scatter intensity is much greater. Also, the light-scattering intensity at 90° is much less than the intensity at the forward (0°) angle. As particles become even larger, this dissymmetry increases even further. This dissymmetry and the change in angular dependence of light scattering with change in the size of particles are very useful for characterization and differentiation of various classes of macromolecules and cells.

Measurement of Scattered Light

Turbidimetry and nephelometry are methods used to measure scattered light. These techniques have proved useful for the quantitation of serum proteins.

Turbidimetry

Turbidity decreases the intensity of the incident beam of light as it passes through a solution of particles. The measurement of this decrease in intensity is called turbidimetry. Analogous to absorption spectroscopy, turbidity is defined as:

$$I = I_0 e^{-bt} \tag{14}$$

or

$$t = \frac{1}{b} \ln \frac{I_0}{I} \tag{15}$$

where
t = turbidity;
b = path length of incident light through the solution of light-scattering particles;
I = intensity of transmitted light; and
I_0 = intensity of incident light.

A turbidimeter is used to measure the intensity of light scattering. Photometers or spectrophotometers are often used as turbidimeters, as turbidimetric measurements are easily performed on them and require little optimization. The principal concern of turbidimetric measurements is signal-to-noise ratio. Photometric systems with electro-optical noise in the range of ±0.0002 absorbance unit or less are useful for turbidity measurements.

Nephelometry

Nephelometry is defined as the detection of light energy scattered or reflected toward a detector that is not in the direct path of the transmitted light. Common nephelometers measure scattered light at right angles to the incident light. Some nephelometers are designed to measure scattered light at an angle other than 90° to take advantage of the increased forward-scatter intensity caused by light scattering from larger particles (e.g., immune complexes).

Fluorometers are often used to perform nephelometric measurements. However, the angular dependence of light-scattering intensity has resulted in the design of special nephelometers. These devices place the PMT detector at appropriate angles to the excitation light beam. The design principle of a nephelometer is similar to the design principle applied in fluorescence measurements. The major operational difference between the fluorometer and the nephelometer is that the excitation and detection wavelengths of a nephelometer will be set to the same value. The principal parameters of light scatter instrumentation are (1) excitation intensity, (2) wavelength, (3) distance of the detector from the sample cuvet, and (4) minimization of external stray light. As shown in Figure 9-18, the basic components of a nephelometer include (1) a light source, (2) collimating optics, (3) a sample cell, and (4) collection optics, which include light-scattering optics, a detector optical filter, and a detector. The schematic diagram also shows the different angles from the incident light beam where the detector, filter, and optics are placed to measure light scattering. Figure 9-18, a, shows the straight-through arrangement for turbidimetry, whereas Figure 9-18, b and c, shows arrangements frequently found in nephelometers. The detector arrangement shown in Figure 9-18, b, is used for measurement of

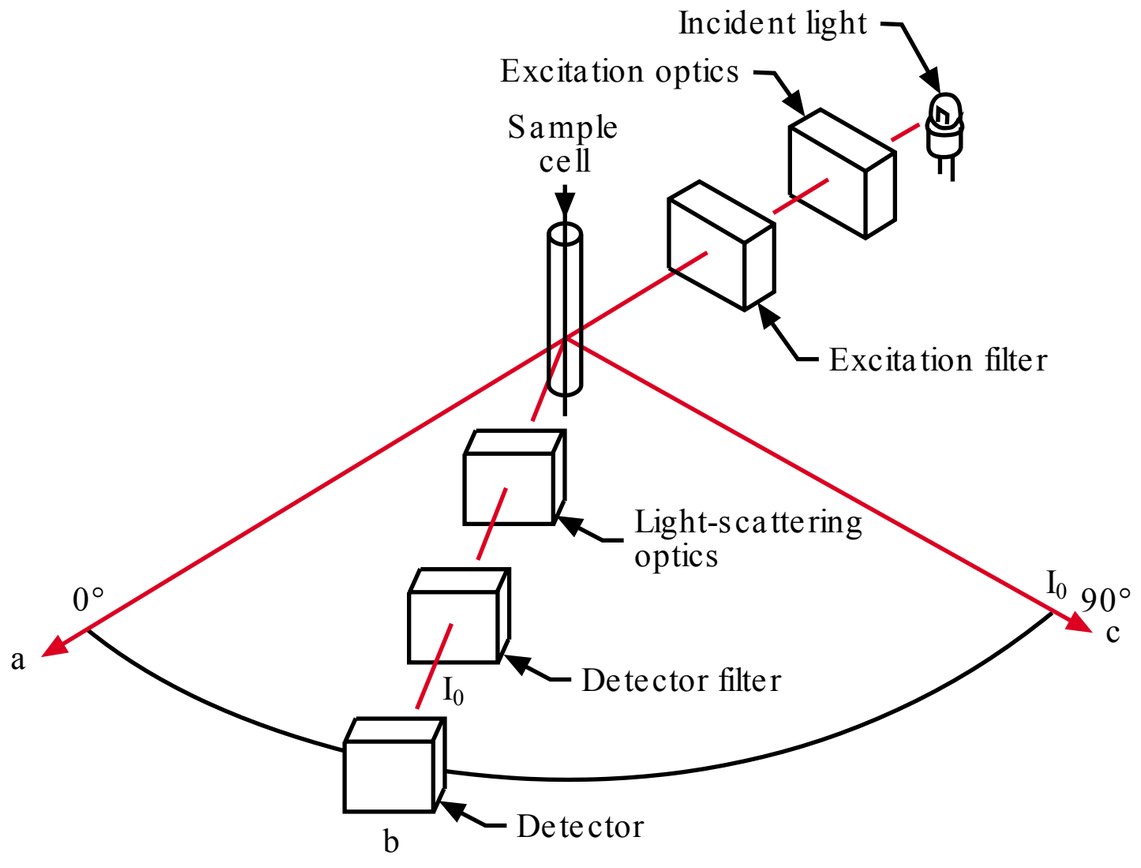

Figure 9-18 Schematic diagram of light-scattering instrumentation shows (a) the optics position for a turbidimeter; (b) the optics position for a forward-scattering nephelometer; and (c) the optics position for a right-angle nephelometer.

forward scatter at 30°—the optical arrangement used in some commercial nephelometers.

Operationally, the optical components used in turbidimeters and nephelometers are similar to those used in fluorometers or photometers. For example, the light sources commonly used are (1) quartz-halogen lamps, (2) xenon lamps, and (3) lasers. Helium-neon (He-Ne) lasers, which operate at 633 nm, have typically been used for light-scattering applications, such as (1) nephelometric (2) immunoassays, (3) particle size determination, and (4) particle shape determination. The laser beam is used specifically in some nephelometers because of its high intensity; in addition, the coherent nature of laser light makes it ideally suited for nephelometric applications. Ratio-referencing fluorometers are also well suited for nephelometric measurements.

Limitations of Light-Scattering Measurements

Antigen excess and matrix effects are limitations encountered in the use of turbidimeters and nephelometers for measurement of analytes of clinical interest.

Antigen Excess

Antigen-antibody reactions are complex and appear to result in a mixture of aggregate sizes. As turbidity increases during addition of antigen to antibodies, the signal increases to a maximum value and then decreases. The point at which the decrease begins marks the beginning of the phase of antigen excess; this phenomenon is explained in Chapter 15. Consequently, light-scattering methods for quantification of antigen-antibody reactions must provide a method for detecting antigen excess. The kinetics of immune complex formation measured by nephelometry or turbidimetry is sufficiently different in each of the three phases— (1) antibody excess, (2) equivalence, and (3) antigen excess—that computer algorithms have been developed to automatically flag antigen excess.[12]

Matrix Effects

Particles, solvent, and all serum macromolecules scatter light. Lipoproteins and chylomicrons in lipemic serum provide the highest background turbidity or nephelometric intensity. With appropriate dilutions, the relative intensity of light scattering from a lipemic sample is less than that from the antiserum blank. However, as the concentration of the antigen in serum decreases and correspondingly less dilute samples are used, the background interference from lipemic samples becomes greater. An effective method for minimizing this background interference is the use of rate measurements, for which the initial sample blank is eliminated.

Large particles, such as suspended dust, also cause significant background interference. This background interference is controlled by filtering all buffers and diluted antisera before analysis is attempted.

Review Questions

1. What units of measurement are traditionally applied when wavelengths in the electromagnetic spectrum are measured?
   a. Millimeters (mm)
   b. Centimeters (cm)
   c. Nanometers (nm)
   d. Micrometers (μm)
2. Oxidation of an organic compound with resultant light emission is known as:
   a. nephelometry.
   b. turbidimetry.
   c. chemiluminescence.
   d. fluorescence.
3. The expression of the relationship between the concentration of a substance in solution and absorbance of light by

that substance is referred to as Beer's law. T is relationship is expressed in a formula as:
a. log (1/T).
b. C = abc.
c. $I_o/I_s \times 100$.
d. A = abc.

4. With regard to atomic absorption spectrophotometry (AAS):
a. the light source used emits a wide range of wavelengths.
b. the technique measures concentration through the detection of absorbance of electromagnetic radiation by the atoms of elements instead of compounds.
c. oxidation of an organic compound such as luminol induces an excited state and light is emitted when the electron returns to the ground state
d. the amount of light scattered at right angles to the incident light is directly proportional to the concentration of the analyte of interest.

5. Which component of a single-beam spectrophotometer isolates radiant energy of a specific wavelength and excludes that of other wavelengths?
a. Monochromator
b. Entrance slit
c. Cuvet
d. Light source

6. Measurement of the concentration of a substance that is performed by measuring the decreased intensity of light blocked by particles in solution at 180° from the source is called:
a. fluorometry.
b. atomic absorption.
c. turbidimetry.
d. nephelometry.

7. A solution that is identical to that of calibrating or unknown solutions except that the substance to be measured and that is used to set 100% T (zero absorbance) at the beginning of a photometric analysis is referred to as a:
a. standard solution.
b. calibrating solution.
c. reference blank.
d. reagent blank.

8. In a fluorescence measurement, if an excited macromolecule is heavily labeled by a fluorophore, the label could be in such close proximity to other fluorophores that the resulting fluorescence is much lower than expected. T is limitation of fluorescence is referred to as:
a. light scattering.
b. concentration quenching.
c. solvent quenching.
d. the sample matrix effect.

9. In a flameless atomic absorption technique, the sample holder is typically a:
a. carbon rod in an enclosed chamber.
b. flame.
c. borosilicate glass cuvet.
d. reflective surface.

10. T e bandwidth of the spectral absorbance curve of an absorbing substance at a point equal to one-half of the maximum absorbance is referred to as the:
a. standard curve.
b. bandpass filter.
c. natural bandwidth.
d. monochromatic bandwidth.

CHAPTER 10

Electrochemistry and Chemical Sensors*

Paul D'Orazio, Ph.D., and Mark E. Meyerhoff, Ph.D.

Objectives

1. Define the following:
   - Amperometry
   - Biosensor
   - Conductometry
   - Coulometry
   - Electrochemistry
   - Electromotive force
   - Indicator electrode
   - Optode
   - Potentiometry
   - Reference electrode
   - Voltage potential
   - Voltammetry
2. Describe the functions of the components of a basic electrochemical cell, including electrodes, filling solutions, and voltmeter.
3. State the principles and clinical applications of the following measurement techniques:
   - Voltammetry/Amperometry
   - Conductometry
   - Coulometry
   - Potentiometry
4. List three basic classifications of potentiometric electrodes; for each classification, state the principles, components, and clinical uses of two electrode types; list two types of reference electrodes and two types of indicator electrodes used in each type of measurement.
5. Describe a PCO_2 electrode, including components and internal reactions.
6. List four examples of biosensors and state their uses in the clinical laboratory; state the principle of affinity biosensors and their uses in the clinical laboratory.
7. List three examples of optodes and state their uses in the clinical laboratory.
8. Describe enzyme-based biosensors, including their combination with electrochemical measurements and uses in the clinical laboratory.
9. State the application of the Nernst equation to electrochemical measurements.
10. Compare galvanic and electrolytic electrochemical cells, including components, electrochemistry of each, and reactions involved.

Key Words and Definitions

Activity (of an ion) The concentration of free, unbound ion in solution.

Amperometry An electrolytic electrochemical process in which current is monitored at a fixed (controlled) voltage between working and reference electrodes in an electrochemical cell.

Biosensor A type of chemical sensor consisting of a biological recognition element and a physicochemical transducer, often an electrochemical or an optical device.

Conductometry An electrochemical technique used to determine the quantity of an analyte present in a mixture by measuring its effect on the electrical conductivity of the mixture.

Coulometry An electrochemical technique that measures the electrical charge passing between two electrodes in an electrochemical cell, with the amount of charge passing between the electrodes being directly proportional to oxidation or reduction of an electroactive substance at one of the electrodes.

Electrochemical cell An electrochemical device that consists of two electrodes (electron or metallic conductors) that are connected by an electrolyte solution that conducts ions (galvanic cell), or an electrochemical device in which an external voltage is applied to a polarizable working electrode with the resulting cathodic or anodic current of the cell being monitored (electrolytic cell).

Electrode A half-cell that consists of a single metallic conductor in contact with an electrolyte solution; the indicator (measuring) electrode is one half-cell and the reference electrode is the second half-cell.

Electrode potential The reduction potential for a redox couple that is measured with respect to a standard hydrogen electrode set at zero; the electromotive force of an electrochemical cell.

Ion-selective electrode An electrode that selectively interacts with a single ionic species; the potential produced at the membrane/sample solution interface is proportional to the logarithm of the ionic activity or the concentration of the ion in question.

*The authors gratefully acknowledge the original contributions of Drs. Richard A. Durst and Ole Siggard-Andersen, on which portions of this chapter are based.

Key Words and Definitions—cont'd

Nernst equation The equation used to determine the reduction potential for a given redox couple and used to correlate chemical energy with the electrical potential of an electrochemical cell.

Optode An optical sensor that measures specific substances such as pH, blood gases, and electrolytes using dye immobilization, fluorescence quenching, or phosphorescence.

Potential difference The work required to move an electrical charge and measured in volts.

Potentiometry An electrochemical technique that measures an electrical potential difference between two electrodes (half-cells) in an electrochemical cell.

Redox couple A conjugate pair of substances that consists of any substance that accepts electrons (the oxidant) and any substance that donates electrons (the reductant); redox processes take place only between two redox couples, with electrons transferred from a reductant (Red_1) to an oxidant (Ox_2).

Voltammetry An electrolytic electrochemical process in which a specific oxidation or reduction reaction occurs at the surface of the working electrode; it is the charge transfer at this interface (current flow) that provides analytical information.

Several analytical methods used in the clinical laboratory are based on electrochemical measurements. In this chapter, the fundamental electrochemical principles of (1) potentiometry, (2) voltammetry/amperometry, (3) conductometry, and (4) coulometry will be summarized and clinical applications presented. Optodes and biosensors also are discussed.

Potentiometry

Potentiometric sensors are widely used clinically for the measurement of pH, PCO_2, and electrolytes (Na^+, K^+, Cl^-, Ca^{2+}, Mg^{2+}, Li^+) in whole blood, serum, plasma, and urine, and as transducers for developing biosensors for metabolites of clinical interest.

Basic Concepts

Potentiometry is the measurement of an electrical potential difference between two electrodes (half-cells) in an **electrochemical cell** (Figure 10-1). Such a **galvanic electrochemical cell** consists of two electrodes (electron or metallic conductors) that are connected by an electrolyte solution that conducts ions. An **electrode**, or half-cell, consists of a single metallic conductor that is in contact with an electrolyte solution. The ion conductors consist of one or more phases that may be in direct contact with each other or separated by membranes permeable only to specific cations or anions (see Figure 10-1). One of the electrolyte solutions is the sample containing the analyte(s) to be measured. This solution may be replaced by an appropriate reference solution of analyte for calibration purposes. By convention, the cell notation is shown so that the left electrode (M_L) is the reference electrode, and the right electrode (M_R) is the indicator (measuring) electrode (see later, Equation 3).[3]

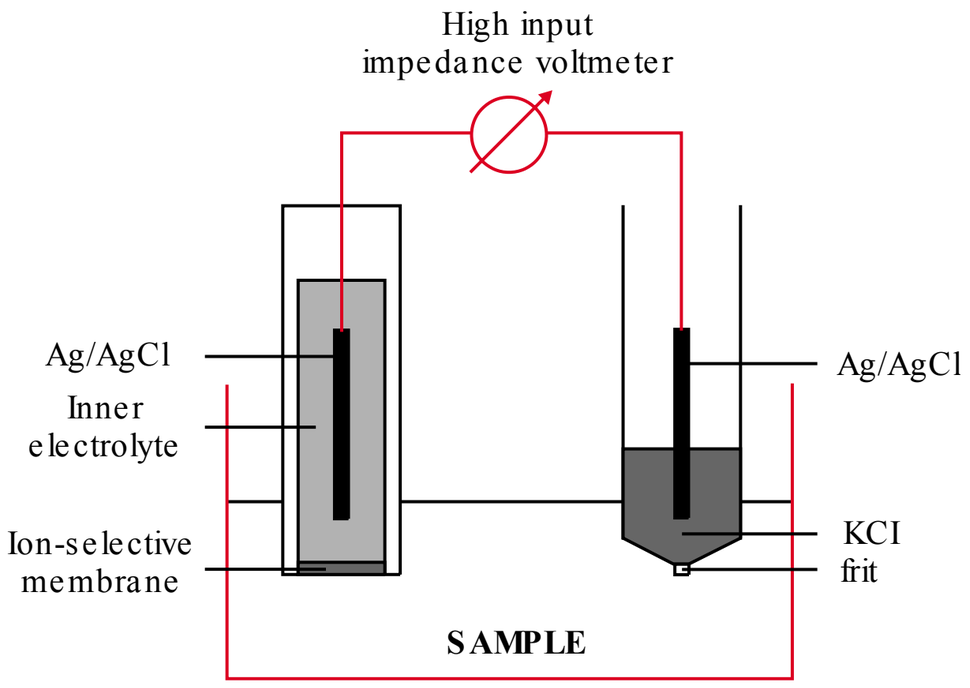

Figure 10-1 Schematic of ion-selective membrane electrode-based potentiometric cell.

The electromotive *force* (E or EMF) is defined as the maximum difference in potential between the two electrodes (right minus left) obtained when the cell current is zero. The cell potential is measured using a potentiometer, of which the common pH meter is a special type. The direct-reading potentiometer is a voltmeter that measures the potential across the cell (between the two electrodes); however, to obtain an accurate potential measurement, it is necessary that the current through the cell is essentially zero. This is accomplished by incorporating high resistance within the voltmeter (input impedance > 10^{12} Ω). Modern direct-reading potentiometers are accurate and have been modified to provide direct digital display or printouts.

Within any one conductive phase, the potential is constant as long as the current is zero. However, a potential difference arises between two different phases in contact with each other. The overall potential of an electrochemical cell is the sum of all potential differences that exist between adjacent phases of the cell. However, the potential of a single electrode with respect to the surrounding electrolyte and the absolute magnitude of the individual potential gradients between the phases are unknown and cannot be measured. Only the **potential difference** between two electrodes (half-cells) are measured. The potential gradients have been classified as (1) redox potentials, (2) membrane potentials, or (3) diffusion potentials. Generally, it is possible to devise a cell in such a manner that all potential gradients except one are constant. This is potential is then related to the activity of a specific ion of interest (e.g., H^+, Na^+).

Types of Electrodes

Different types of potentiometric electrodes are used for clinical applications. They include (1) redox, (2) ion-selective membrane (glass and polymer), and (3) PCO_2 gas-sensing electrodes.

Redox Electrodes

Redox potentials are the result of chemical equilibria involving electron transfer reactions:

$$\text{Oxidized form (Ox)} + ne^- \leftrightarrow \text{Reduced form (Red)} \quad (1)$$

where n represents the number of electrons (e^-) involved in the reaction. Any substance that accepts electrons is an oxidant (Ox), and any substance that donates electrons is a reductant (Red). The two forms, Ox and Red, represent a **redox couple** (conjugate redox pair). Usually, homogeneous redox processes take place only between two redox couples. In such cases, the electrons are transferred from a reductant (Red_1) to an oxidant (Ox_2). In this process, Red_1 is oxidized to its conjugate Ox_1, whereas Ox_2 is reduced to Red_2:

$$Red_1 + Ox_2 \leftrightarrow Ox_1 + Red_2 \quad (2)$$

In an electrochemical cell, electrons may be accepted from or donated to an inert metallic conductor (e.g., platinum). A reduction process tends to charge the electrode positively (remove electrons), and an oxidation process tends to charge the electrode negatively (add electrons). By convention, a heterogeneous redox equilibrium (Equation 2) is represented by the cell

$$M_L \mid Red_1 - Ox_1 \,\|\, Ox_2 - Red_2 \mid M_R \quad (3)$$

A positive potential ($E > 0$) for this cell signifies that the cell reaction proceeds spontaneously from left to right; $E < 0$ signifies that the reaction proceeds from right to left; and $E = 0$ indicates that the two redox couples are at mutual equilibrium.

The **electrode potential** (reduction potential) for a redox couple is defined as the couple's potential measured with respect to the standard hydrogen electrode, which is set equal to zero (see hydrogen electrode later). This potential, by convention, is the electromotive force of a cell, where the standard hydrogen electrode is the reference electrode (left electrode) and the given half-cell is the indicator electrode (right electrode). The reduction potential for a given redox couple is given by the **Nernst equation:**

$$E = E^\circ - \frac{N}{n} \times \log \frac{a_{Red}}{a_{Ox}} = E^\circ - \frac{0.0592V}{n} \times \log \frac{a_{Red}}{a_{Ox}} \quad (4)$$

where

E = electrode potential of the half-cell;
E° = standard electrode potential when $a_{Red}/a_{Ox} = 1$;
n = number of electrons involved in the reduction reaction;
$N = (R \times T \times \ln 10)/F$ (the Nernst factor if n = 1);
N = 0.0592V if T = 298.15 K (25 °C);
N = 0.0615V if T = 310.15 K (37 °C);
R = gas constant (= 8.31431 Joules × K^{-1} × mol^{-1}) ;
T = absolute temperature (unit: K, kelvin);
F = Faraday constant (= 96,487 Coulombs × mol^{-1});
ln 10 = natural logarithm of 10 = 2.303;
a = activity; and
a_{Red}/a_{Ox} = ratio of activities of reduced and oxidized species (also called the reaction quotient)…

Redox electrodes currently in use may be (1) inert metal electrodes immersed in solutions containing redox couples or (2) metal electrodes whose metal functions as a member of the redox couple.

Inert Metal Electrodes

Platinum and gold are examples of inert metals used to record the potential of a redox couple dissolved in an electrolyte solution. The hydrogen electrode is a special redox electrode for pH measurement. It consists of a platinum or gold electrode that is electrolytically coated (platinized) with highly porous platinum (platinum black) to catalyze the electrode reaction.

$$H^+ + e^- \leftrightarrow \frac{1}{2}H_2 \quad (5)$$

The electrode potential is given by

$$E = E^\circ - N \times \log \frac{(f_{H_2})^{1/2}}{a_{H^+}} \quad (6)$$

Or

$$E = E^\circ - N \times [\log(f_{H_2})^{1/2} - \log a_{H^+}] \quad (7)$$

where

E° = 0 at all temperatures (by convention);
f_{H_2} = fugacity of hydrogen gas;
a_{H^+} = activity of hydrogen ions; and
$-\log a_{H^+}$ = negative log of the H^+ activity (pa_{H^+} or pH).

When the partial pressure of hydrogen (PH_2) in the solution (and hence f_{H_2}) is maintained constant by bubbling hydrogen through the solution, the potential is a linear function of $\log a_{H^+}$. Because the pH of the solution is $-\log a_{H^+}$, the cell potential is linearly related to the pH. In the standard hydrogen electrode (SHE), the electrolyte consists of an aqueous solution of hydrogen chloride with a_{HCl} equal to 1.000 (or c_{HCl} = 1.2 mol/L) in equilibrium with a gas phase, and with f_{H_2} equal to 1.000 (or PH_2 = 101.3 kPa = 1 atm). The SHE is also used as a reference electrode.

Metal Electrodes Participating in Redox Reactions

The silver-silver chloride electrode is an example of a metal electrode that participates as a member of a redox couple. The silver-silver chloride electrode consists of a silver wire or rod coated with $AgCl_{(solid)}$ that is immersed in a chloride solution of constant activity; this sets the half-cell potential. It should be noted that rather than being deposited on the silver electrode, the $AgCl_{(solid)}$ can be dispersed into the solution with fixed chloride activity. The Ag/AgCl electrode itself is considered a potentiometric electrode because its phase boundary potential is governed by an oxidation-reduction electron transfer equilibrium reaction that occurs at the surface of the silver:

$$AgCl_{(solid)} + e^- \leftrightarrow Ag_{(solid)} + Cl^- \quad (8)$$

The Nernst equation for the reference half-cell potential of an Ag/AgCl reference electrode also is written as:

$$E_{Ag/AgCl} = E^{\circ}_{Ag/AgCl} + \frac{RT}{nF} \times \ln \frac{a_{AgCl}}{a_{Ag}a_{Cl^-}} \quad (9)$$

Because AgCl and Ag are both solids, their activities are equal to unity ($a_{AgCl} = a^0_{Ag} = 1$). Therefore, from Equation 9, the half-cell potential is controlled by the activity of chloride ion in solution (a_{CL^-}) contacting the electrode.

The Ag/AgCl electrode is used both as an internal reference element in potentiometric **ion-selective electrodes** (ISEs) and as an external reference electrode half-cell of constant potential, required to complete a potentiometric cell (see Figure 10-1). In both cases, the Ag/AgCl electrode must be in equilibrium with a solution of constant chloride ion activity.

The Ag/AgCl element of the external reference electrode half-cell is in contact with a high-concentration solution of a soluble chloride salt. Saturated potassium chloride is commonly used. A porous membrane or frit is frequently employed to separate the concentrated KCl from the sample solution. The frit serves both as a mechanical barrier to hold the concentrated electrolyte within the electrode and as a diffusional barrier to prevent proteins and other species in the sample from coming into contact with the internal Ag/AgCl element, which could poison and alter its potential. The interface between two dissimilar electrolytes (concentrated KCl/calibrator or sample) occurs within the frit and develops the liquid-liquid junction potential (E_j), which represents a source of error in potentiometric measurements. The difference in liquid-liquid junction potential between calibrator and sample (residual liquid junction potential) is responsible for this error but is minimized and usually is neglected in practice if the compositions of the calibrating solutions are matched as closely as possible to the sample with respect to ionic content and ionic strength. An equitransferent* electrolyte at high concentration as the reference electrolyte further helps to minimize the residual liquid junction potential. Potassium chloride at a concentration ≥2 mol/L is preferred.

The presence of erythrocytes in the sample may affect the magnitude of the residual liquid junction potential in a less predictable manner. For example, erythrocytes in blood of normal hematocrit are estimated to produce approximately 1.8 mmol/L positive error in the measurement of sodium by ISEs when an open, unrestricted liquid-liquid junction is used.[5] This bias may be minimized if a restrictive membrane or frit is used to modify the liquid-liquid junction.

The saturated calomel electrode is another example of a metal electrode that participates as a member of a redox couple. The calomel electrode consists of mercury covered by a layer of relatively insoluble calomel (Hg_2Cl_2) (or present as insoluble salt dispersed in the electrolyte), which is in contact with an electrolyte solution containing Cl^-. The oxidation-reduction equilibrium reaction is as shown:

$$Hg_2Cl_2 + 2e^- \leftrightarrow 2Hg^\circ + 2Cl^- \quad (10)$$

As with the Ag/AgCl electrode, the half-cell potential is controlled by the activity of chloride ion contacting the electrode. Calomel electrodes are frequently used as reference electrodes for pH measurements using glass pH electrodes.

Ion-Selective Electrodes

Membrane potentials are caused by the permeability of certain types of membranes to selected anions or cations. Such membranes are used to fabricate ISEs that selectively interact with a single ionic species. The potential produced at the membrane/sample solution interface is proportional to the logarithm of ionic activity or of the concentration of the ion in question. Measurements with ISEs are (1) simple, (2) often rapid, (3) nondestructive, and (4) applicable to a wide range of concentrations.

The ion-selective membrane is the "heart" of an ISE, as it controls the selectivity of the electrode. Ion-selective membranes typically consist of (1) glass, (2) crystalline, or (3) polymeric materials. The chemical composition of the membrane is designed to achieve an optimal permselectivity toward the ion of interest. In practice, other ions exhibit finite interaction with membrane sites and will display some degree of interference for determination of an analyte ion. In clinical practice, if the interference exceeds an acceptable value, a correction is required.

The Nicolsky-Eisenman equation describes the selectivity of an ISE for the ion of interest over interfering ions:

$$E = E^{\circ} + \left(\frac{2.303RT}{z_iF}\right) \log\left(a_i + \sum_j K_{i/j}a_j^{zi/zj}\right) \quad (11)$$

where

a_i = activity of the ion of interest;
a_j = activity of the interfering ion;
$K_{i/j}$ = selectivity coefficient for the primary ion over the interfering ion. Low values indicate good selectivity for the analyte "i" over the interfering ion "j";
z_i = charge of the primary ion; and
z_j = charge of the interfering ion.

All other terms are identical to those in the Nernst equation (Equation 4).

Glass membrane and polymer membrane electrodes are two types of ISEs that are commonly used in clinical chemistry applications.

The Glass Electrode

Glass membrane electrodes are used to measure pH and Na^+ and as an internal transducer for PCO_2 sensors. The H^+ response of thin glass membranes was first demonstrated in 1906 by Cremer. In the 1930s, practical application of this

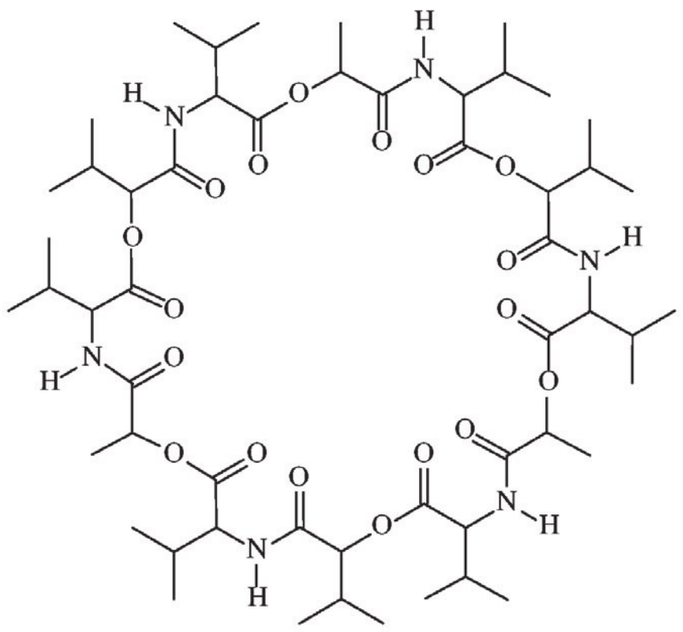
*An electrolyte is equitransferent if the ions have the same mobility in solution, measured as the ionic equivalent conductivity.

phenomenon for measurement of acidity in lemon juice was made possible by the invention of the pH meter by Arnold Beckman.[3] Glass electrode membranes are formulated from melts of silicon and/or aluminum oxide mixed with oxides of alkaline earth or alkali metal cations. By varying the glass composition, electrodes with selectivity for H^+, Na^+, K^+, Li^+, Rb^+, Cs^+, Ag^+, Tl^+, and NH_4^+ have been produced. However, glass electrodes for H^+ and Na^+ are today the only types with sufficient selectivity over interfering ions to allow practical application in clinical chemistry. A typical formulation for H^+ selective glass is 72% SiO_2; 22% Na_2O; 6% CaO. This formulation has a selectivity order of $H^+ >>> Na^+ > K^+$, and has sufficient selectivity for H^+ over Na^+ to allow error-free measurements of pH in the range of 7.0 to 8.0 ($[H^+] = 10^{-7}$ to 10^{-8} mol/L) in the presence of >0.1 mol/L Na^+. By altering slightly the formulation of the glass membrane to 71% SiO_2; 11% Na_2O; 18% Al_2O_3, its selectivity order becomes $H^+ > Na^+ > K^+$, and the preference of the glass membrane for H^+ over Na^+ is greatly reduced, resulting in a practical sensor for Na^+ at pH values typically found in blood.

Polymer Membrane Electrodes

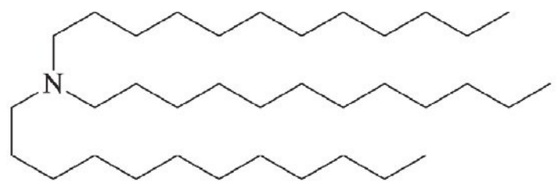
Polymer membrane ISEs are employed for monitoring pH and for measuring electrolytes, including K^+, Na^+, Cl^-, Ca^{2+}, Li^+, Mg^{2+}, and CO_3^{2-} (for total CO_2 measurements). They are the predominant class of potentiometric electrodes used in modern clinical analysis instruments.

The mechanisms of response of these ISEs fall into three categories: (1) charged, dissociated ion exchanger, (2) charged associated carrier, and (3) neutral ion carrier (ionophore). An early charged associated ion exchanger–type ISE for Ca^{2+} was developed and commercialized for clinical application in the 1960s. This electrode was based on the Ca^{2+}-selective ion exchange/complexation properties of 2-ethylhexyl phosphoric acid dissolved in dioctyl phenyl phosphonate (charged associated carrier). A porous membrane was impregnated with this solution and mounted at the end of an electrode body. This type of sensor was referred to as the liquid membrane ISE. Later, a method was devised whereby these ingredients were cast into a plasticized poly(vinyl chloride) (PVC) membrane that was more rugged and convenient to use than its wet liquid predecessor. This same approach is still used today to formulate PVC-based ISEs for clinical use.



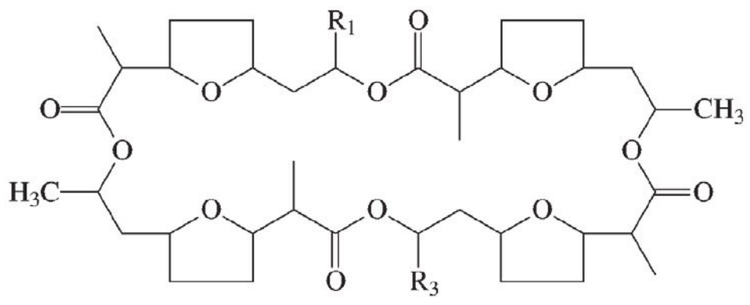
A major breakthrough in the development and routine application of PVC-type ISEs was the discovery that the neutral antibiotic valinomycin could be incorporated into organic liquid membranes (and later plasticized PVC membranes), resulting in a sensor with high selectivity for K^+ over Na^+ ($K_{K/Na} = 2.5 \times 10^{-4}$).[16] The K^+ ISE based on valinomycin is extensively used today for routine measurement of K^+ in blood. A wide linear range of over three orders of magnitude makes this ISE suitable for the measurement of K^+ in blood and urine. The K^+ range in blood is only a small portion of the electrode linear range and is spanned by a total EMF of about 9 mV. Interference from other cations, seen as deviation from linearity, is not apparent at K^+ activities $>10^{-4}$ mol/L. Other, less selective polymer-based ISEs (e.g., for the measurement of Mg^{2+} and Li^+) are subject to interference from Ca^{2+}/Na^+, and Na^+, respectively, requiring simultaneous determination and correction for the presence of significant concentrations of interfering ions.

Studies regarding the relationship between molecular structure and ionic selectivity have resulted in the development of polymer-based ISEs using a number of naturally occurring and synthetic ionophores, with sufficient selectivity for application in clinical analysis. The chemical structures of several of these neutral ionophores are illustrated in Figure 10-2.

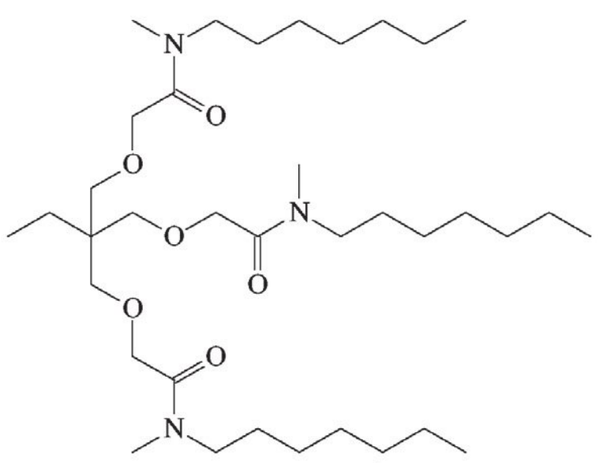


Dissociated anion exchanger–based electrodes employing lipophilic quaternary ammonium salts as active membrane components also are still used commercially for the determination of Cl^- in whole blood, serum, and plasma despite some limitations. Selectivity for this type of ISE is controlled by extraction of the ion into the organic membrane phase and is a function of the lipophilic character of the ion (because, unlike the carriers described previously, no direct binding interaction occurs between the exchanger site and the anion in the membrane phase). Thus the selectivity order for a Cl^- ISE based on an anion exchanger is fixed as $R^- > ClO_4^- > I^- > NO_3^- > Br^- > Cl^- > F^-$, where R^- represents anions that are more lipophilic than ClO_4^-. The application of the Cl^- ion-exchange electrode is therefore limited to samples without significant concentrations of anions more lipophilic than Cl^-. Blood samples containing salicylate or thiocyanate, for example, will produce positive interference for the measurement of Cl^-. Repeated exposure of the electrode to the anticoagulant heparin will lead to loss of electrode sensitivity toward Cl^- caused by extraction of the negatively charged heparin into the membrane. Indeed, this extraction process has been used successfully to devise a method to detect heparin concentrations in blood by potentiometry.[12]

High selectivity for carbonate anion has been achieved using a neutral carrier ionophore possessing trifluoroacetophenone groups doped within a polymeric membrane.[10] Such ionophores form negatively charged adducts with carbonate anions, and the resulting electrodes have proved useful in commercial instruments for determination of total carbon dioxide in serum/plasma after dilution of the blood to a pH value in the range of 8.5 to 9.0, where a significant fraction of total carbon dioxide will exist as carbonate anions.



In practice, the ultimate detection limits of polymer membrane–type ISEs are partially controlled by the leakage of analyte ions from the internal solution to the outer surface of the membrane and into the sample phase in close contact with the membrane.[13] Hence, much lower limits of detection are achieved by decreasing the concentration of the primary analyte ion within the internal solution of the electrode. Further, this leakage of analyte ions, coupled with an ion-exchange process at the membrane/sample interface when the selectivity of the membrane over other ions is assessed, often yields a measured potentiometric selectivity coefficient that underestimates the true selectivity of the membrane. In determining "unbiased" selectivity coefficients by the separate solution method, the membrane should not be exposed to the analyte



Valinomycin: K^+

ion for extended periods, and the concentration of analyte ion in the internal solution should be low.

Electrodes for PCO_2

Electrodes are available that measure PCO_2 in body fluids. T e first PCO_2 electrode, developed in the 1950s by Stow and Severinghaus, used a glass pH electrode as the internal element in a potentiometric cell for measurement of the partial pressure of carbon dioxide.[2] T is important development led to the commercial availability of the three-channel blood analyzer (pH, PCO_2, PO_2) that clinically provides the complete picture of the oxygenation and acid-base status of blood.

Figure 10-3 shows a diagram of a typical Stow-Severinghaus–style electrode for PCO_2. A thin membrane that is approximately 20 μm thick and is permeable only to gases and water vapor is in contact with the sample. Membranes of silicone rubber, Teflon, and other polymeric materials are suitable for this purpose. On the opposite side of the membrane is a thin electrolyte layer consisting of a weak bicarbonate salt (about 5 mmol/L) and a chloride salt. A pH electrode and an Ag/AgCl reference electrode are in contact with this solution. T e PCO_2 electrode is a self-contained potentiometric cell. Carbon dioxide gas from the sample or calibration matrix diffuses through the membrane and dissolves in the internal

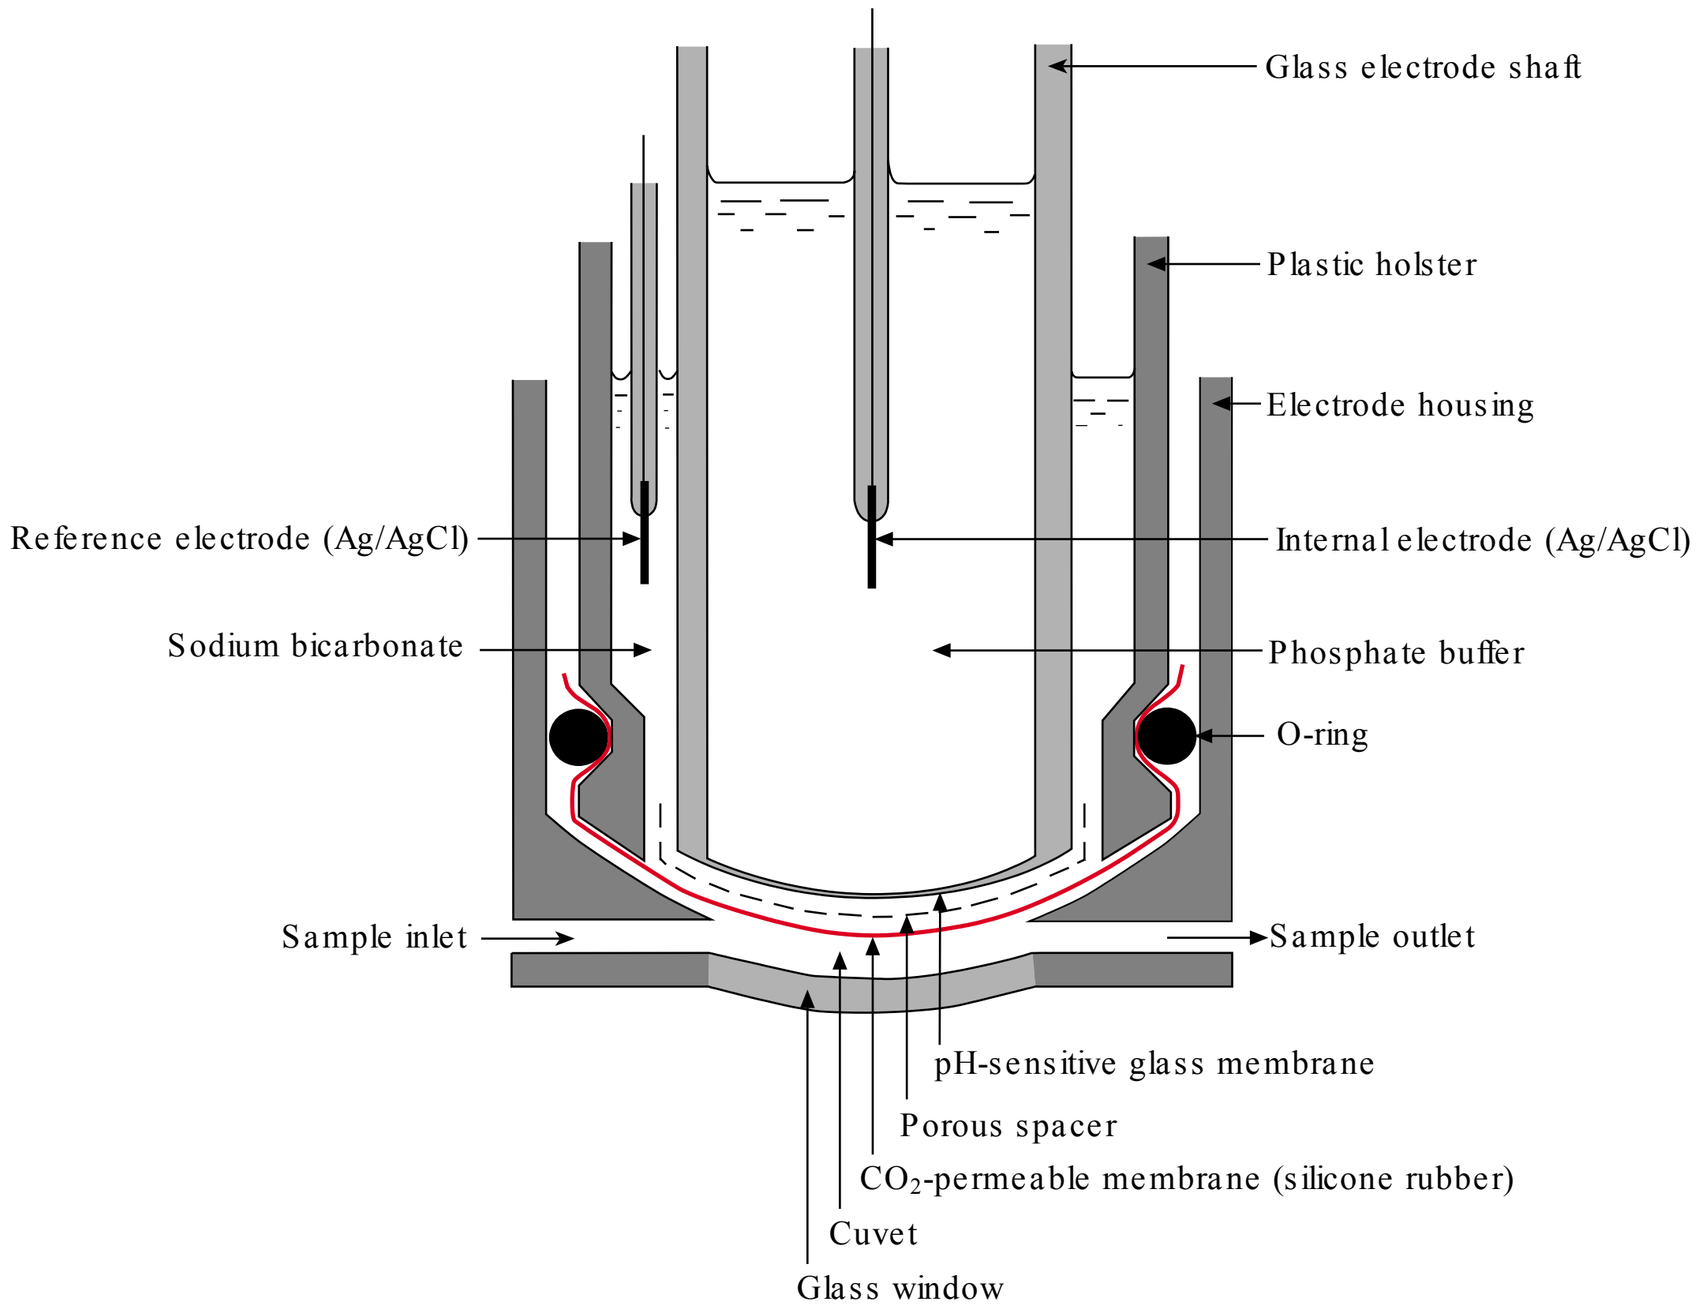

Figure 10-3 Schematic of Stow-Severinghaus–style PCO_2 sensor used to monitor CO_2 concentrations in blood samples. (From Siggard-Andersen O. The acid-base status of the blood, 4th ed. Baltimore: Williams & Wilkins, 1974:172.)

electrolyte layer. Carbonic acid is formed and dissociates, shifting the pH of the bicarbonate solution within the internal layer:

$$CO_2 + H_2O \leftrightarrow H_2CO_3 \leftrightarrow H^+ + HCO_3^- \quad (12)$$

and

$$\Delta \log PCO_{2(\text{sample})} \approx \Delta pH_{(\text{internal layer})} \quad (13)$$

The relationship between the sample PCO_2 and the signal generated by the internal pH electrode is logarithmic and is governed by the Nernst equation (Equation 4). The electrode may be calibrated using exact gas mixtures or solutions with stable PCO_2 concentrations. Although Stow-Severinghaus–style electrodes for PCO_2 have gained widespread use in modern blood gas analyzers, the format in which such sensors may be constructed is limited by their (1) size, (2) shape, and (3) ability to fabricate the internal pH-sensitive element.

A slightly different potentiometric cell for PCO_2 is shown in Figure 10-4. This cell arrangement uses two PVC-type pH-selective electrodes in a differential mode. The electrode membranes contain a lipophilic amine–type neutral ionophore that exhibits very high selectivity for H^+ (see Figure 10-2). One electrode has an internal layer, which is buffered, and the other is unbuffered, consisting of a low concentration of bicarbonate salt. Carbon dioxide gas from the sample or calibration matrix diffuses across the outer H^+-selective PVC membranes of both sensors. On the unbuffered side, CO_2 diffusion produces a

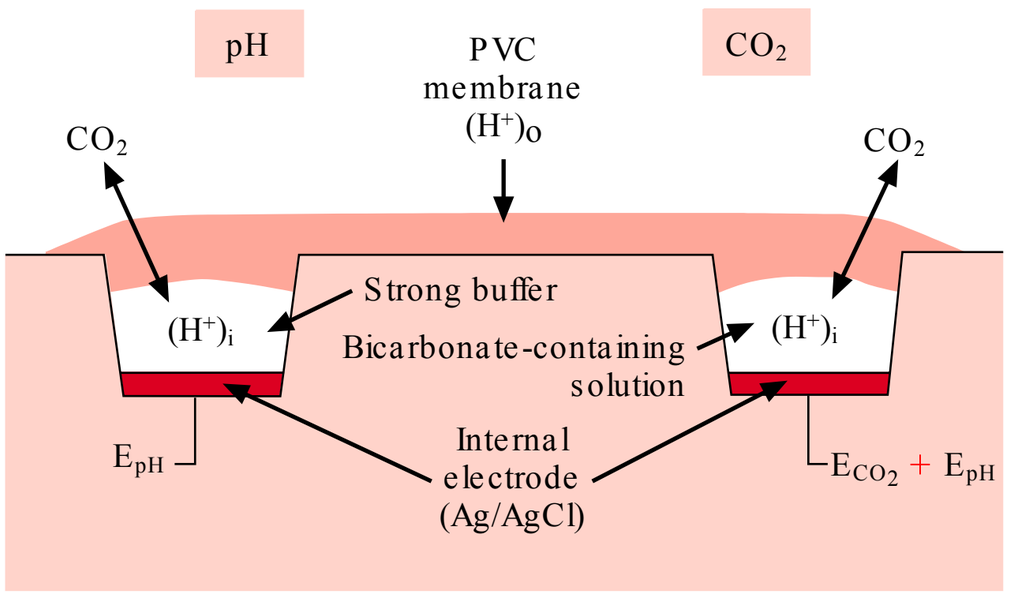

Figure 10-4 Differential planar PCO_2 potentiometric sensor design based on two identical polymeric membrane pH electrodes but with different internal reference electrolyte solutions. Both pH-sensing membranes are prepared with H^+-selective ionophore.

potential shift at the internal interface of the pH-responsive membrane proportional to the sample PCO_2 concentration. The signal at the electrode with the buffered internal layer is unaffected by CO_2 that diffuses across the membrane. Consequently, one-half of the sensor responds to pH alone, and the other half responds to both pH and PCO_2. The signal difference between the two electrodes cancels any contribution of sample pH to the overall measured cell potential. The differential signal is proportional only to PCO_2.

Direct Potentiometry by ISE—Units of Measure and Reporting for Clinical Applications

Most analytical methods measure the total concentration (c) of a given ion in the sample, usually expressed in units of millimoles of ion per liter of sample (mmol/L). Molality (m) is a measure of the moles of ion per mass of water (mmol/kg) in the sample. With the sodium ion used as an example, the relationship between concentration and molality is given by:

$$c_{Na^+} = m_{Na^+} \times \rho H_2C \quad (14)$$

where ρH_2O is the mass concentration of water in kg/L. For blood plasma from healthy individuals, the mass concentration of water is approximately 0.93 kg/L, but in specimens with elevated lipids or protein, the value may be as low as 0.8 kg/L. In these specimens, the difference between concentration and molality may be as great as 20%. A significant advantage of direct potentiometry by ISE for the measurement of electrolytes is that the technique is sensitive to molality and therefore is not affected by variations in the concentration of protein or lipids in the sample. Techniques such as flame photometry and other photometric methods requiring sample dilution are affected by the presence of protein and lipids. With these methods, only the water phase of the sample is diluted, producing results lower than molality as a function of the concentration of protein and lipids in the sample. T us, there is a risk for error, such as a falsely low Na^+ concentration (pseudohyponatremia), in cases of extremely elevated protein and lipid concentrations.[1]

In addition to the difference between molality and concentration, measurement of ions by direct potentiometry provides yet another unit of measurement known as activity (a), the concentration of free, unbound ion in solution. Unlike methods sensitive to total ion concentration, ISEs do not sense the presence of complexed or electrostatically "hindered" ions in the sample. T e relationship between activity and concentration, using, again, sodium ion as an example, is expressed as:

$$a_{Na^+} = \gamma_{Na^+} \times c_{Na^+} \quad (15)$$

where γ is a dimensionless quantity known as the activity coefficient. T e activity coefficient is primarily dependent on the ionic strength of the sample as described by the Debye-Hückel equation:

$$\log\gamma = -\frac{A \times z^2 \times I^{1/2}}{1 + B \times a \times I^{1/2}} \quad (16)$$

where A and B are temperature-dependent constants (A = 0.5213 and B = 3.305 in water at 37 °C), a is the ion size parameter for a specific ion, and I is the ionic strength ($I = 0.5\Sigma m \times z^2$, where z is the charge number of the ions). Equation 16 shows that a decrease in the activity coefficient occurs with an increase in ionic strength. T is effect is more pronounced when the charge (z) of the ion is high. Activity coefficients for ions in biological fluids, such as blood and serum, are difficult to calculate with accuracy because of the uncertain contribution of macromolecular ions, such as proteins, to the overall ionic strength. However, if it is assumed that the normal ionic strength of blood plasma is 0.160 mol/kg, then estimates of activity coefficients at 37 °C are as follows: $Na^+ = 0.75$, $K^+ = 0.74$, and $Ca^{2+} = 0.31$. In reference to Equation 15, activity and concentration will differ greatly in samples of physiological ionic strength, especially for divalent ions.

Physiologically, ionic activity is assumed to be more relevant than concentration when chemical equilibria or biological processes are considered. Practically, however, ionic concentration is the more familiar term in clinical practice, forming the basis of reference intervals and medical decision concentrations for electrolytes. Early in the evolution of ISEs as practical tools in clinical chemistry, it was decided that changing clinical reference intervals to a system based on activity instead of concentration was impractical and carried the risk for clinical misinterpretation. A pragmatic approach for using ISEs in modern analyzers without changing established concentration-based reference intervals is to formulate calibration solutions with ionic strengths and ionic compositions as close as possible to those of blood plasma from healthy individuals. T us the activity coefficient of each ion in the calibrating solutions approximates that in the sample matrix, allowing calibration and measurement of electrolytes in units of concentration instead of activity.

Voltammetry/Amperometry

Voltammetric and amperometric techniques are among the most sensitive and widely applicable of all electroanalytical methods.

Basic Concepts

In contrast to potentiometry, voltammetric and amperometric methods are based on electrolytic electrochemical cells, in which an external voltage is applied to a polarizable working electrode (measured vs. a suitable reference electrode: $E_{appl} = E_{work} - E_{ref}$), and the resulting cathodic (for analytical reductions) or anodic (for analytical oxidations) current of the cell is monitored and is proportional to the concentration of analyte present in the test sample. Current flows only if E_{appl} is greater than a certain voltage (decomposition voltage), as determined by the thermodynamics for a given redox reaction of interest ($Ox + ne^- \leftrightarrow Red$; defined by the E° value for that reaction [standard reduction potential]) and the kinetics for heterogeneous electron transfer at the interface of the working electrode. Often, slow kinetics of electron transfer for the redox reaction on a given inert working electrode (Pt, carbon, gold, etc.) requires use of a much more negative (for reductions) or positive (for oxidations) E_{appl} than predicted based merely on the E° for a given redox reaction. T is is called an overpotential (η). Regardless of whether an overpotential for electron transfer exists, in **voltammetry/amperometry**, a specific oxidation or reduction reaction occurs at the surface of the working electrode, and it is the charge transfer at this interface (current) that provides the analytical information.

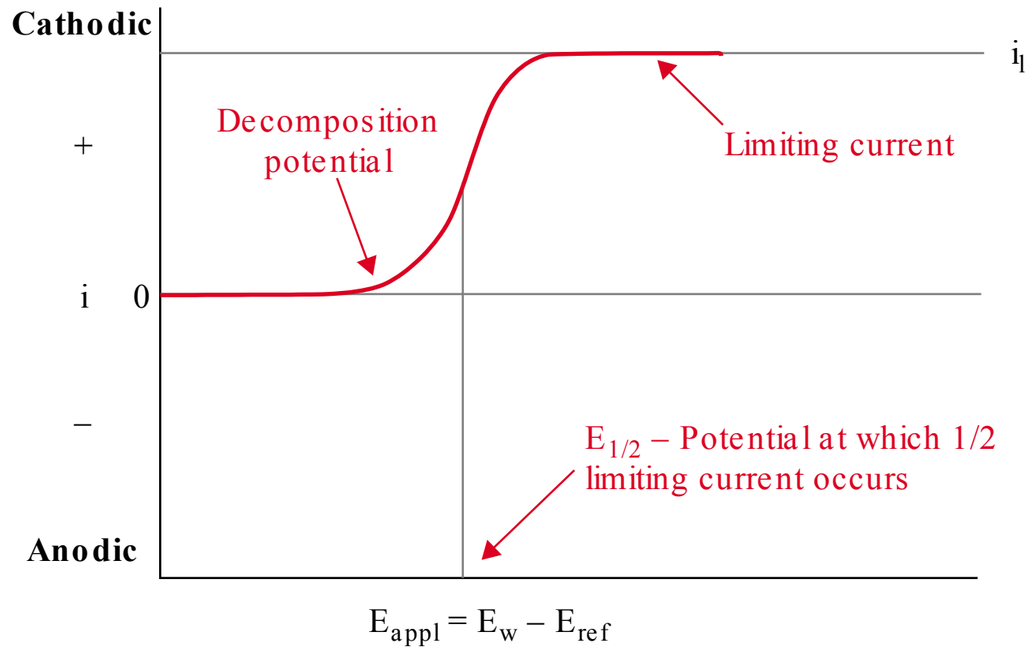

Figure 10-5 Illustration of the current versus voltage curve (voltammogram) obtained for oxidized species (Ox) reduced to Red at the surface of the working electrode, as the E_{appl} is scanned more negative and the solution is stirred to yield a steady state response.

For electrolytic cells that form the basis of voltammetric and amperometric methods:

$$E_{appl} = E_{cell} + \eta - iR_{cell} \qquad (17)$$

where E_{cell} is the thermodynamic potential between working and reference electrodes in the absence of an applied external voltage. When the external voltage is greater or less than this equilibrium potential, plus or minus any overpotential (η), then current will flow because of an oxidation or reduction reaction at the working electrode. A voltammogram is simply the plot of observed current, i, versus E_{appl} (Figure 10-5). In amperometry (see later), a fixed voltage is applied, and the resulting current is monitored. T e amount of current is inversely related to the resistance of the electrolyte solution and to any "apparent" resistance that develops because of the mass transfer of the analyte species to the surface of the working electrode. Because the electrochemical reactions are heterogeneous and occur only at the surface of the working electrode, the amount of current observed is highly dependent on the surface area (A) of the working electrode.

When a potential is applied to a working electrode that will oxidize or reduce a species in the solution phase contacting the electrode, the electrochemical reaction causes the concentration of electroactive species to decrease at the surface of the electrode (Figure 10-6) through a process termed concentration polarization. T is in turn causes a concentration gradient of the analyte species between the bulk sample solution and the surface of the electrode. When the bulk solution is stirred, the diffusion layer of analyte grows out from the surface of the electrode very quickly to a fixed distance controlled by how vigorously the solution is stirred. T is diffusion layer, which is termed the Nernst layer, has a finite thickness (δ) after a relatively short time (see Figure 10-6) when the solution is moving (convection). Voltammetry carried out in the presence of convection (by stirring the solution, rotating the electrode, flowing solution by electrode, etc.) is called steady state voltammetry. When the solution is motionless, the diffusion layer is not constant and grows with time, creating larger and

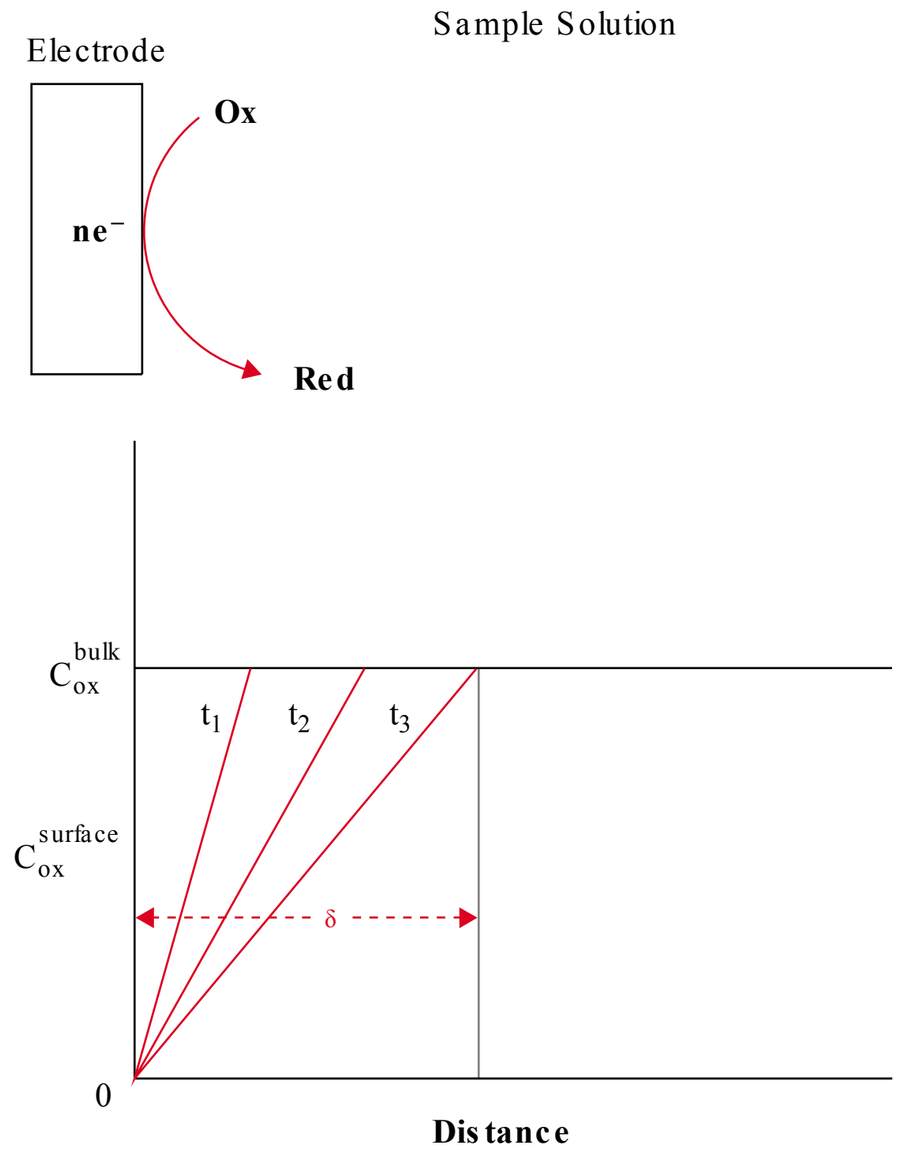

Figure 10-6 Concept of electrochemical reaction increasing diffusion layer thickness (concentration polarization) of the analyte via reduction (or oxidation) at the surface of the working electrode. As time (t) increases, the diffusion layer thickness grows quickly to a value that is determined by degree of convection in the sample solution.

larger δ values. T is is termed non–steady state voltammetry and often results in peak currents in i versus E_{appl} plots for electrolytic cells.

In steady state voltammetry, when the potential of the working electrode is scanned past a value that will cause an electrochemical reaction, the current will rise rapidly and then eventually will reach a near-constant value, even as E_{appl} changes further. Figure 10-5 illustrates such a wave for a hypothetical reduction of an oxidized species (Ox) via an n electron transfer from a reduced species (Red). When the applied potential is much more negative than required, the current reaches a limiting value (termed the limiting current, i_l). T is limiting current is proportional to the concentration of the electroactive species (Ox in this case) as expressed by the following equation:

$$i_l = nFA \frac{D'}{\delta} C_{ox} \qquad (18)$$

where i is the measured current in amperes, n equals the number of electrons in the electrochemical reaction (reduction in this case), F is Faraday's constant (96,487 coulombs/mol), A is the electrochemical surface area of the working electrode (in cm^2) (if a planar electrode geometry is assumed), D is the diffusion coefficient (in cm^2/s) of the electroactive species (Ox in this case), δ is the diffusion layer thickness (in centimeters), and C is the concentration of the analyte species in mol/cm^3. T e D/δ term is often denoted as m_o, the mass transfer coefficient

of the Ox species to the surface of the working electrode. Note that Equation 18 indicates a linear relationship for limiting current and concentration. The same equation applies for detecting reduced species by an oxidation reaction at the working electrode. In this case, by convention, the resulting anodic current is considered a negative current. As shown in Figure 10-5, the potential of the working electrode that corresponds to a current that is exactly one-half the limiting current is termed the $E_{1/2}$ value. This value is not dependent on analyte concentration but is determined by the thermodynamics (E°) of the given redox reaction, the solution conditions (e.g., if protons are involved in reaction, the pH will influence the $E_{1/2}$ value), and any overpotential caused by slow electron transfer, and so forth, at a particular working electrode surface. The $E_{1/2}$ values are indicative of a given species undergoing an electrochemical reaction under specified conditions; hence, the $E_{1/2}$ values enable one to distinguish one electroactive species from another in the same sample. If the $E_{1/2}$ values for various species differ significantly (e.g., >120 mV), then measurement of several limiting currents in a given voltammogram is capable of yielding quantitative results for several different species simultaneously.

Electrochemical cells employed to carry out voltammetric or amperometric measurements typically involve a two- or three-electrode configuration. In the two-electrode mode, the external voltage is applied between the working electrode and a reference electrode, and the current is monitored. Because the current must also pass through the reference electrode, such current flow will alter the surface concentration of electroactive species that poises the actual half-cell potential of the reference electrode, changing its value through a concentration polarization process. For example, if an Ag/AgCl reference electrode were used in a cell in which a reduction reaction for the analyte occurs at the working electrode, an oxidation reaction would take place at the surface of the reference electrode:

$$Ag^{\square} + Cl^- \rightarrow AgCl_{(s)} + 1e^- \qquad (19)$$

Consequently, the activity/concentration of chloride ions near the surface of the electrode would decrease, which would make the potential of the reference electrode more positive than its true equilibrium value based on the actual activity of chloride ion in the reference half-cell, because the Nernst equation for this half-cell is:

$$E_{Ag/AgCl} = E^{\square}_{Ag/AgCl} - 0.059\log\left(a^{surface}_{Cl^-}\right) \qquad (20)$$

Such concentration polarization of the reference electrode is prevented by maintaining the current density (J; amperes/cm^2) very low at the reference electrode. This is achieved in practice by making sure that the area of the working electrode in the electrochemical cell is much smaller than the surface area of the reference electrode; consequently, the total current will be limited by this much smaller area, and J values for the reference will be very small, as desired, to prevent concentration polarization.

To completely eliminate changes in reference electrode half-cell potentials, a three-electrode potentiostat is often employed. In simple terms, the potentiostat applies a voltage to the working electrode that is measured versus a reference electrode via a zero current potentiometric-type measurement, but the current flow is between the working electrode and a third electrode, called the counter electrode. Thus if reduction takes place at the working electrode, oxidation would occur at the counter electrode, but no net reaction would take place at the surface of the reference electrode, because no current flows through this electrode.

In voltammetric methods, the E_{appl} is varied via some waveform to alter the working electrode potential as a function of time, and the resulting current is measured. The current change occurs at the decomposition potential range, which is expected to be specific for a given analyte. However, the location of the current response as a function of E_{appl} provides information on the nature of the species present (e.g., $E_{1/2}$), along with a concentration-dependent signal. This is scan of E_{appl} is linear (linear sweep voltammetry), or it can have more complex shapes that enable greatly enhanced sensitivity to be achieved for monitoring the concentration of a given electroactive species (e.g., normal pulsed voltammetry, differential pulse voltammetry, square wave voltammetry). When a dropping mercury electrode (DME) is used, such voltammetric methods are considered polarographic methods of analysis.

Amperometric methods differ from voltammetry methods in that E_{appl} is fixed, generally at a potential value that occurs in the limiting current plateau region of the voltammogram. The resulting current is proportional to concentration. Amperometry usually is more sensitive than common voltammetric methods because background charging currents that arise from changing the E_{appl} as a function of time in voltammetry do not exist. Hence, when selectivity is ensured at a given E_{appl} value, amperometry may be preferred to voltammetric methods for more sensitive quantitative measurements.

Applications

Molecular oxygen is capable of undergoing several reduction reactions, all with significant overpotentials at solid electrodes, such as Pt, Au, or Ag. For example, the following reaction:

$$O_2 + 2H_2O + 4e^- \rightarrow 4OH^- \quad (E^{\square} = +0.179 \text{ vs Ag/AgCl;1mol/L } Cl^-) \qquad (21)$$

exhibits an $E_{1/2}$ of approximately −0.500 V on a Pt electrode (vs. Ag/AgCl), with a limiting current plateau beginning at approximately −0.600 V. This reaction has been used to monitor the partial pressure of oxygen (PO_2) in blood and is the basis of the widely used Clark style amperometric oxygen sensor (Figure 10-7). This device employs a small area planar platinum electrode as a working electrode (encased in insulating glass or other material) and an Ag/AgCl reference electrode, typically with a cylindrical design (see Figure 10-7). This two-electrode electrolytic cell is placed within a sensor housing on which a gas-permeable membrane (e.g., polypropylene, silicone rubber, Teflon) is held at the distal end. The inner working platinum electrode is pressed tightly against the gas-permeable membrane to

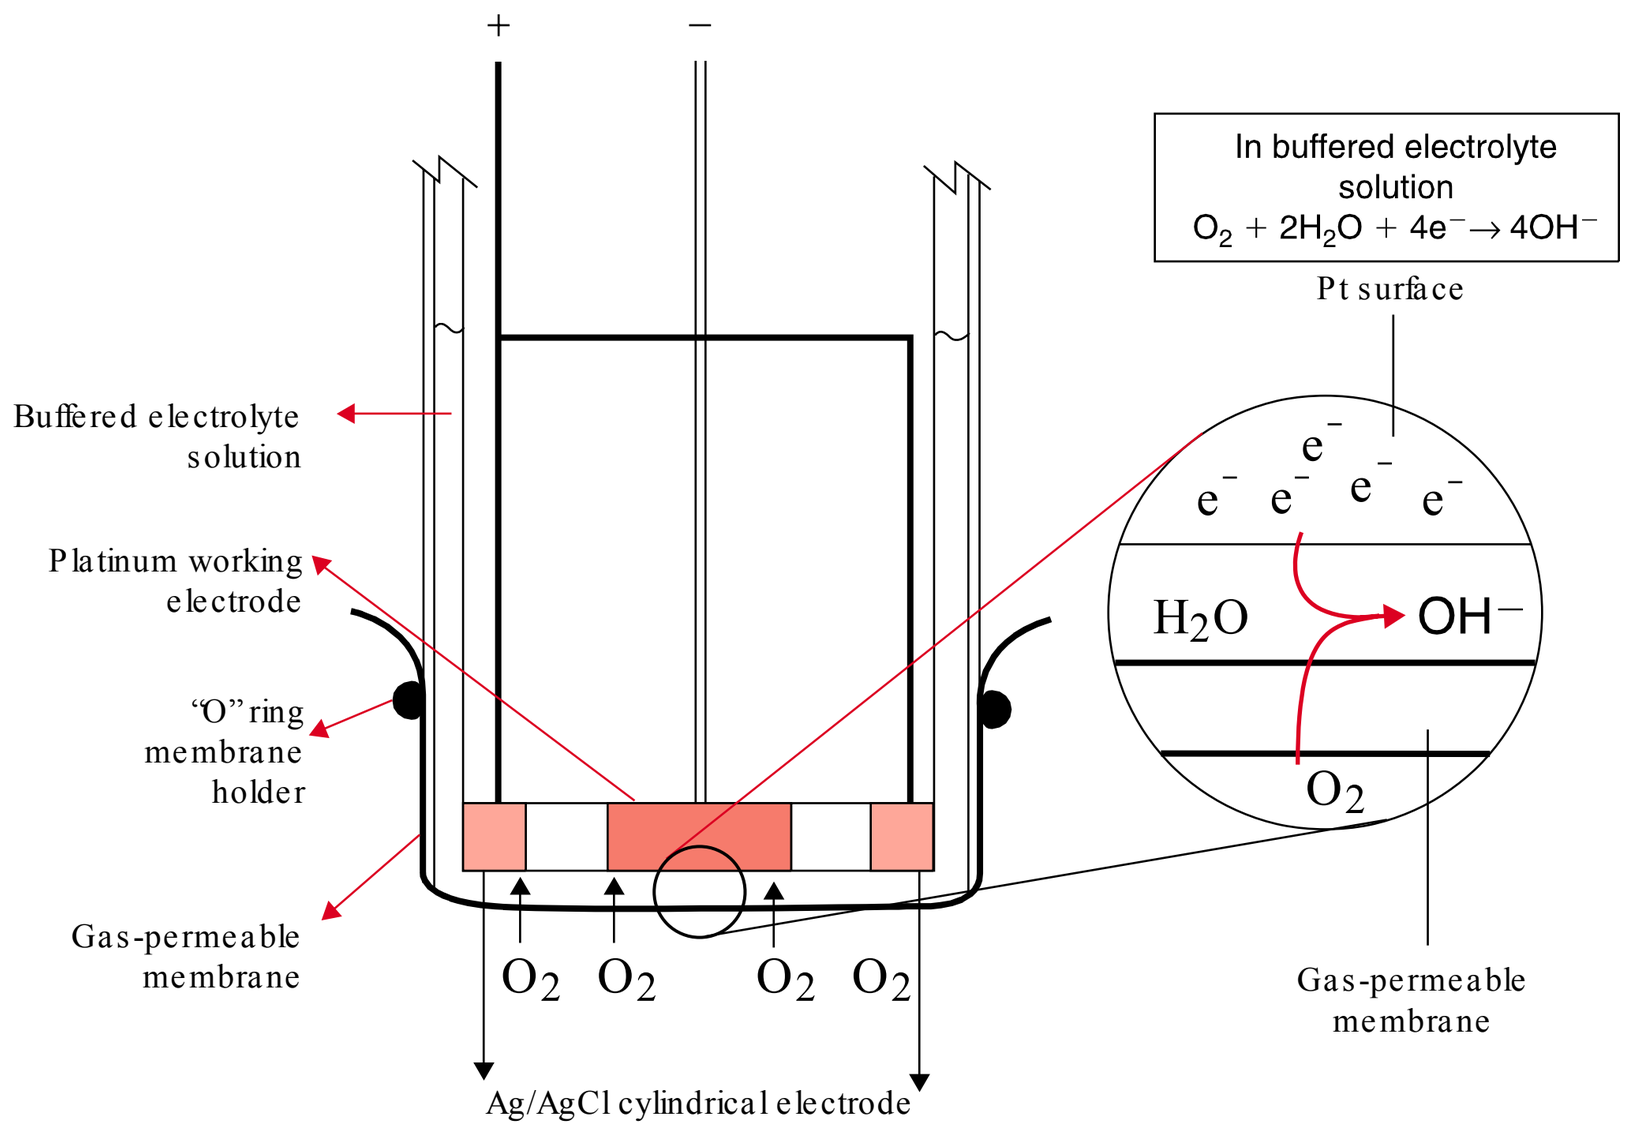

Figure 10-7 Design of Clark-style amperometric oxygen sensor used to monitor PO_2 concentrations in blood.

create a thin film of internal electrolyte solution (usually buffer with KCl added). Oxygen in the sample permeates across the membrane and is reduced in accordance with the above electrochemical reaction. An E_{appl} of −0.650 or −0.700 V versus Ag/AgCl (within the limiting current regime) to the Pt working electrode will result in an observed current that is proportional to the PO_2 present in the sample (including whole blood). In the absence of any oxygen, the current at this applied voltage under amperometric conditions will be very near zero.

The outer gas-permeable membrane enables the Clark electrode to detect oxygen with very high selectivity over other easily reduced species that might be present in a given sample (e.g., metal ions, cystine). Indeed, only other gas species or highly lipophilic organic species will partition into and pass through such gas-permeable membranes. One type of interference in clinical samples is seen with certain anesthesia gases, such as nitrous oxide, halothane, and isoflurane. These species also (1) diffuse through the outer membrane of the sensor, (2) are electrochemically reduced at the platinum electrode, and (3) yield a false-positive value for the measurement of PO_2. However, optimized gas-permeable membrane materials and appropriate control of the applied potential to the cathode of the sensor have greatly reduced this problem in modern instruments. The outer gas-permeable membranes also help restrict the diffusion of analyte to the inner working electrode; hence the membrane can control the mass transport of analyte (D/δ term in Equation 18), such that in the presence or absence of sample convection, mass transport of oxygen to the surface of the platinum working electrode is essentially the same.

The basic design of the Clark amperometric PO_2 sensor has been extended to detect other gas species by altering the applied voltage to the working electrode. For example, it is possible to detect nitric oxide (NO) with high selectivity using a similar gas electrode design in which the platinum is polarized at +0.900 versus Ag/AgCl to oxidize diffusing NO to nitrate at the platinum anode.[4] Such NO sensors have been used for a variety of biomedically important studies to deduce the amount of NO locally at or near the surface of various NO-producing cells.

Beyond amperometric devices, one specialized method for detecting trace concentrations of toxic metal ions in clinical samples is anodic stripping voltammetry (ASV). In ASV, a carbon working electrode is used (sometimes further coated with an Hg film), and the E_{appl} is first fixed at a very negative E_{appl} voltage so that all metal ions in the solution will be reduced to elemental metals (M°) within the mercury film and/or on the surface of the carbon. Then the E_{appl} is scanned more positive, and the reduced metals deposited in and/or on the surface of the working electrode are reoxidized, giving a large anodic current peak proportional to the concentration of metal ions in the original sample. The potential at which these peaks are observed indicates which metal is present, and the height of stripping peak current is directly proportional to the concentration of the metal ion in the original sample. Such ASV techniques have been used to detect the total concentration of Pb in whole blood samples, providing a rapid screening method for lead exposure and poisoning.[9]

Another biomedical example of modern voltammetry is a rapid scan cyclic voltammetric technique that has been used to quantify dopamine in brain tissue of freely moving animals.[17] In this application, oxidation of dopamine to a quinone species at an implanted microcarbon electrode (at approximately +0.600 V vs. Ag/AgCl) yields peak currents proportional to dopamine concentrations. The electrode has been used to

measure this neurotransmitter in different regions of the brain or in a fixed location.

Voltammetric/amperometric techniques are applied to detect a wide range of species; however, the selectivity offered for measurements in complex clinical samples—where many species can be electroactive—is rather limited. For example, as stated in the previous discussion relevant to the Clark oxygen sensor, in the absence of the gas-permeable membrane, other species that are reduced at or near the same E_{appl} as oxygen would cause significant interference.

To greatly expand the range of analytes detected by voltammetric/amperometric methods, electrochemical techniques have been used as highly sensitive detectors for modern high-performance liquid chromatographic (HPLC) systems (see Chapter 12). In liquid chromatography with electrochemical detection (LC-EC), eluting solutes are detected by flow-through electrodes (usually carbon or mercury) designed to have extremely low dead volumes (Figure 10-8). T ese electrodes are operated in amperometric or voltammetric modes (with high scan speeds), and several electrodes are able to be operated simultaneously in series or in parallel flow arrangements to gain additional selectivity. For example, homocysteine has been measured with (1) the addition of reducing agents to a serum sample to generate free homocysteine, (2) precipitation of proteins in the sample (with trichloroacetic acid), and (3) separation of the serum components on a reversed phase octadecylsilane HPLC column. T e eluting homocysteine is detected and measured with online electrochemical detection via homocysteine oxidation to the corresponding mercuric dithiolate complex.

Conductometry

Conductometry is an electrochemical technique used to determine the quantity of an analyte present in a mixture by measuring its effect on the electrical conductivity of the mixture. It is the measure of the ability of ions in solution to carry current under the influence of a potential difference. In a conductometric cell, an electrical potential is applied between two inert metal electrodes. An alternating potential with a frequency between 100 and 3000 Hz is used to prevent concentration polarization of the electrodes. A decrease in solution resistance results in an increase in conductance, and more current is passed between the electrodes. T e resulting current flow is also alternating. T e current is directly proportional to solution conductance. Conductance is considered the inverse of resistance and may be expressed in units of ohm^{-1} (siemens). In clinical analysis, conductometry is frequently used to measure the volume fraction of erythrocytes in whole blood (hematocrit) and serves as the transduction mechanism for some biosensors.

Erythrocytes act as electrical insulators because of their lipid-based membrane composition. T is phenomenon was first used in the 1940s to measure hematocrit by conductivity and is used today to measure hematocrit on multianalyte instruments for clinical analysis. In addition, Na^+ and K^+ concentrations are usually measured in conjunction with hematocrit on systems designed for clinical analysis, and they are used to correct for the background conductivity of the plasma.

Conductivity-based hematocrit measurements have limitations. For example, abnormal protein concentrations will change plasma conductivity and interfere with the measurement. Low protein concentrations resulting from dilution of blood with protein-free electrolyte solutions during cardiopulmonary bypass surgery will result in erroneously low hematocrit values by conductivity. Preanalytical variables, such as insufficient mixing of the sample, will also lead to errors. Hemoglobin is the preferred analyte to monitor blood loss and the need for transfusion during trauma and surgery. However, the electrochemical measurement of hematocrit in conjunction with blood gases and electrolytes remains in use

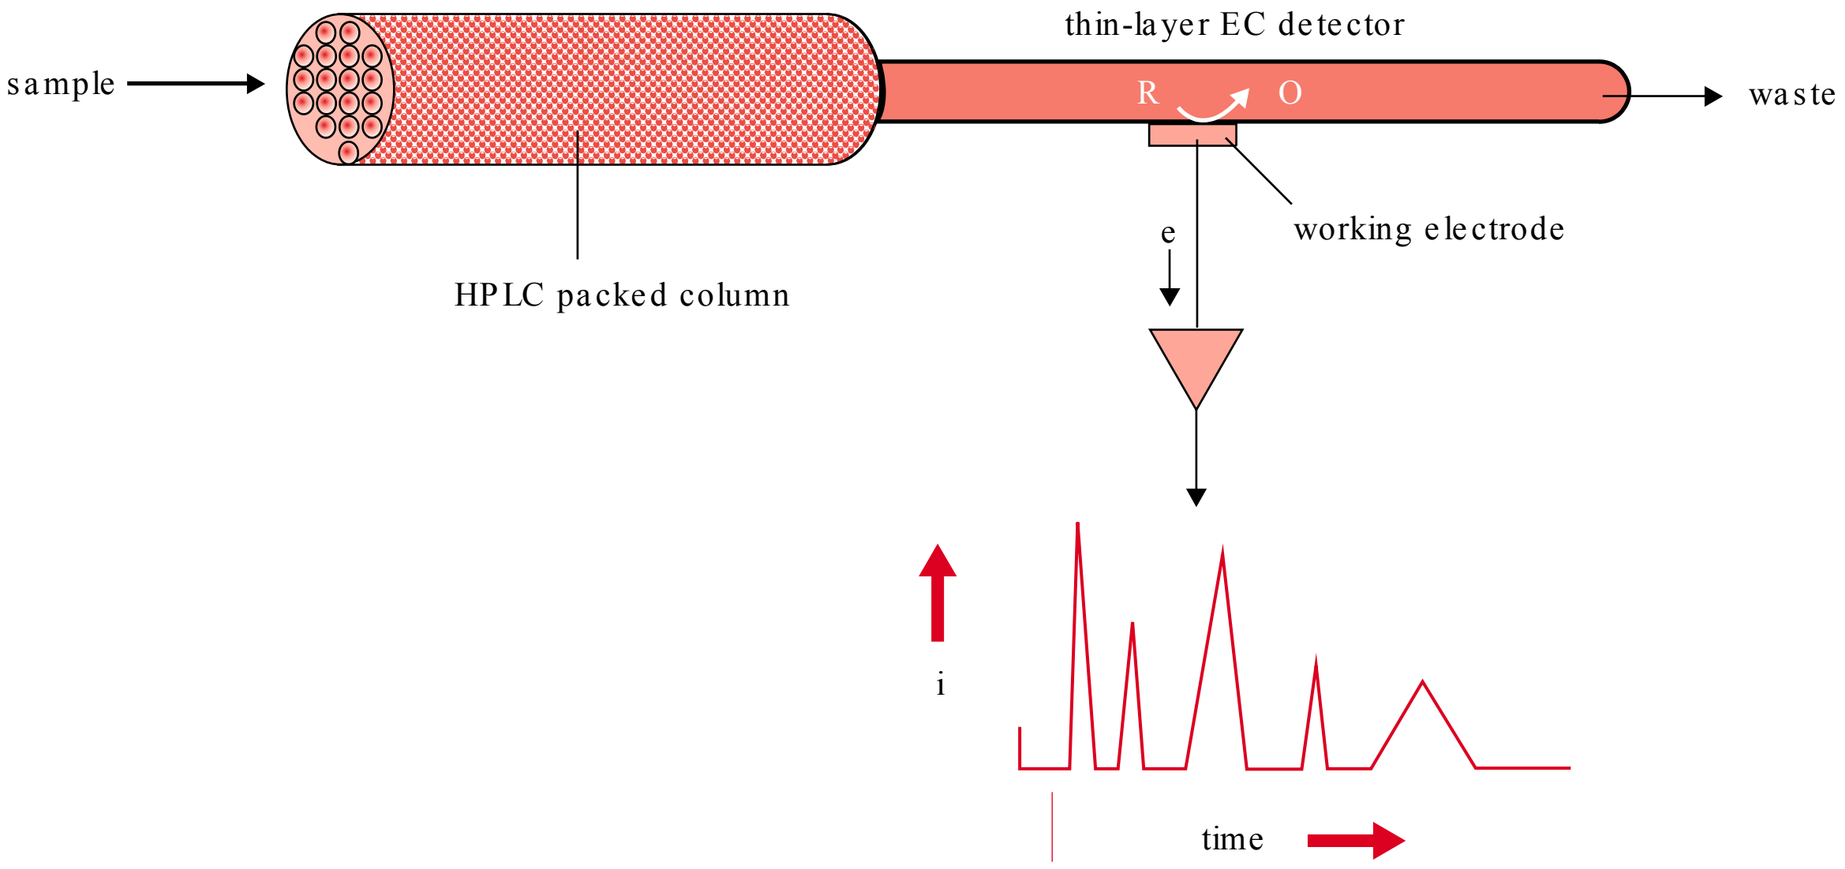

Figure 10-8 Schematic of liquid chromatography with electrochemical detection (LC-EC) system, with electrochemical detector monitoring the elution of analytes from an high-performance liquid chromatographic (HPLC) column by their oxidation or reduction (shown here as an example) at a suitable thin-layer working electrode.

mainly because of simplicity and convenience, despite some limitations.

Another clinical application of conductance is seen in electronic counting of blood cells in suspension. Termed the Coulter principle, it relies on the fact that the conductivity of blood cells is lower than that of a salt solution used as a suspension medium.[6] The cell suspension is forced to flow through a tiny orifice. Two electrodes are placed on either side of the orifice, and a constant current is established between the electrodes. Each time a cell passes through the orifice, resistance increases; this causes a spike in the electrical potential difference between electrodes. The pulses are then amplified and counted.

Coulometry

Coulometry measures the electrical charge passing between two electrodes in an electrochemical cell. The amount of charge passing between the electrodes is directly proportional to oxidation or reduction of an electroactive substance at one of the electrodes. The number of coulombs transferred in this process is related to the absolute amount of electroactive substance by Faraday's law:

$$Q = n \times N \times F \tag{22}$$

where

Q = the amount of charge passing through the cell (unit: C = coulomb = ampere • second);
n = the number of electrons transferred in the oxidation or reduction reaction;
N = the amount of substance reduced or oxidized in moles; and
F = the Faraday constant (96,487 coulombs/mole).

Measurement of current is related to charge as the amount of charge passed per unit of time (ampere = coulomb/s). Coulometry is used in clinical applications for the determination of chloride in serum or plasma and as the mode of transduction in certain types of biosensors.

Commercial coulometric titrators have been developed for determining chloride in blood, plasma, or serum. A constant current is applied between a silver wire (anode) and a platinum wire (cathode). At the anode, Ag is oxidized to Ag^+. At the cathode, H^+ is reduced to hydrogen gas. At a constant applied current, the number of coulombs passed between the anode and the cathode is directly proportional to time (coulombs = amperes × seconds). Thus the absolute number of silver ions produced at the anode may be calculated from the length of time that current passes through it. In the presence of Cl^-, Ag^+ ions formed are precipitated as $AgCl_{(solid)}$ and the amount of free Ag^+ in solution is low. When all Cl^- ions have been complexed, a sudden increase in the concentration of Ag^+ in solution is noted. The excess Ag^+ is sensed amperometrically at a second Ag electrode, polarized at negative potential. The excess Ag^+ is reduced to Ag, producing a current. When this current exceeds a certain value, the titration is stopped. The absolute number of Cl^- ions present in the sample is calculated from the time during which titration with Ag^+ was in progress. Knowing the volumetric amount of serum or plasma sample originally used, it is possible to calculate the concentration of Cl^- in the sample. Coulometric titration is one of the most accurate electrochemical techniques because the method measures the absolute amount of electroactive substance in the sample. Coulometry is considered the gold standard for determining chloride in serum or plasma. However, the method is subject to interference from anions in the sample with affinity for Ag^+ greater than chloride, such as bromide.

Optical Chemical Sensors

An **optode** is an optical sensor used in analytical instruments to measure (1) pH, (2) blood gases, and (3) electrolytes. Optodes provide certain advantages over electrodes, including (1) ease of miniaturization, (2) less electronic noise (no transduction wires), (3) long-term stability using ratiometric-type measurements at multiple wavelengths, and (4) no need for a separate reference electrode. These advantages initially promoted the development of optical sensor technology for design of intravascular blood gas sensors. However, the same basic sensing principles have been used in clinical chemistry instrumentation designed for more classical in vitro measurements on discrete samples. With such systems, light is passed to and from the sensing site by optical fibers or simply by appropriate positioning of light sources (light-emitting diodes [LEDs]), filters, and photodetectors to monitor absorbance (by reflectance), fluorescence, or phosphorescence (Figure 10-9).

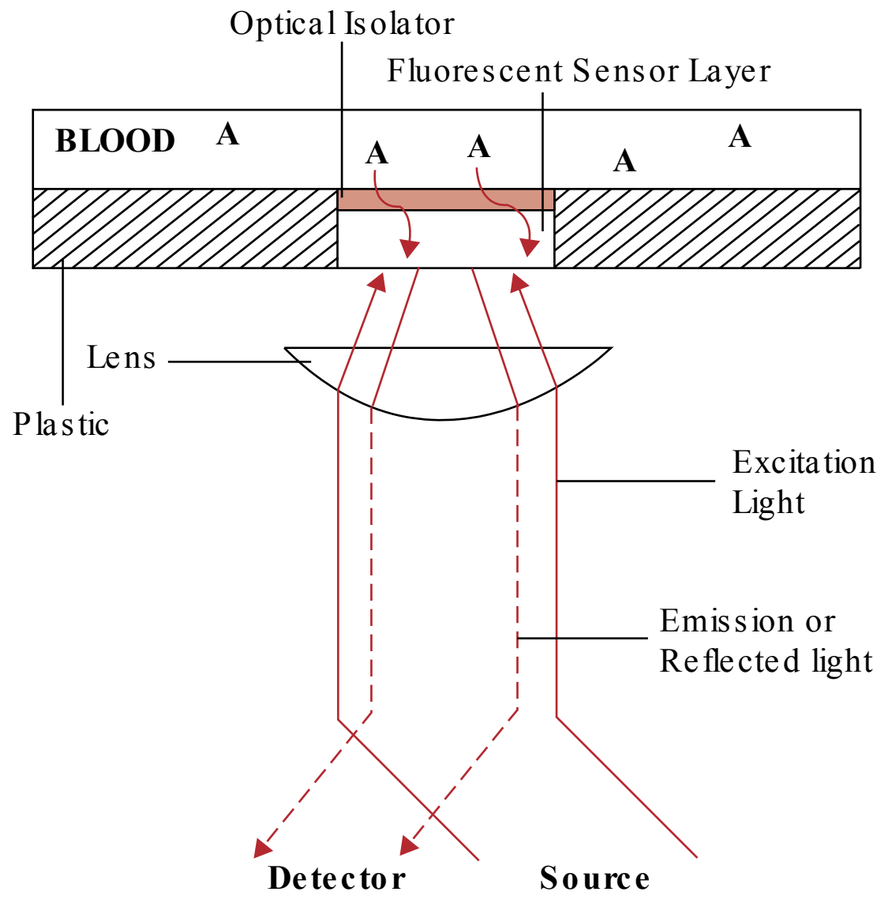

Figure 10-9 General design for an in vitro optical sensor to detect a given analyte (A) in blood. Polymer film contains dye that changes spectral properties in proportion to the amount of analyte in the sample phase. The example shown is used for sensing film that changes luminescence (fuorescence or phosphorescence).

Basic Concepts

Optical sensors devised for PO_2 measurements are typically based on the immobilization of certain organic dyes, such as (1) pyrene, (2) diphenylphenanthrene, (3) phenanthrene, (4) fluoranthene, and (5) metal ligand complexes (such as ruthenium[II] tris[dipyridine] and Pt and Pd metalloporphyrins) within hydrophobic polymer films (e.g., silicone rubber) in which oxygen is very soluble. The fluorescence or phosphorescence of such species at a given wavelength is often quenched in the presence of paramagnetic species, including molecular oxygen. In the case of embedded fluorescent dyes, the intensity of the emitted fluorescence of such films will decrease in proportion to the partial pressure of O_2 of the sample in contact with the polymer film in accordance with the Stern-Volmer equation for quenching:

$$\frac{I_0}{I_{PO_2}} = kPO_2 + 1 \qquad (23)$$

where

I_0 = fluorescence intensity in the absence of oxygen;
I_{PO_2} = fluorescence intensity at a given partial pressure of PO_2; and
k = quenching constant for the particular fluorophore used.

As indicated, the relationship between the ratio I_0/I_{PO2} and the PO_2 in the sample phase is linear. Also, the larger the quenching constant, the greater is the degree of quenching for the given fluorophore. However, it is important that the quenching constant is in a range that will yield linear Stern-Volmer behavior over the physiologically relevant range of PO_2 in blood.

Phosphorescence intensity or phosphorescence lifetime measurements of immobilized metal ligand complexes have also been employed to measure pH, blood gases, or electrolytes. Sensors based on changes in luminescent lifetime offer the inherent advantage of being insensitive to perturbations in the optical pathlength and the amount of active dye present in the sensing layer.

Optical pH sensors require immobilization of appropriate pH indicators within thin layers of hydrophilic polymers (e.g., hydrogels) because equilibrium access of protons to the indicator is essential. Fluorescein, 8-hydroxy-1,2,6-pyrene trisulfonate (HPTS), and phenol red have been used as indicators. The absorbance or fluorescence of the protonated or deprotonated form of the dye is used for sensing purposes. One problem with respect to using immobilized indicators for accurate physiological pH measurements is the effect of ionic strength on the pKa of the indicator. Because optical sensors measure the concentration of protonated or deprotonated dye as an indirect measure of hydrogen ion activity, variations in the ionic strength of the physiological sample have been known to influence the accuracy of pH measurement.

Applications

Optical sensors suitable for the determination of PCO_2 employ optical pH transducers (with immobilized indicators) as inner transducers in an arrangement quite similar to the classic Stow-Severinghaus–style electrochemical sensor design (see Figure 10-3). The addition of bicarbonate salt within the pH-sensing hydrogel layer creates the required electrolyte film layer, which varies in pH depending on the partial pressure of PCO_2 in equilibrium with the film. The optical pH sensor is covered by an outer gas-permeable hydrophobic film (e.g., silicone rubber) to prevent proton access while allowing CO_2 equilibration with the pH-sensing layer. As the partial pressure of PCO_2 in the sample increases, the pH of the bicarbonate layer decreases, and the corresponding decrease in the concentration of the deprotonated form of the indicator (or increase in the concentration of the protonated form) is sensed optically.

Two approaches have been used to sense electrolyte ions optically in physiological samples. One method employs many of the same lipophilic ionophores developed for polymer membrane–type ion-selective electrodes (see Figure 10-2). These species are doped into very thin hydrophobic polymeric films along with a lipophilic pH indicator. In the case of cation ionophores (e.g., valinomycin for sensing potassium), when cations from the sample are extracted by the ionophore into the thin film, the pH indicator (RH) loses a proton to the sample phase to maintain charge neutrality within the organic film (yielding R^-). This results in a change in the optical absorption or fluorescence spectrum of the polymer layer. If the thickness of the films is kept <10 μm, equilibrium response times on the order of <1 minute have been achieved. The main limitation of this design is that the pH of the sample phase influences the overall extraction equilibrium for ions into the film. Thus simultaneous and independent measurement of sample pH is required, or buffered dilution and/or pH control of the sample phase are necessary to obtain accurate measurements of electrolytes.

A second method used to sense electrolyte ions consists of immobilizing a cation and/or anion recognition agent within a hydrogel matrix similar to the pH sensors described previously. The recognition agent in this case is not usually lipophilic; therefore it must be covalently anchored to the hydrogel so that it does not leach into the sample phase. The agent is designed so that selective cation or anion binding alters the absorbance or fluorescence spectrum of the species within the hydrogel. Typically, this is achieved by linking ion recognition and chromophoric properties within a single organic molecule. Such ion sensors have been employed successfully in at least one commercial blood gas–electrolyte analyzer using an array of sensors of the generic design similar to that illustrated in Figure 10-9.

Biosensors

A **biosensor** is a specific type of chemical sensor that consists of a biological recognition element and a physicochemical transducer, often an electrochemical[18] or optical device. The biological element is capable of recognizing the presence and activity and/or concentration of a specific analyte in solution. The recognition may involve a biocatalytic reaction

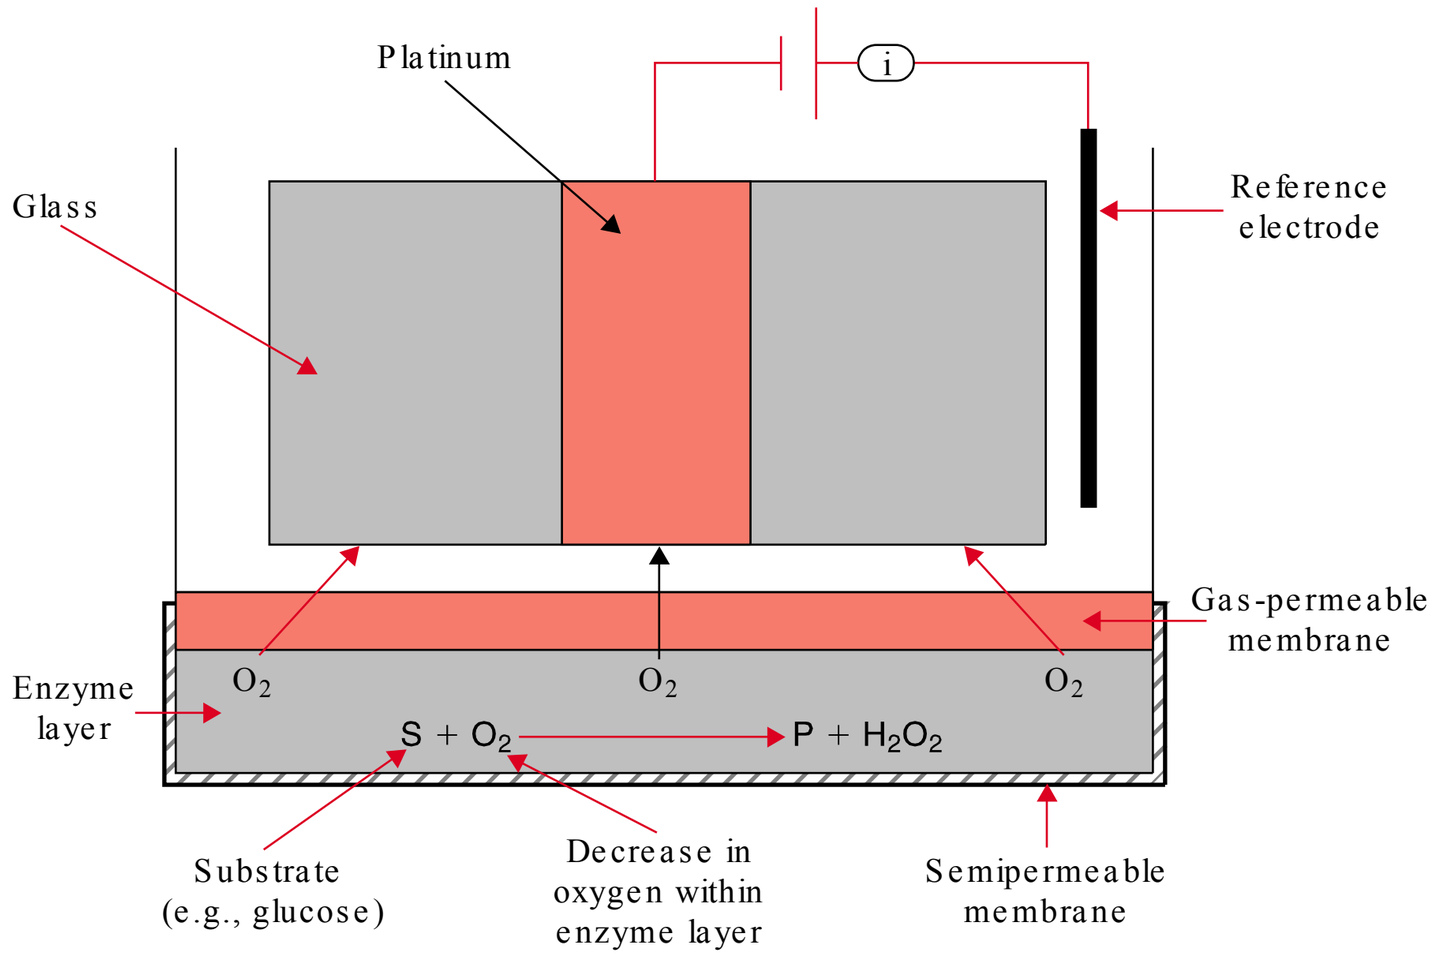

Figure 10-10 Illustration of an enzyme electrode prepared using oxidase enzyme immobilized at the surface of an amperometric PO_2 sensor. An increase in substrate concentration S reduces the amount of oxygen present at the surface of the sensor.

(enzyme-based biosensor) or a binding process (affinity-based biosensor), when the recognition element is, for example, (1) an antibody, (2) a DNA segment, or (3) a cell receptor. The interaction of the recognition element with a target analyte results in a measurable change in a solution property locally at the surface of the device, such as formation of a product or consumption of a reactant. The transducer then converts the change in solution property into an electrical signal. The mode of transduction may be one of several, including electrochemical or optical, and may involve the measurement of mass or heat. The present discussion will be limited to biosensors based on electrochemical and optical modes of transduction because they compose the majority of biosensors used for clinical applications.

Enzyme-Based Biosensors With Amperometric Detection

Enzyme-based biosensors based on electrochemical transducers, specifically, amperometric electrodes, are widely used for clinical analyses and are the most frequently cited in the literature. In 1962 Clark and Lyons developed an enzyme electrode for glucose that coupled a PO_2 electrode with a glucose oxidase catalyzed reaction. A decrease in PO_2, resulting from the action of glucose oxidase on glucose, was proportional to the glucose concentration of the sample. Within this device, a solution of glucose oxidase was physically entrapped between the gas-permeable membrane of the PO_2 electrode and an outer semi-permeable membrane (see Figure 10-10, general design). The outer membrane allowed substrate (glucose) and oxygen from the sample to pass, but not proteins and other macromolecules.

If the polarizing voltage of the PO_2 electrode is reversed, making the platinum electrode positive (anode) relative to the Ag/AgCl reference electrode, and if the gas-permeable membrane is replaced with a hydrophilic membrane containing the immobilized enzyme, it is possible to oxidize the H_2O_2 produced by the glucose oxidase reaction. The steady state current produced is directly proportional to the concentration of glucose in the sample.

In practice, a sufficiently high voltage (overpotential) is applied to the platinum anode to drive the oxidation of the hydrogen peroxide. An applied voltage of +0.7 volt or greater (relative to Ag/AgCl) is typically used. Figure 10-11 illustrates this basic hydrogen peroxide detection design, which is suitable for use in devising clinically useful sensors for glucose and for a host of other substrates for which suitable oxidase enzymes generate hydrogen peroxide (e.g., lactate).

Immobilization of enzymes in the early biosensors was a simple entrapment method behind a membrane of low-molecular-weight cutoff, and this approach is still used in some commercial applications. Many other schemes for enzyme immobilization for biosensor development have been suggested. Most common are (1) cross-linking of the enzyme with an inert protein, such as bovine serum albumin (BSA), using glutaraldehyde, (2) simple adsorption of enzyme to electrode surfaces, and (3) covalent binding of enzymes to insoluble carriers, such as nylon or glass. Another immobilization technique involves bulk modification of an electrode material, mixing enzymes with carbon paste that serves as both the enzyme immobilization matrix and the electroactive surface.

One of the first biosensor-based systems for the measurement of glucose in blood was commercialized by Yellow Springs Instruments, Inc. (YSI), Yellow Springs, Ohio, in 1975; it used the amperometric detection of H_2O_2 as the measurement principle (see Figure 10-11). Dependence of the measured glucose value on the oxygen concentration in the sample was a problem because significantly less than the stoichiometric amount of dissolved oxygen is present in blood to support the glucose oxidase reaction and produce a linear relationship of signal with glucose concentration found in blood. This is especially true at high concentrations of glucose found in samples from diabetic patients (>500 mg/dL). This problem with

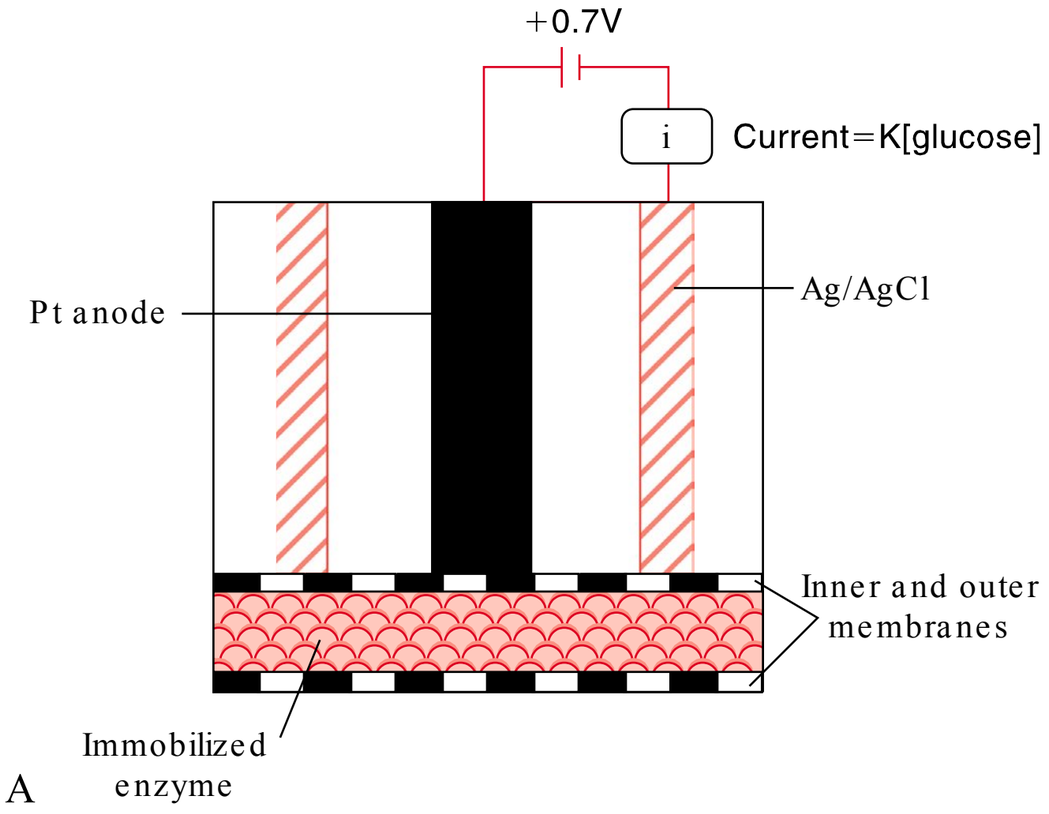

Figure 10-11 Design of amperometric enzyme electrode based on anodic detection of hydrogen peroxide generated from an oxidase enzymatic reaction (e.g., glucose oxidase) (A), and expanded view of the sensing surface showing the different membranes and electrochemical processes that yield the anodic current proportional to the substrate concentration in the sample (B). (From Meyerhoff M. New in vitro analytical approaches for clinical chemistry measurements in critical care, Clin Chem 1990;36:1570.)

the YSI design was resolved by diluting the sample and calibration solutions by at least 1:10 with buffer, thereby fixing the oxygen concentration in both the calibrator and the sample at a comparable concentration.

T e problem of oxygen limitation for biosensors based on oxidase enzymes has been resolved by (1) designing semipermeable membranes that restrict the diffusion of the primary analyte (substrate) to the enzyme layer, (2) avoiding saturation of the enzyme, and (3) keeping the ratio of oxygen to analyte always in excess of 1. T is extends the linearity of response to analyte concentrations substantially higher than the K_m of the enzyme and reduces the signal dependence on oxygen. Outer track-etched polycarbonate membranes are commonly used, as are membranes of poly(vinyl chloride), polyurethane, and silicone emulsions. Another approach has been to use an oxygen-rich electrode material as a reservoir of oxygen to support the bioreaction. A fluorocarbon (Kel-F oil) has been used to formulate a carbon paste electrode to act both as a source of oxygen and as the working electrode.[20]

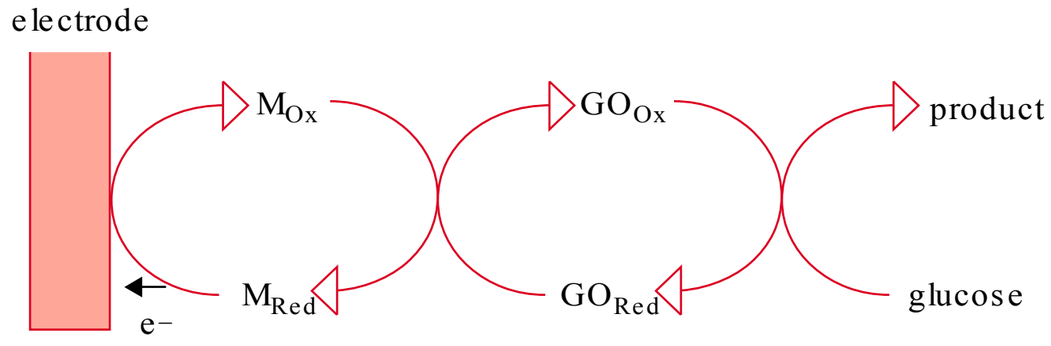

Figure 10-12 Scheme showing the use of electroactive mediator in the design of an amperometric enzyme electrode. The mediator accepts electrons directly from the enzyme and is oxidized at the surface of the working electrode, creating a more oxidized mediator to continue this process. (From D'Orazio P. Electrochemistry. In: Lewandrowski, K, ed. Clinical chemistry laboratory management and clinical correlations. Philadelphia: Lippincott Williams & Wilkins, 2002:464.)

Electron acceptors other than oxygen also have been used in the glucose oxidase reaction and have completely eliminated any dependence of the amperometric response on oxygen concentration of the sample. T e electron acceptor, usually co-immobilized with the enzyme, transports electrons to the anode surface, where it is reoxidized, resulting in a cyclic reaction mechanism (Figure 10-12). Acceptors with electron transfer kinetics (little or no overpotential) more favorable than that of oxygen allow operation of the sensor at lower applied potentials (+0.2 V vs. Ag/AgCl or lower) than are typically used for the oxidation of H_2O_2. T is approach not only eliminates dependency of the reaction rate on oxygen, it also serves to reduce the contribution from oxidizable interfering substances (e.g., uric acid, ascorbic acid, acetaminophen) to the sensor response. Examples of acceptors that have been used include (1) quinones, (2) conductive organic salts, such as tetrathiafulvalene-tetracyanoquinodimethane (TTF-TCNQ), and (3) ferricyanide and ferrocene derivatives.

Another technique that can be used to decrease interferences from easily oxidized species in a blood sample when traditional H_2O_2 electrochemical detection is used employs selectively permeable membranes in proximity to the electrode surface that allow transport of H_2O_2 to the electrode surface, but it rejects the interfering substances on the basis of size exclusion (see Figure 10-11, B). An example is a low-molecular-weight cutoff membrane, such as cellulose acetate, which is used in many commercial amperometric biosensors. Also used are electropolymerized films, such as poly(phenylenediamine) formed in situ, to reject interfering substances on the basis of size.[8] Another approach employed in a commercial application involves using a second correcting electrode, identical to the working electrode but without enzyme, sensitive only to the presence of oxidizable interfering substances. T e resulting differential signal is proportional to the concentration of analyte.

A novel approach used to eliminate electroactive interfering substances in a commercially available glucose sensor consists of directly "wiring" the redox center of the enzyme glucose oxidase to a metallic, amperometric electrode using an osmium (III/IV)-based redox hydrogel.[15] T e osmium sites effectively facilitate transfer of electrons directly from the entrapped

enzyme to the metallic electrode, without the need for oxygen. This approach allows the operating potential of the electrode to be dramatically lowered to +0.2 V versus SCE (saturated calomel reference electrode), where currents resulting from electro-oxidation of possible interferences such as (1) ascorbate, (2) urate, (3) acetaminophen, and (4) l-cysteine are negligible.

Substitution of other oxoreductase enzymes for glucose oxidase allows amperometric biosensors for other substrates of clinical interest to be constructed. For example, sensors have been developed to measure (1) blood lactate, (2) cholesterol, (3) pyruvate, (4) alanine, (5) glutamate, and (6) glutamine. In addition, by using a multiple enzyme cascade, an amperometric biosensor for creatinine has been developed.

Enzyme-Based Potentiometric and Conductometric Biosensors

Ion-selective electrodes also have been used as transducers in potentiometric biosensors. An example is a biosensor for urea (blood urea nitrogen [BUN]) that is based on a poly(vinyl chloride) membrane ISE for ammonium ion (Figure 10-13). The enzyme urease is immobilized at the surface of the ammonium selective ISE based on the antibiotic nonactin (see structure of ionophore in Figure 10-2) and catalyzes the hydrolysis of urea to NH_3 and CO_2. The ammonia produced dissolves to form NH_4^+, which is sensed by the ISE. The signal generated by the NH_4^+ produced is proportional to the logarithm of the concentration of urea in the sample. The response may be steady state or transient. Typically, correction for background potassium is required because the nonactin ionophore has limited selectivity for ammonium over potassium ($K_{NH4/K} = 0.1$). Potassium is measured simultaneously with urea and is used to correct the output of the urea sensor using the Nicolsky-Eisenman equation (Equation 11).

The above approach for measurement of urea using an enzyme-based potentiometric biosensor assumes that the turnover of urea to ammonium at steady state provides a constant ratio of ammonium ions to urea, independent of concentration. This is rarely the case, especially at higher substrate concentrations resulting in a nonlinear sensor response. The linearity of the sensor is also limited by the fact that hydrolysis of urea produces a local alkaline pH in the vicinity of the ammonium-sensing membrane, partially converting NH_4^+ to NH_3 (pKa = 9.3). Ammonia (NH_3) is not sensed by the ISE. The degree of nonlinearity may be reduced by placement of a semi-permeable membrane between enzyme and sample to restrict diffusion of urea to the immobilized enzyme layer.

A change in solution conductivity has also been used as a transduction mechanism in enzyme-based biosensors. Examples include the measurement of (1) glucose, (2) creatinine, and (3) acetaminophen using interdigitated electrodes.[7] Practical applications of conductometric biosensors are few because of the variable ionic background of clinical samples and the requirement to measure small conductivity changes in a medium with high ionic strength. A commercial system used to measure urea in serum, plasma, and urine is a BUN analyzer based on the enzyme urease. Dissolution of the products to NH_4^+ and HCO_3^- produces a change in sample conductivity. The initial rate of change in conductivity is measured to compensate for the background conductivity of the sample. This approach is limited to the measurement of analytes at relatively high concentrations because of small changes in conductivity produced by low concentrations of analyte.

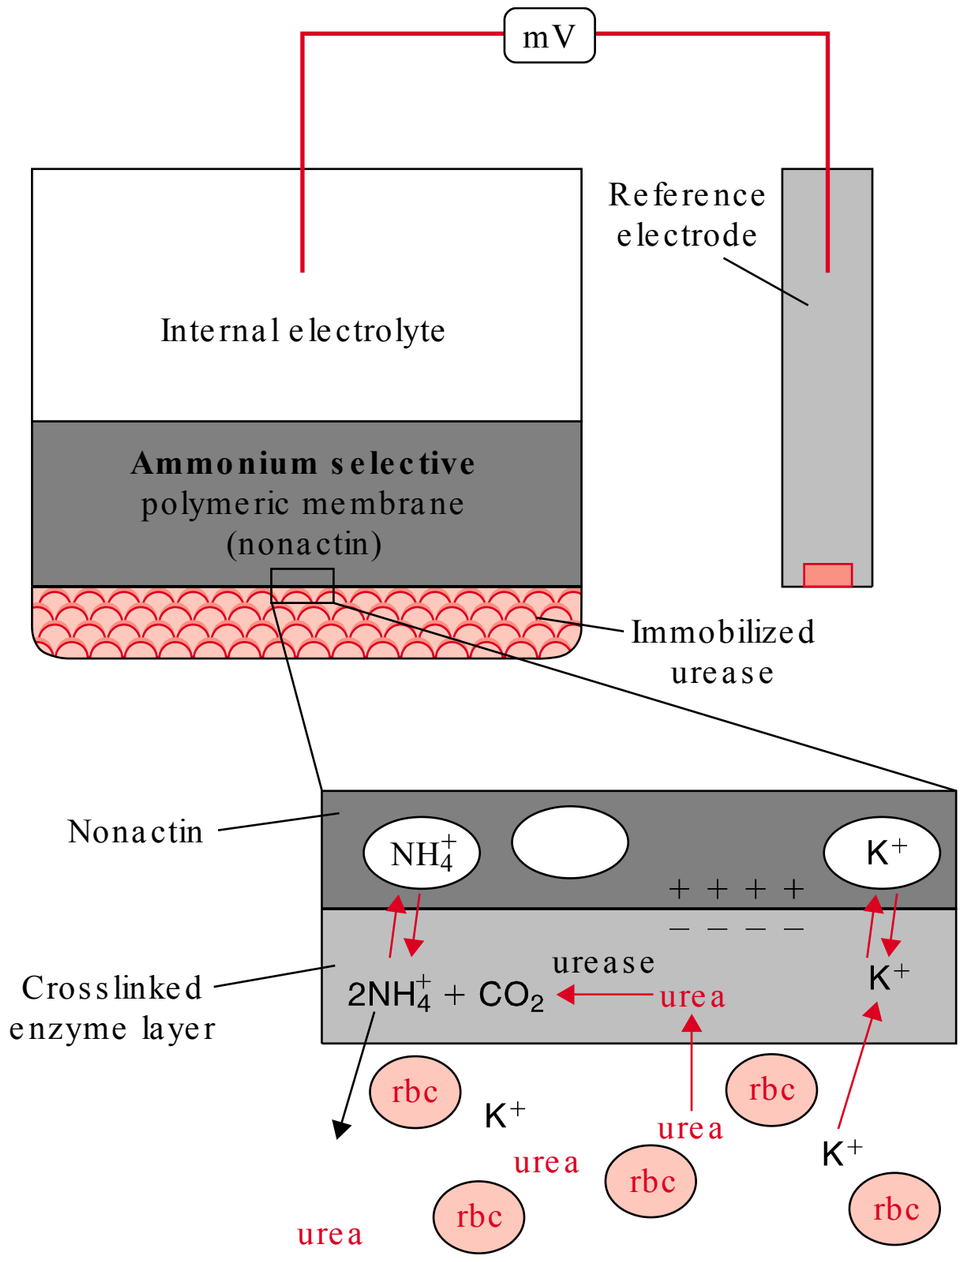

Figure 10-13 Potentiometric enzyme electrode for determination of blood urea based on the urease enzyme immobilized on the surface of an ammonium ion–selective polymeric membrane electrode.

Enzyme-Based Biosensors With Optical Detection

Optical sensors with immobilized enzymes and indicator dyes have been developed for the measurement of glucose and other substrates of clinical interest. These biosensors rely on measurements of pH or oxygen by (1) absorbance, (2) reflectance, (3) fluorescence, and (4) luminescence, coupled with an enzyme-catalyzed reaction. Enzyme immobilization methods resemble those used to construct electrochemical biosensors, including (1) physical entrapment or encapsulation in a gel matrix, (2) physical adsorption onto substrates, and (3) covalent binding to or absorption on an insoluble support. Using an example based on an optode for PO_2, a sensitive indicator is co-immobilized with an oxidase enzyme at the end of a fiber optic probe. The probe is used to monitor fluorescence of the indicator. Quenching of fluorescence of the indicator by O_2 is followed. A decrease in PO_2 resulting from a substrate reaction catalyzed by the enzyme will result in less quenching of the indicator and a fluorescent signal directly proportional to the concentration of the substrate. In an example of an optical biosensor probe for glucose, an oxygen-sensitive cationic dye $Ru[phen]_3^{2+}$ is immobilized along with glucose oxidase on the

surface of an optical fiber.[14] A decrease in PO_2 arising from the enzyme-catalyzed oxidation of glucose results in an increase in luminescence intensity of the ruthenium tris (phenanthrene).

Similar optical biosensors have been prepared for other analytes. For example, a cholesterol optical biosensor has been devised that is based on fluorescence quenching of an oxygen-sensitive dye coupled to consumption of oxygen resulting from the enzyme-catalyzed oxidation of cholesterol by the enzyme cholesterol oxidase.[19] Serum bilirubin has been detected using bilirubin oxidase, co-immobilized with a ruthenium dye, on an optical fiber.[11] The bilirubin sensor (1) exhibited a lower detection limit of 10 μmol/L, (2) had a linear range up to 30 mmol/L, and (3) exhibited a typical reproducibility of 3% (coefficient of variation [CV]).

The pH change resulting from enzyme-catalyzed reactions has also been measured optically. The dye fluorescein is often used as a pH-sensitive indicator to construct such sensors. The protonated form of fluorescein does not fluoresce, but the conjugate base strongly fluoresces at 530 nm when excited at 490 nm. Using glucose oxidase as the enzyme, a pH optode has been employed to follow the formation of glucuronic acid. A disadvantage of optical sensors based on pH changes is that they are strongly dependent on the pH and buffer capacity of the sample. Moreover, the working range of the sensor is determined by the pKa of the indicator, at 6.8 to 7.2 for fluorescein, depending on the ionic strength of the sample matrix. A pH-sensitive indicator may also be used to follow enzymatic reactions that produce ammonia (e.g., urease action on urea).

Affinity Sensors

Affinity sensors are a special class of biosensors in which the immobilized biological recognition element is (1) a binding protein, (2) an antibody (immunosensors), or (3) an oligonucleotide (e.g., DNA, RNA, aptamers) that has high binding affinity and high specificity toward a clinically important analyte. Such sensors have been developed as alternatives to conventional binding assays to enhance the speed and convenience of a wide range of assays that would be typically run on sophisticated immunoassay analyzers. Ideally, direct binding of the immobilized species to its target in a clinical sample should yield a sensor signal proportional to the concentration of the analyte. However, "direct" sensing at analyte concentrations that would cover the full range of clinical applications is very difficult to achieve. Further, high affinity of such binding reactions, required to achieve optimal sensitivity, limits the reversibility of such devices. Affinity sensors based on electrochemical, optical, or other transduction modes are typically single-use devices, thus obviating the need for some type of regeneration step (pH change, etc.) to dissociate the tight binding between the recognition element and the target.

The number of research reports related to affinity biosensors continues to increase. However, commercialization has lagged behind research output, and movement of these types of biosensors from the research laboratory to the clinical laboratory has been slow. Affinity biosensors with promise of clinical utility are typically based on labeled reagents, such as enzymes, fluorophores, and electrochemical tags; hence they function more like traditional binding/immunoassays, except that one recognition element is immobilized on the surface of a suitable electrode or another type of transducer. For example, electrochemical oxygen sensors have been employed to perform heterogeneous enzyme immunoassays (sandwich or competitive type), using catalase as a labeling enzyme (catalyzes $H_2O_2 \rightarrow 2H^+$ and O_2) and immobilizing capture antibodies on the outer surface of the gas-permeable membrane. After binding equilibration and washing steps, the amount of bound enzyme is detected by adding the substrate and following the increase in current generation caused by local production of oxygen near the surface of the sensor.

Affinity Sensors for DNA Analysis Using Fluorescent Labels

Affinity-type sensors based on oligonucleotide binding represent perhaps the most promising application of affinity sensors to clinical chemistry. Fluorescent labels were the first to be used in an early commercial biosensor for DNA analysis (the GeneChip, introduced in 1996). High-density oligonucleotide arrays are formed on glass substrates. Target DNA is isolated and amplified using the polymerase chain reaction (PCR), while a fluorescent label is incorporated. The sample is incubated on the array, and detection of hybridization of labeled DNA to its complementary strands takes place by monitoring light emitted by the fluorescent labels. The primary application of the device has been for DNA sequencing, so the focus has been primarily on increasing the density of the DNA arrays. Applications of the device continue to expand with a variety of arrays developed for gene expression and whole genomic analysis related to (1) cancer, (2) inflammatory disease, (3) infectious disease, and (4) diabetes.

Affinity Sensors for DNA Analysis Using Electrochemical Labels

DNA sensors in which a segment of DNA complementary to a target strand is immobilized on a suitable electrochemical sensor have been demonstrated. These devices operate in direct (based on electrochemical oxidation of guanine in target DNA) (Figure 10-14, A) or indirect (with exogenous electrochemical markers/labels, see later and Figure 10-14, B) transduction modes. Although most of the proposed electrochemical DNA biosensors require amplification methods, such as PCR, to multiply small amounts of DNA into measurable quantities, some are sensitive enough to eliminate the need for target amplification. Nanotechnology has been proposed, in the indirect format, for signal amplification. For example, a capture probe DNA is immobilized on a gold electrode. Reporter probes with electrostatically bound ruthenium complexes $[Ru(NH_3)_6]^{3+}$ are loaded onto gold nanoparticles (AuNP) and are capable of hybridizing with one of two sequences on target DNA. The other sequence on the target DNA is capable of hybridizing with the immobilized capture probe. Hybridization events on the electrode surface bring multiple reporter probes for each AuNP. Electroactive $[Ru(NH_3)_6]^{3+}$ is reduced at the electrode surface, and the coulometric signal is proportional to the concentration of target DNA[21]. A commercial example of electrochemical

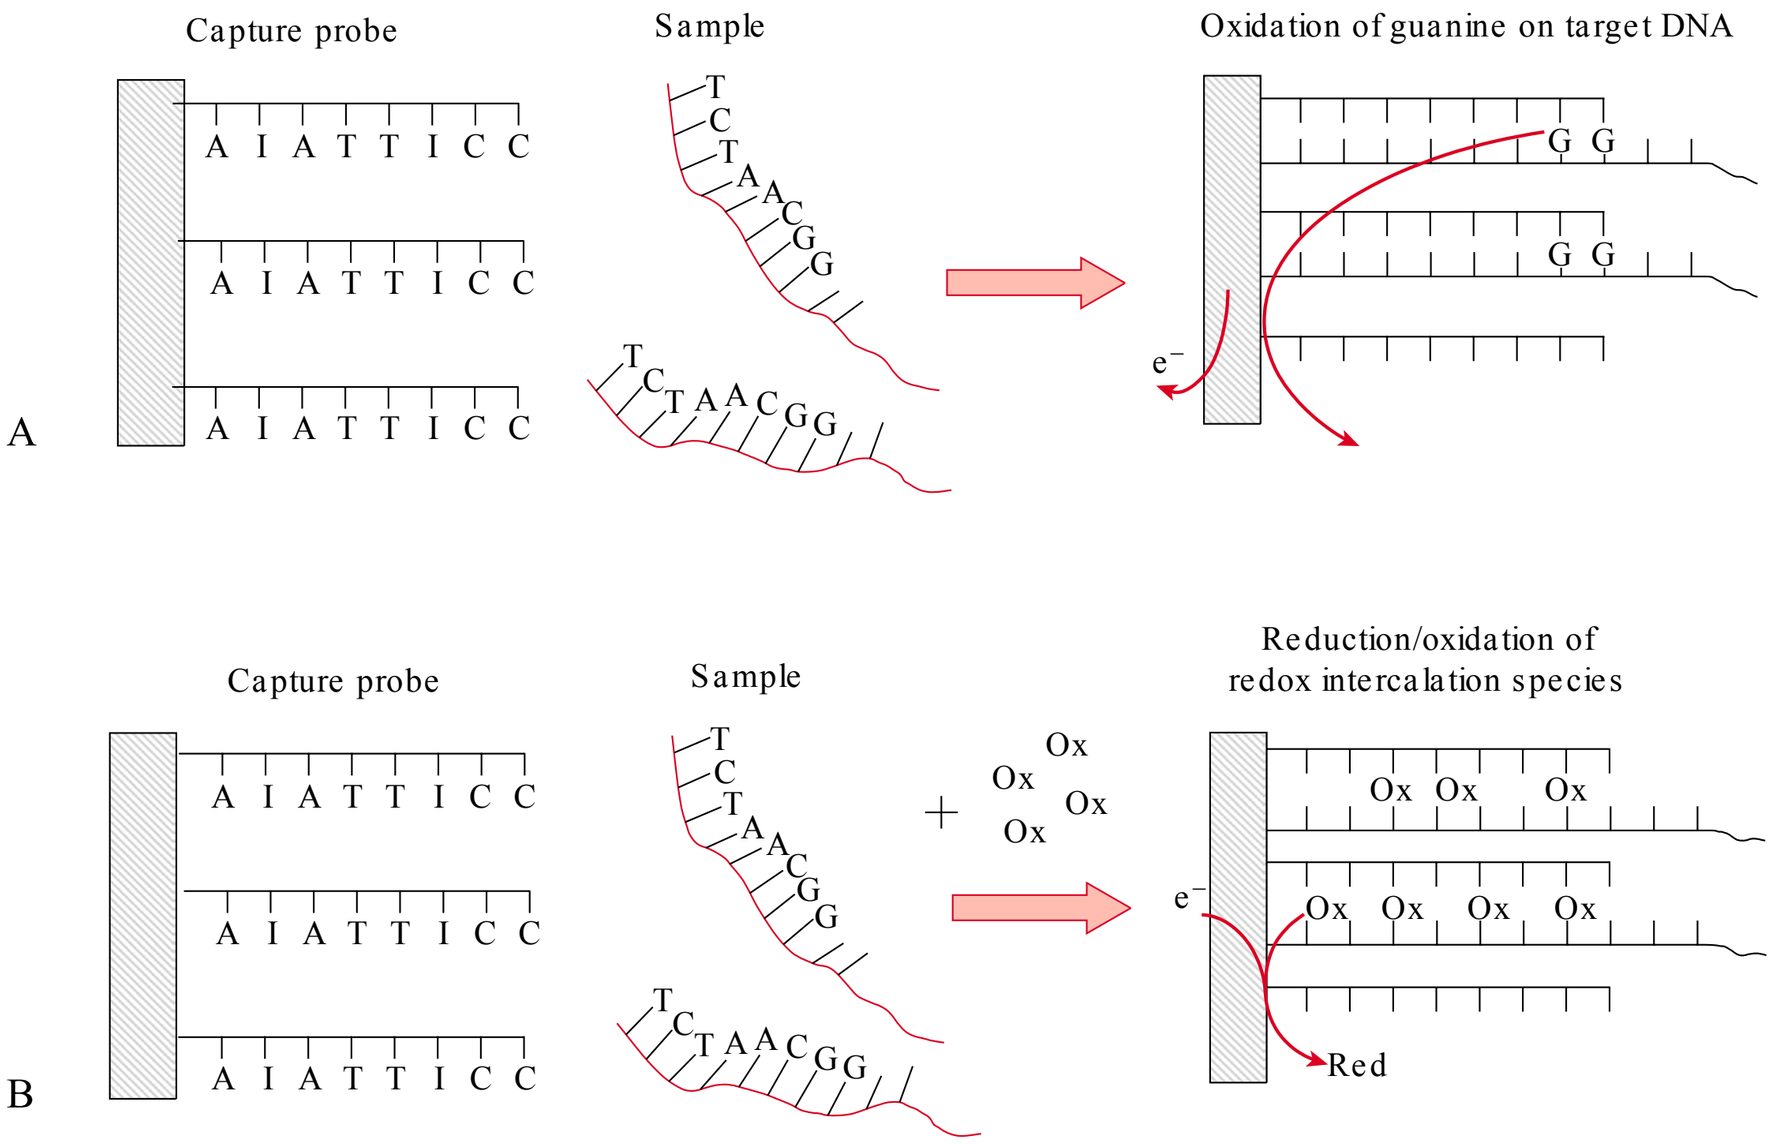

Figure 10-14 Examples of DNA biosensor configurations: (A) direct electro-oxidation detection of guanosine bases in target DNA after hybridization with immobilized capture probe on electrode surface; (B) electrochemical detection of hybridization using exogenous redox species that intercalate into a hybridized complex between the immobilized capture DNA probe and the target DNA.

DNA sensing, along with AuNP probes without need for PCR amplification, is the Verigene system (Nanosphere, Northbrook, IL), which is capable of detecting single-nucleotide polymorphisms related to common genetic disorders, such as (1) thrombophilia, (2) alterations of folate metabolism, (3) cystic fibrosis, and (4) hemochromatosis.

Another example of an electrochemical "gene" sensor array uses electrochemical probes that are selectively inserted into hybridized DNA duplexes. In one approach, after the immobilized capture of oligo anchored to the electrode surface is allowed to bind the target sequence, hybridization is detected by exposing the surface of the electrode to an exogenous electroactive species (Co[III]tris-phenanthroline, ruthenium complexes, etc.) that intercalates within the duplex, but not to single-stranded DNA. After unbound electroactive species are removed by washing, the presence of hybridization is readily detected by voltammetry, scanning the potential of the underlying electrode to oxidize or reduce any intercalated electroactive species, with the current detected being proportional to the number of duplex DNA species on the surface of the electrode.

Review Questions

1. Ion-selective electrodes measure electrical potential difference across a membrane using the principles of:
   a. coulometry.
   b. potentiometry.
   c. amperometry.
   d. conductivity.
2. An optical sensor used in analytical instruments to measure pH, blood gases, and electrolytes is referred to as a(n):
   a. potientiometer.
   b. optode.
   c. affinity-type sensor.
   d. coulometer.
3. Voltammetry/amperometry measurements are based on which of the following electrochemical cell types?
   a. Ion-selective electrode cells
   b. Galvanic electrochemical cells
   c. Electromotive force cells
   d. Electrolytic electrochemical cells
4. An affinity-based biosensor is one in which:
   a. the biological element recognizes the analyte on the basis of its binding to an immobilized substance.
   b. the fluorescence of a solution is coupled to an enzyme-catalyzed reaction.
   c. the biological element reacts with an ion-selective electrode that is used as a potentiometric transducer.
   d. an electron acceptor is used to form a colored reaction product.
5. A voltmeter that measures the potential across an electrochemical cell (between the two electrodes) is referred to as a:
   a. conductometer.
   b. amperometer.
   c. direct-reading potentiometer.
   d. redox meter.

6. Membrane potentials caused by the permeability of certain types of membranes to selected anions or cations are measured by which type of electrode?
   a. Ion-selective electrode
   b. Saturated calomel electrode
   c. Platinum electrode
   d. Gas-sensing electrode
7. The maximum difference in potential between the two electrodes in an electrochemical cell obtained with the current at zero is the definition of:
   a. electrical potential.
   b. electromotive force.
   c. electrochemical gradient.
   d. Nernst equation.
8. In this type of measurement, a constant current is applied to a solution, and a substance in that solution is changed to a different state through oxidation or reduction. The time it takes for this to occur is measured. This is electrochemical technique is called:
   a. amperometry.
   b. voltammetry.
   c. potentiometry.
   d. coulometry.
9. The measurement of ions by direct potentiometry provides a value for the concentration of free, unbound ion in solution that is called the ionic:
   a. force.
   b. potential.
   c. activity.
   d. action.
10. The predominant class of potentiometric electrodes used in the clinical laboratory is the:
    a. gas-sensing electrode.
    b. glass membrane electrode.
    c. coulometric electrode.
    d. polymer membrane ion-selective electrode.

CHAPTER 11

Electrophoresis

Lindsay A.L. Bazydlo, Ph.D., and James P. Landers, Ph.D.

Objectives

1. Define the following:
   - Agarose
   - Ampholyte
   - Amphoteric
   - Blot/blotting
   - Densitometry
   - Electroendosmosis
   - Electrophoresis
   - Electrophoretic mobility
   - Polyacrylamide
   - Wick flow
2. State the theory of electrophoresis.
3. List and describe the components of an electrophoresis system, including buffers, support media, separation techniques, stains, and detection methods; quantify the individual fractions of a scanned gel when given total protein value.
4. Identify how each of the following affects electrophoresis: size and shape of molecule, heat and current produced by the power supply, buffer pH, specific type of gel used, and specimen appearance.
5. Describe and compare the following types of electrophoretic techniques, including clinical uses, system components, and detection methods:
   - Capillary
   - Disc
   - Isoelectric focusing
   - Microchip
   - Two-dimensional
   - Zone
6. Compare Southern, Northern, and Western blotting, including technical relations to electrophoresis, laboratory uses, and techniques.
7. State three advantages of capillary electrophoresis over conventional electrophoresis.
8. Explain how the following technical aspects affect the performance of the electrophoresis process: endomosis, buffer and stain integrity, sample type or appearance, and overapplication or underapplication of the sample; evaluate an electrophoresis pattern and identify problems.

Key Words and Definitions

Ampholyte A molecule that is positively or negatively charged on the basis of the pH of the solution in which it resides; proteins, because they contain many ionizable amino and carboxyl groups, behave as ampholytes in solution and are considered amphoteric.

Capillary electrophoresis A method in which the classic techniques of electrophoresis are carried out in a small-bore, fused silica capillary tube coated with a polymeric covering.

Densitometry A measuring technique that uses an optical system to scan and quantify electrophoretic fractions separated on a gel or other medium.

Electrophoresis The migration of charged solutes or particles within a liquid medium under the influence of an electrical field.

Electrophoretic mobility (μ) The rate of migration (cm/s) of a charged solute in an electrical field, expressed per unit field strength (volts/cm).

Electropherogram A densitometric display of protein zones on a support material after separation and staining.

Endosmosis (electroendosmotic flow) Preferential movement of water in one direction through an electrophoresis medium due to selective binding of one type of charge on the surface of the medium.

Isoelectric focusing An electrophoretic technique that separates amphoteric compounds within a medium that possesses a stable pH gradient.

Isoelectric point (pI) The pH at which a molecule has no net charge and will not migrate during electrophoresis.

Microchip electrophoresis An electrophoretic technique whereby separation is conducted in fluidic channels on a microchip and detection occurs through laser-induced fluorescence.

Wick flow Movement of water from the buffer reservoirs toward the center of an electrophoresis gel or strip to replace water lost by evaporation.

Electrophoresis is a versatile and powerful analytical technique that is capable of separating and analyzing a diverse range of ionized analytes. T is chapter discusses (1) basic concepts and definitions, (2) theory, (3) description and types of electrophoresis, including capillary and microchip electrophoresis, and (4) their applications in the routine clinical laboratory, as well as in the developing fields of genomics and proteomics.

Basic Concepts and Definitions

Electrophoresis is a comprehensive term that refers to the migration of charged solutes or particles within a liquid medium under the influence of an electrical field. Iontophoresis is a similar term that applies only to the migration of small ions. Zone electrophoresis is the technique most commonly used in clinical applications. With this technique, charged molecules migrate as zones, usually in a porous supporting medium such as agarose gel film, after the sample is mixed with a buffer solution. It generates an **electropherogram,** a display of protein zones, each sharply separated from neighboring zones, on the support material. Protein zones are visualized when the support medium is stained with a protein-specific stain; then the medium is dried and zones are quantified in a densitometer. T e support medium is dried and is kept as a permanent record.

Theory of Electrophoresis

In an electrophoresis system, ionized chemical species that have an electrical charge move toward the cathode (negative electrode) or the anode (positive electrode). Positive ions (cations) migrate toward the cathode, and negative ions (anions) migrate toward the anode (Figure 11-1). An **ampholyte** molecule (also called a zwitterion) contains both positive and negative charges, depending on the functional groups present in the molecule and the pH of the liquid in which they reside. T e **isoelectric point (pI)** of an ampholyte molecule is the pH at which such a molecule has no electrical charge and does not migrate within an electrical field. Electrochemically, an ampholyte molecule takes on a positive charge in a solution that is more acidic than its pI and migrates toward the cathode. In a more alkaline solution, an ampholyte molecule is negatively ionized and migrates toward the anode. Because proteins contain many ionizable amino ($-NH_2$) and carboxyl ($-COOH$) groups, they behave as ampholytes in solution.

T e rate of migration is dependent on factors such as (1) the net electrical charge of the molecule, (2) the size and shape of the molecule, (3) electrical field strength, (4) properties of the supporting medium, and (5) the temperature of operation. **Electrophoretic mobility (μ)** is defined as the rate of migration (cm/s) per unit field strength (volts/cm). Equation 1 expresses electrophoretic mobility and is derived from two formulas: one expressing the driving force of the electrical field on the ion and the other expressing the retarding force caused by frictional resistance of the medium.[5]

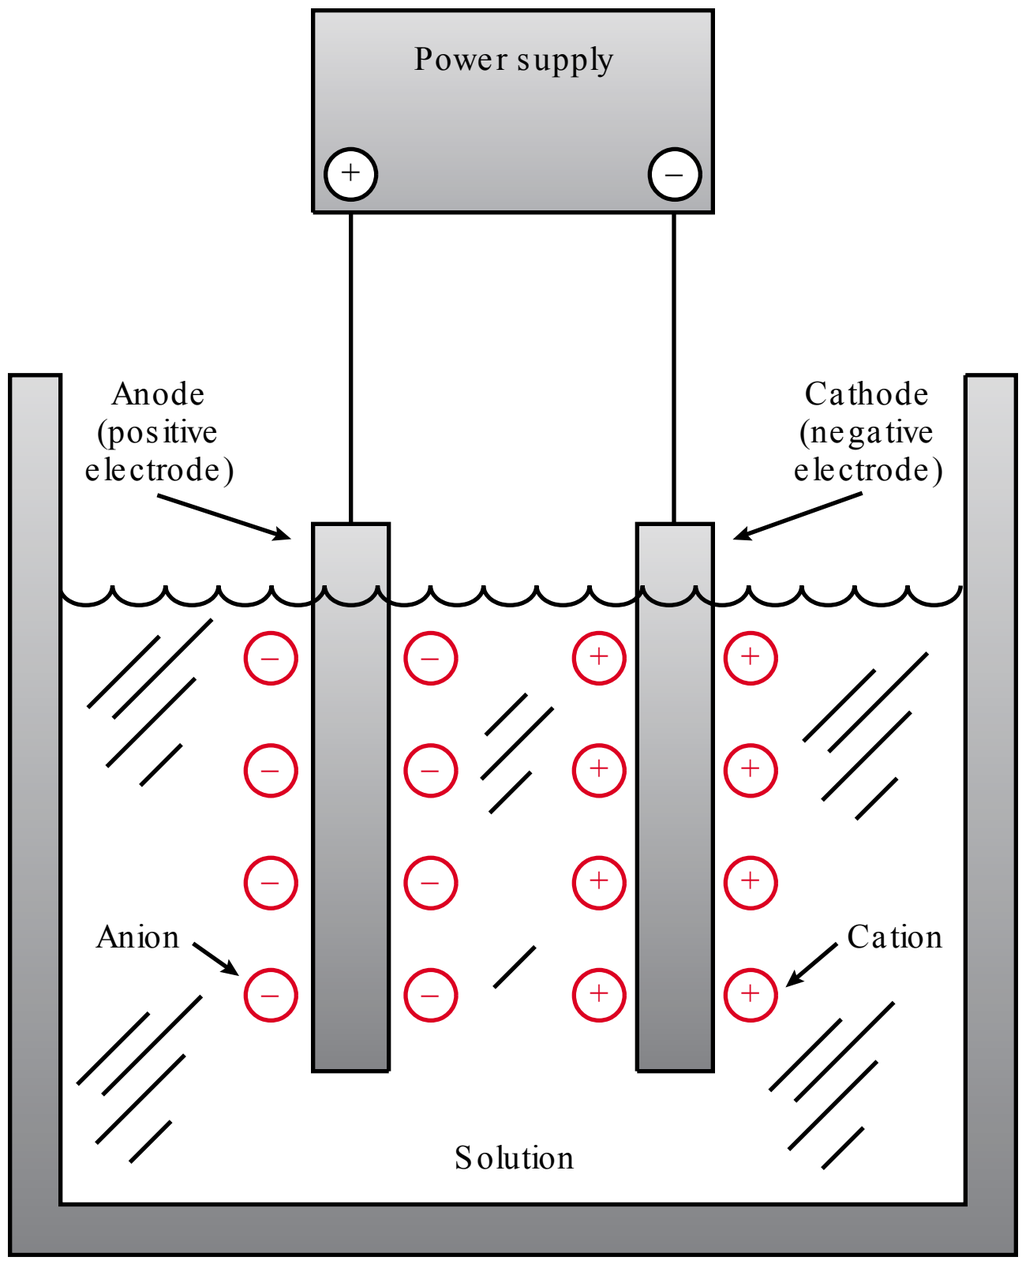

Figure 11-1 Movement of cations and anions within an electrical field.

$$\mu = \frac{Q}{6\pi r \eta} \quad (1)$$

where

μ = electrophoretic mobility in $cm^2/(V)(s)$;
Q = the net charge on the ion;
r = the ionic radius of the solute; and
η = the viscosity of the buffer solution in which migration is occurring.

T us electrophoretic mobility is directly proportional to net charge and inversely proportional to molecular size and viscosity of the electrophoresis medium.

Other factors that affect mobility include endosmotic flow (which will be discussed in a later section of this chapter) and **wick f ow**. T e latter is a result of the electrophoretic process that generates heat, causing evaporation of solvent from the electrophoretic support. T is drying effect causes buffer to rise into the electrophoresis support from both buffer compartments. T is flow of buffer from both directions is called wick f ow, and it affects protein migration and hence mobility.

Description of Technique

Topics discussed in this section include (1) electrophoresis instrumentation, (2) reagents, and (3) a general procedure.

Instrumentation and Reagents

A schematic diagram of a conventional electrophoresis system is shown in Figure 11-2. Two buffer chambers (1) with baffle plates contain the buffer used in the process. Each buffer box contains an electrode (2) made of platinum or carbon, the polarity of which is determined by the mode of connection to the power supply. The electrophoresis support (3) on which separation takes place may contact the buffer directly or by means of wicks (4). The entire apparatus is covered (5) to minimize evaporation and protect the system and is powered by a direct current power supply.

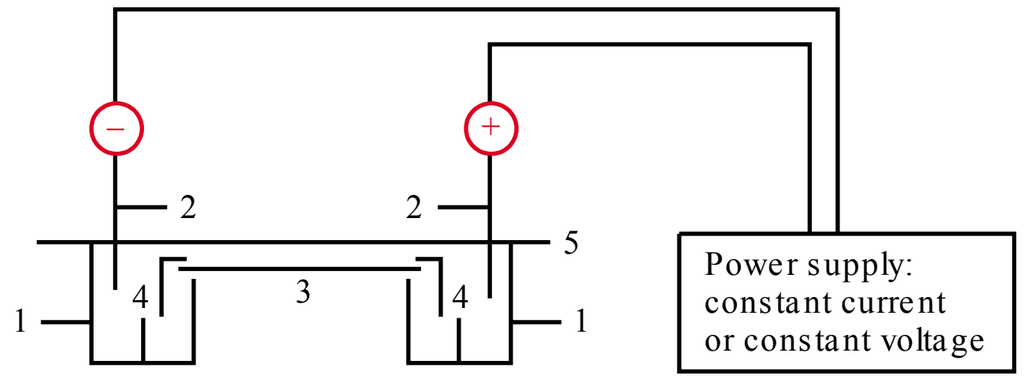

Figure 11-2 A schematic diagram of a typical electrophoresis apparatus showing two buffer chambers with baffe plates (1), electrodes (2), electrophoretic support (3), wicks (4), cover (5), and power supply.

Power Supplies

The function of a power supply in an electrophoretic process is to supply electrical power. Commercially available power supplies allow operation under conditions of (1) constant current, (2) constant voltage, or (3) constant power, all of which are adjustable. The flow of current through a medium that offers electrical resistance is associated with production of Joule heat:

$$\text{Heat} = (E)\ (I)\ (t) \qquad (2)$$

where

E = electromotive force (EMF) in volts (V);
I = current in amperes (A); and
t = time in seconds (s).

Heat evolved during electrophoresis increases the conductance of the system (decreases resistance). With constant-voltage power sources, the resultant rise in current, which is due to the increase in thermal agitation of all dissolved ions, causes an increase in both the migration rate of the protein and the rate of evaporation of water from the stationary support medium. The water loss causes an increase in ion concentration and further decreases resistance (R). To minimize these effects on migration rate, it is best to use a constant-current power supply. According to Ohm's law:

$$E = (I)\ (R) \qquad (3)$$

Therefore, if R is decreased, the applied EMF also decreases (current remains constant). This in turn decreases the heat effect and keeps the migration rate relatively constant.

For **isoelectric focusing** (IEF), a power supply capable of constant power is recommended because both current and voltage change as separation occurs during performance of this technique. **Capillary electrophoresis** (CE) systems (discussed later in this chapter) use power supplies capable of providing voltages in the kilovolt range. Pulsed-power or pulsed-field techniques periodically change the orientation of the applied field relative to the direction of migration by alternately applying power to different pairs of electrodes or electrode arrays. During each cycle, molecules must reorient themselves to the new field direction to fit through the pores in the gel before migration continues. Because reorientation time depends on molecular size, net migration becomes a function of the frequency of field alteration. This permits separation of very large molecules such as DNA fragments that are not resolved by the relatively small pores in agarose or polyacrylamide gels.[12]

Buffers

The buffer serves as a multifunctional component of the electrophoretic process as it (1) carries the applied current, (2) establishes the pH at which electrophoresis is performed, and (3) determines the electrical charge on the solute. The buffer's ionic strength influences (1) the conductance of the support, (2) the thickness of the ionic cloud (buffer and nonbuffer ions) surrounding a charged molecule, (3) the rate of its migration, and (4) the sharpness of the electrophoretic zones. With increasing buffer concentration, the ionic cloud increases in size, and the molecule becomes hindered in its movement. High ionic strength buffers yield sharper band separations but also produce increased Joule heat as the result of increased current levels—an effect that leads to denaturation of heat-labile proteins.

Ionic strength (also denoted by the symbol μ) is computed according to the following:

$$\mu = 0.5 \sum c_i\ z_i^2 \qquad (4)$$

where

c_i = ion concentration in mol/L; and
z_i = the charge on the ion.

The ionic strength of an electrolyte (buffer) composed of monovalent ions is equal to its molarity (mol/L). The ionic strength of a 1 mol/L electrolyte solution with one monovalent and one divalent ion is 3 mol/L, and for a doubly divalent electrolyte, it is 4 mol/L.

Support Media

The support medium provides the matrix in which separation takes place. Various types of support media are used in electrophoresis and vary from pure buffer solutions in a capillary to insoluble gels (e.g., sheets, slabs, or columns of starch, agarose, or polyacrylamide) or membranes of cellulose acetate. Gels are cast in a solution of the same buffer to be used in the procedure and may be used in a horizontal or vertical orientation. In either case, maximum resolution is achieved if the sample is applied within a very fine starting zone. Separation

is based on differences in charge-to-mass ratio of the proteins and, depending on the pore size of the medium, possibly molecular size.

Starch Gel and Cellulose Acetate

Starch gel was the first material to be used as a support medium for electrophoresis. It was used to separate macromolecules on the basis of both surface charge and molecular size. Because preparation of a reproducible starch gel is difficult, this medium is now rarely used in the clinical laboratory. Cellulose acetate membranes are dry, opaque, brittle films made by treating cellulose with acetic anhydride. Because they need to be soaked in buffer to soften them before use and also need to be cleared before scanning for densitometry, they are seldom used in routine clinical applications. Currently, agarose and polyacrylamide gels are the support media of choice for electrophoresis.

Agarose

Agarose is a purified, essentially neutral fraction of agar obtained by separating agarose from agaropectin, a more highly charged fraction caused by acidic sulfate and carboxylic side groups. It is used in agarose gel electrophoresis (AGE) for the separation of a variety of analytes including (1) serum, urine, or CSF proteins, (2) hemoglobin variants, (3) isoenzymes,and (4) lipoproteins. Because the pore size in agarose gel is large enough for all proteins to pass through unimpeded, separation is based only on the charge-to-mass ratio of the protein. Advantages of agarose gel include its lower affinity for proteins and its native clarity after drying, which permits excellent densitometric examination. It is essentially free of ionizable groups and so exhibits little **endosmosis** (discussed later in this chapter).

Most routine procedures for AGE today are carried out on commercially produced, prepackaged microzone gels. Sample is applied by means of a thin plastic template with small slots corresponding to sample application points in manual procedures or a comb applicator if an automated system is used. The template is placed on the agarose surface, and 5- to 7-μL samples are placed on each slot. After sample is allowed to diffuse into the agarose for 5 minutes, any excess is removed by blotting, and the template is removed. An AGE separation for most routine serum applications requires an electrophoresis time of 20 to 30 minutes.

Operationally, 0.5 to 1.0 g of agarose/dL of buffer provides a gel with suitable strength and good migration properties for proteins and DNA fragments in the range of 0.5 to 20.0 kbp (kilobase pairs). Smaller DNA fragments may be resolved with special grades of agarose. Because all nucleic acids have essentially the same charge-to-mass ratios, separation is based primarily on molecular size and in part on molecular form, both of which determine how fast the molecule or fragment migrates through the pores of the gel. Smaller DNA fragments have migration rates in agarose that are inversely proportional to the logs of their molecular weights, but this relationship decreases as their fragment size increases. Fragments larger than 50 to 100 kbp migrate at the same rate through agarose and require an alternative technique such as pulse-field electrophoresis for separation.

Polyacrylamide

Polyacrylamide is a polymer that is prepared by heating acrylamide with a variety of catalysts, with or without cross-linking agents. Polyacrylamide gel is (1) thermostable, (2) transparent, (3) strong, and (4) relatively chemically inert. Furthermore, these gels are uncharged, thus eliminating endosmosis, and they are prepared in a variety of pore sizes. As compared with agarose gel, the average pore size in a typical 7.5% polyacrylamide gel is about 5 nm (50 Å)—large enough to allow most serum proteins to migrate unimpeded—but proteins with a molecular radius and/or length that exceeds critical limits will be more or less impeded in their migration. Some of these proteins are (1) fibrinogen, (2) β_1-lipoprotein, (3) α_2-macroglobulin, and (4) γ-globulins. With polyacrylamide, proteins are separated on the basis of both charge-to-mass ratio and molecular size—a phenomenon referred to as molecular sieving. Because of the potential carcinogenic character of acrylamide, appropriate caution must be exercised when this material is handled if gels are prepared manually.

When used for the separation of nucleic acids, polyacrylamide is capable of resolving DNA molecules that differ by as little as 2% in length (1 bp in 50 bp). It accommodates a larger amount of sample (up to 10 μg) in a single sample slot, and, compared with DNA from agarose, the DNA recovered from a polyacrylamide gel is extremely pure, containing no inhibitors. Polyacrylamide is most useful for mixtures of smaller DNA fragments and is able to resolve fragments smaller than 1 kbp; however, its small pore size prevents supercoiled DNA from entering the gel.

Automated Systems

Because of increased volume of testing, primarily for serum proteins, many laboratories are converting to automated systems for electrophoresis. These systems provide (1) automated sample and reagent application, (2) electrophoretic separation, (3) staining of analytes, and (4) drying of a variety of gel sizes. They are capable of processing 10 to 100 samples simultaneously. Most capillary systems have autosampling capability for sequentially processing specimens and some permit simultaneous processing of multiple samples with the use of multiple capillaries. Newer microchip-based analyzers significantly miniaturize and increase the speed of the process for separating proteins, nucleic acids, or even entire cells. These advances substantially reduce the labor component associated with this technique.

Description of a Conventional Electrophoretic Procedure

General operations performed in conventional electrophoresis include (1) separation, (2) staining detection, and (3) quantification. In addition, several electrophoretic "blotting" techniques have been developed. Following here is a description of the details associated with a general electrophoretic separation.

Separation

To perform an electrophoretic separation, a hydrated support material, such as a precast microzone agarose or polyacrylamide gel, is blotted to remove excess buffer and then is placed into the electrophoresis chamber. Care should be taken that the gel has neither excess liquid nor bubbles on it. Next, the sample is added to the support material, and it is placed in contact with buffer previously added to the electrode chambers. Electrophoresis is conducted for a determined length of time under conditions of constant voltage or constant current.

Staining Detection

When electrophoresis is completed, the support is removed from the electrophoresis cell and is rapidly dried or placed in a fixative to prevent diffusion of sample components. It is then stained to allow visualization of the individual protein zones. After a washing step to remove excess dye, the support is dried.

Stains used to visualize the separated protein fractions are listed in Table 11-1 and differ according to type of application. The amount of dye taken up by the sample is affected by many factors such as the type of protein and the degree of its denaturation by fixing agents. Most commercial methods for serum protein electrophoresis use Amido Black B or members of the Coomassie Brilliant Blue series of dyes for staining. Isoenzymes are typically visualized by incubating the gel in contact with a solution of substrate, which is linked structurally or chemically to a dye, before fixing. Silver nitrate or silver diamine has been used to stain proteins and polypeptides with sensitivity 10- to 100-fold greater than that of dyes used for the same purpose.[14] Selective fixing and staining of protein subclasses also has been achieved by combining a stain molecule with an antiglobulin, as is done in immunofixation.

TABLE 11-1 Suggested Wavelengths for Quantification of Protein Zones by Direct Densitometry

Separation Type	Dye	Nominal Wavelength, nm
Serum proteins in general	Amido Black (Naphthol Blue Black)	640
	Coomassie Brilliant Blue G-250 (Brilliant Blue G)	595
	Coomassie Brilliant Blue R-250 (Brilliant Blue R)	560
	Ponceau S	520
Isoenzymes ormazan	Nitrotetrazolium Blue (as the formazan)	570
Lipoprotein zones	Fat Red 7B (Sudan Red 7B)	540
	Oil Red O	520
	Sudan Black B	600
DNA fragments	Ethidium bromide (fluorescent)	254 (Ex) 590 (Em)
CSF proteins	Silver nitrate	—

CSF, Cerebrospinal fluid.

Detection and Quantification

Once the steps of electrophoretic separation and staining are complete, it is possible to quantify the individual zones as a percentage of the total or as absolute concentration by direct **densitometry,** if the total protein concentration is known. In the densitometer, the gel (or other medium) is moved past a measuring optical system, and the absorbance of each fraction is displayed on a recorder chart or on an electronic display. Typically, the area under each peak is automatically integrated. Reliable quantification of stained zones using densitometry requires (1) light of an appropriate wavelength, (2) a linear response from the instrument, and (3) a transparent background in the strip being scanned. The response linearity may be verified with a neutral density filter designed with separated or adjacent zones of density, which increase in a linear fashion and have expected absorbance values. Recording the pattern of absorbance obtained for each zone checks the (1) optical, (2) mechanical, and (3) electrical functions of the densitometer.

Useful features generally found in a densitometer include (1) the ability to scan gels 25 to 100 mm in length; (2) automatic gain control, which adjusts the most intense peak of an electropherogram to full scale; (3) automatic background zeroing, which selects the lowest point in the electropherogram as baseline so that minor peaks are not lost or "cut off"; (4) variable wavelength control over the range of 400 to 700 nm; (5) variable slits to allow adjustment of the beam size; (6) an integrating device with both automatic and manual selection of cut points between peaks; (7) automatic indexing—a feature that advances the electrophoresis strip from one sample channel to the next; and (8) the ability to measure ultraviolet fluorescence.

Other desirable features of an electrophoretic instrument and densitometer include (1) computerized integration and printout, (2) built-in diagnostics for instrument troubleshooting, (3) choice of one of several scanning speeds, and (4) ability to measure in the reflectance mode. Models with a separate personal computer for data processing permit (1) storage and reformatting of data, if desired, and (2) reprinting or delayed transmission to a host computer.

Modern DNA analysis techniques, which may produce several dozen bands of DNA fragments of different length, require a type of densitometer referred to as a flat bed scanner or a digital image analyzer.[3] These instruments use ultrasensitive charge-coupled device (CCD) detectors or cameras, have resolution of up to 1200 dots per inch, and are capable of scanning and storing digitized light intensity readings from large areas.

In addition to scanning by densitometry, electrophoresis gels are now being analyzed by mass spectrometers to (1) determine the molecular weights of proteins, (2) determine the cleavage products of proteins,[11] and (3) perform peptide sequencing.[4]

Types of Electrophoresis

The original moving boundary electrophoresis system devised by Tiselius in 1937 separated serum proteins into only five component mixtures: albumin, α_1-, α_2-, β-, and γ-globulins, with the α_1 fraction incompletely separated from albumin.

Modern techniques use different media in different physical formats and a variety of instrumental configurations to achieve much better separations than those obtained by Tiselius. The following section describes several different techniques used for the separation of various analytes.

Zone Electrophoresis

Zone electrophoresis techniques produce zones of proteins that are heterogeneous and physically separated from one another, as shown in Figure 11-3. They are classified according to the type and structure of support materials used and are commonly referred to as (1) agarose gel electrophoresis (AGE), (2) cellulose acetate electrophoresis (CAE), and (3) polyacrylamide gel electrophoresis (PAGE).

Slab Gel Electrophoresis

Traditional methods that use a rectangular gel regardless of thickness are referred to collectively by the term slab gel electrophoresis. Its main advantage is its ability to simultaneously separate several samples in one run. Starch, agarose (AGE), and polyacrylamide (PAGE) media have been used in this format. It is the primary method used in clinical chemistry laboratories for separation of various classes of serum or cerebrospinal fluid (CSF) proteins and DNA or RNA fragments. Gels (usually agarose) may be cast on a sheet of plastic backing or completely encased within a plastic walled cell, which allows horizontal or vertical electrophoresis and submersion for cooling, if necessary.

Slab gels may be cast with additives such as (1) ampholytes, which create a pH gradient (see "Isoelectric Focusing Electrophoresis [IEF]"), or (2) sodium dodecyl sulfate (SDS), which denatures proteins (see "Two-Dimensional [2D] Electrophoresis"). In addition to conventional serum proteins, applications include separation of (1) isoenzymes, (2) lipoproteins, (3) hemoglobins, and (4) fragments of DNA and RNA. One-dimensional separations of the last two often involve the addition of a mixture of known fragment size markers, referred to as a ladder, to one lane to enable size identification of sample fragments.

Disc Electrophoresis

Protein electrophoresis using agarose gel yields only five zones, namely, (1) albumin, (2) α_1-, (3) α_2-, (4) β-, and (5) γ-globulins, although some subfractionation of the α_2- and β-globulins is possible with high-resolution gels. Because the pore size in a polyacrylamide gel is controlled by the percent composition of the polyacrylamide and is much smaller than that found in agarose gel, these gels may yield 20 or more fractions and are widely used to study individual proteins in serum, especially genetic variants and isoenzymes.

With PAGE, samples are separated in individual gels prepared in open-ended glass tubes (referred to as rod PAGE), which form a bridge between two buffer reservoirs. Although precast gel tubes are now commercially available, the original technique involved a three-gel system consisting of a small-pore separating gel, a larger-pore spacer gel, and a thin layer of large-pore monomer solution containing about 3 µL of serum. The different compositions caused discontinuities in the electrophoretic matrix and gave the technique its original name, disc electrophoresis. In this system, when electrophoresis begins, all protein ions migrate easily through the large-pore gels (which do not impede movement of most proteins in serum) and stack up on the separation gel in a very thin zone. This process improves resolution and concentrates protein components at the border (or starting zone) so that preconcentration of specimens with low protein content (e.g., CSF) may not be necessary. Separation then takes place in the bottom separation gel with retardation of some proteins caused by the molecular sieve phenomenon.

Isoelectric Focusing Electrophoresis

Isoelectric focusing electrophoresis (IEF) separates amphoteric compounds such as proteins with increased resolution in a medium possessing a stable pH gradient. The protein migrates to a zone in the medium where the pH of the gel matches the protein's pI. At this point, the charge of the protein becomes zero, and its migration ceases. Figure 11-4 illustrates the procedure and shows electrophoretic conditions before

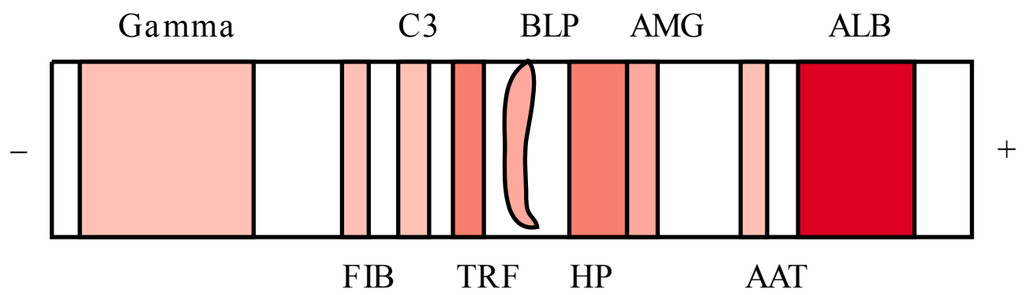

Figure 11-3 A simplified schematic drawing of a protein pattern from the serum of a subject with haptoglobin type 2-1 (separation by polyacrylamide gel electrophoresis [PAGE]). Some zones contain more than the one protein shown, as demonstrated by immunological techniques. AAT, α_1-antitrypsin; ALB, albumin; AMG, α_2-macroglobulin; BLP, β-lipoprotein; C3, complement 3; FIB, fibrinogen; gamma, γ-globulin; HP, haptoglobin; TRF, transferrin.

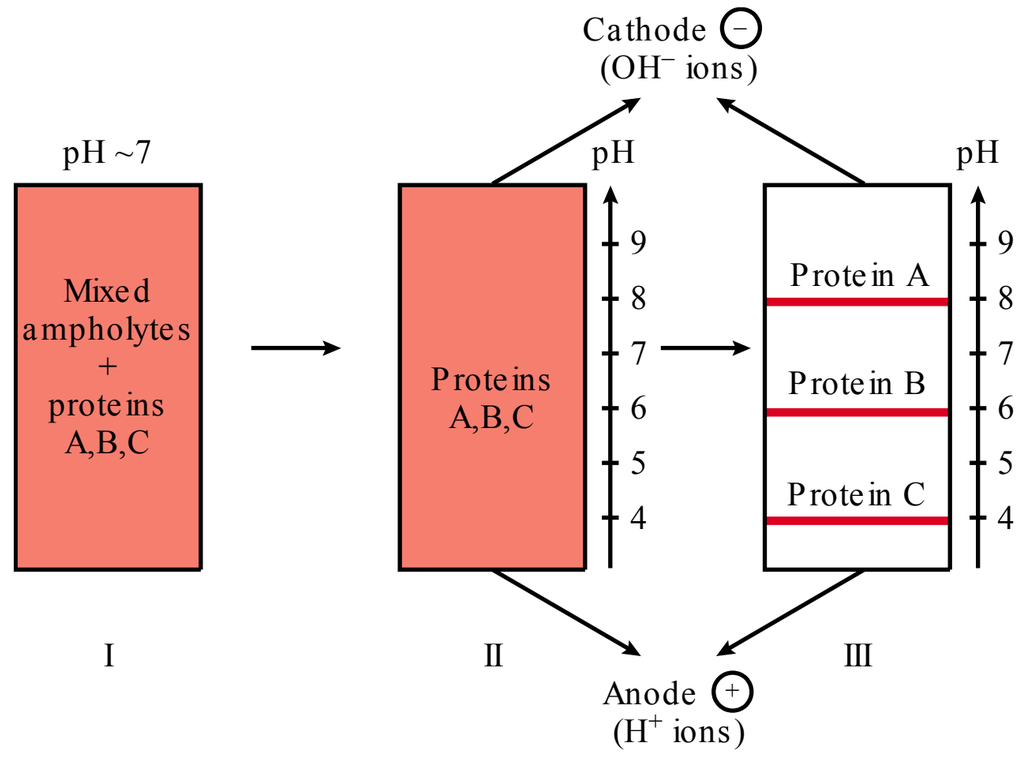

Figure 11-4 Schematic of an isoelectric focusing (IEF) procedure. I, A homogeneous mixture of carrier ampholytes, pH range 3 to 10, to which proteins A, B, and C with pI 8, 6, and 4, respectively, were added. II, Current is applied and the carrier ampholytes rapidly migrate to the pH zones where net charge is zero (the isoelectric point [pI] value). III, The proteins A, B, and C migrate more slowly to their respective pI zones, where migration ceases. The high buffering capacity of the carrier ampholytes creates stable pH zones in which each protein may reach its pI.

and after current is applied. The protein zones are very sharp because the region associated with a given pH is very narrow. Normal diffusion is counteracted because the protein acquires a charge as it migrates from its pI position and subsequently migrates back because of electrophoretic forces. Proteins that differ in their pI values by only 0.02 pH units have been separated by IEF.

The pH gradient is created with carrier ampholytes, a group of amphoteric polyaminocarboxylic acids that have slight differences in pKa values and molecular weights of 300 to 1000 Da. Mixtures of 50 to 100 different compounds are added to the medium and create a "natural pH gradient" when the individual ampholytes reach their pI values during electrophoresis. Narrow buffered zones are established with stable but slightly different pHs, through which the slower-moving proteins migrate and stop at their individual pIs. Because carrier ampholytes are generally used in relatively high concentrations, a high-voltage power source (up to 2000 V) is necessary. As a result, the electrophoretic matrix must be cooled. IEF is widely used in neonatal screening programs to test for variant hemoglobins.

Two-Dimensional (2D) Electrophoresis

Two-dimensional (2D) electrophoresis is extensively used to (1) study families of proteins, (2) search for genetic or disease-based differences, and (3) study the protein content of cells of various types.[8] This technique uses charge-dependent IEF electrophoresis in the first dimension and molecular weight–dependent electrophoresis in the second dimension. The first-dimension electrophoresis is carried out in a large-pore medium, such as agarose gel or large-pore polyacrylamide gel. Ampholytes are added to yield a pH gradient. The second dimension is often polyacrylamide in a linear or gradient format. This type of electrophoresis achieves the highest resolving power for separation of DNA fragments. With this application, normal AGE is carried out in the first dimension and ethidium bromide is added to the gel for the second dimension to open the fragments and cause changes in their electrophoretic mobility.

The 2D electrophoresis method of O'Farrell uses rod PAGE-IEF for the first dimension and incorporates ampholytes that cover a pH range of 3 to 10 units. The gel is extruded from the gel tube at the end of electrophoresis and is placed in contact with a thin polyacrylamide gradient gel slab that incorporates SDS. Separated proteins may be detected by using a variety of techniques, including (1) staining with Coomassie dyes, (2) silver stain, (3) radiography (exposure of photographic film to emissions of isotopically labeled polypeptides), or (4) fluorographic analysis (X-ray film exposed to tritium-labeled polypeptides in the presence of a scintillator). The latter two methods are 100 to 1000 times more sensitive than the use of Coomassie dyes.

Analytical and preparative 2D electrophoresis provides high-resolution techniques for protein separation, which are the methods of choice when complex samples need to be arrayed for characterization, as in **proteomics**.[1]

Newer developments in proteomics combine analytical techniques to achieve 2D separation by linking, for example, liquid IEF with nonporous silica reversed-phase, high-performance liquid chromatography (HPLC; see Chapter 12) and by detecting intact proteins by electrospray ionization and time of flight mass spectrometry[4] (see Chapter 13).

Blotting Techniques

In 1975, Edward Southern developed a technique that is widely used to detect fragments of DNA. This technique, known as Southern blotting, first requires electrophoretic separation of DNA or DNA fragments by AGE. Next a strip of nitrocellulose or a nylon membrane is laid over the agarose gel, and the DNA or DNA fragments are transferred or "blotted" onto it by (1) capillary blotting, (2) electroblotting, or (3) vacuum blotting. They are then detected and identified by hybridization with a labeled complementary nucleic acid probe. This technique is widely used in molecular biology for (1) identifying a particular DNA sequence; (2) determining the presence, position, and number of copies of a gene in a genome; and (3) typing DNA.

Northern and Western blotting techniques, named by analogy to Southern blotting, were subsequently developed to separate and detect ribonucleic acid (RNA) and proteins, respectively. Northern blotting is carried out identically to Southern blotting, except that a labeled RNA probe is used for hybridization. Western blotting is used to (1) separate, (2) detect, and (3) identify one or more proteins in a complex mixture. It involves first separating the individual proteins in polyacrylamide gel and then transferring or "blotting" them onto an overlying strip of nitrocellulose or a nylon membrane by electroblotting. The strip or membrane is then reacted with a reagent that contains an antibody raised against the protein of interest. (See Chapter 15 for further details and applications of this technique.)

Capillary Electrophoresis

In capillary electrophoresis (CE), the classic techniques of electrophoresis are carried out in a small-bore, fused silica capillary tube typically coated with a thin (exterior) polymeric covering (polyimide). For example, the outer diameter of the capillary tubing used to make such tubes typically ranges from 180 to 375 μm, the inner diameter from 20 to 180 μm, and the total length from 20 cm up to several meters. This capillary tube serves as a capillary electrophoretic chamber that is connected to a detector at its terminal end[16] and, via buffer reservoirs, to a high-voltage power supply (Figure 11-5). The main advantage of CE comes from efficient heat dissipation, which permits the application of voltages in the range of 25 to 30 kV. This enhances separation efficiency and reduces separation time in some cases to less than 1 minute.[9] Sample volumes are kept in the picoliter-to-nanoliter range to minimize distortions in the applied field caused by the presence of sample.

Buffers for CE

As with conventional electrophoresis, the choice of a buffer is critical for obtaining successful separation with CE. In practice, it is critical to select a buffer that (1) does not interfere with the ability to detect the analytes of interest, (2) maintains

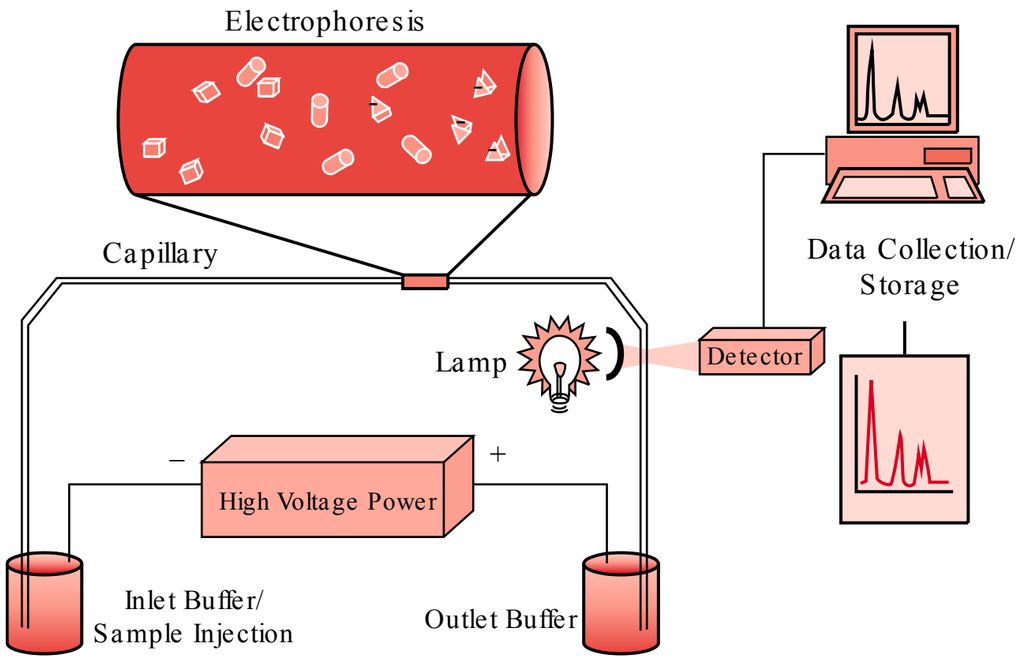

Figure 11-5 Schematic for capillary electrophoresis (CE) instrumentation.

solubility of the analytes, (3) maintains buffering capacity through the analysis, and (4) produces the desired separation. For low-pH buffers, (1) phosphate, (2) acetate, (3) formate, and (4) citrate have commonly been used effectively. For buffers in the basic pH range, (1) Tris, (2) Tricine, (3) borate, and (4) CAP (N-cyclohexyl-3-aminopropanesulfonic acid) buffers are used.

Ionic strength is an important variable that has been known to have adverse effects (both positive and negative) on electrophoretic separation, mainly because high ionic strength buffers generate excessive Joule heat. Although capillary thermostatting (inherent dissipation combined with active cooling) is very effective, the current (Joule heat) associated with buffer concentrations greater than 100 mmol/L may overcome capillary thermostatting at higher applied voltages. One exception to this rule is borate buffer, a classic CE buffer that generates relatively low current (and therefore, Joule heat) in high applied fields. Consequently, in the pH 7 to 9 range, 500 mmol/L borate is the buffer of choice for CE separations.

Sample Injection

To perform a CE separation, sample volumes of 1 to 50 nL are injected into the capillary chamber by hydrodynamic injection or electrokinetic injection. With hydrodynamic injection, an aliquot of sample is introduced by applying positive pressure to the sample inlet vial. Alternatively, gravity may be used by raising the inlet vial (or lowering the outlet reservoir) to allow siphoning to occur. The volume of sample loaded is governed by a number of parameters, including (but not restricted to) (1) the inner diameter of the capillary, (2) buffer viscosity, (3) applied pressure, (4) temperature, and (5) time. With electrokinetic (EK) injection, an aliquot of a sample is introduced by applying a voltage between a sample vial and the outlet buffer reservoir for a timed interval. The magnitude of the voltage is dependent on the analyte and buffer system used but typically involves field strength 3 to 5 times lower than that used for separation. It is important to note that although hydrodynamic methods introduce a sample representative of the bulk specimen, EK injection favors those analytes that have higher electrophoretic mobility; thus it is consider a "biased" injection mode. With either mode, to maintain high separation efficiency, the length of the sample plug should remain at <2% of the total capillary length.

Detection

The detection modes that have been designed for HPLC are equally applicable to CE. For example, ultraviolet-visible photometers are widely used as detectors to monitor CE separations.[13] However, as opposed to being distinct from flow cells in liquid chromatograpy (LC) systems, the inner diameter of the capillary tube (20 to 100 μm) defines the optical pathlength (OPL) for detection. Because optical detection is governed by Beer's law, the 20 to 100 μm inner diameter (i.d.) of the capillary limits ultraviolet–visible spectroscopy (UV-Vis) absorbance detection to 10^{-6} to 10^{-8} mol/L. In addition to OPL constraints, when nanoliter volumes are injected, the mass of analyte injected is extremely small. More sensitive optical techniques that have been used with CE include (1) fluorescence, (2) refractive index, (3) chemiluminescence, and (4) laser-induced fluorescence (LIF), which is the most sensitive method and is capable of detection limits of 10^{-18} to 10^{-21} mol/L.

In addition to the use of sensitive detectors, techniques have been developed to preconcentrate the sample. One of the simplest techniques used for this involves inducing a "stacking" effect with the sample components—something that is easily accomplished by exploiting ionic strength differences between the sample matrix and the separation buffer.[2] This can be done because sample ions have decreased electrophoretic mobility in a higher conductivity environment. When voltage is applied to the system, sample ions in the sample plug instantaneously accelerate toward the adjacent separation buffer zone. Upon crossing the boundary, the higher conductivity environment induces a decrease in electrophoretic velocity and subsequent "stacking" of the sample components into a smaller buffer zone than was seen in the original sample plug. Within a short time, the ionic strength gradient dissipates and the charged analyte molecules begin to move from the "stacked" sample zone toward the cathode. Stacking is used with hydrostatic or EK injection and typically yields a tenfold enhancement in sample concentration and hence lower limits of detection.

An alternative approach to stacking is a "focusing" technique that is based on pH differences between the sample plug and the separation buffer. This has been shown to be very useful for analysis of peptides, mainly because of their relative stability over a wide pH range.[10]

Modes of Operation

CE is capable of multiple modes of operation, including (1) capillary zone electrophoresis, (2) capillary gel electrophoresis, and (3) capillary IEF..

Capillary zone electrophoresis (CZE), the simplest form of CE, is unique as a result of its ability to electrophoretically resolve analytes in the absence of a separation medium (polymer, ampholytes). The power of the CZE mode is its ability to resolve charged species electrophoretically without a sieving matrix; it is broadly applicable to a spectrum of analytes,

including (1) proteins,[17] (2) peptides, (3) amino acids, and (4) other small molecules such as drugs and ions.[15] A submode of CZE is capillary ion electrophoresis, which refers to analysis of inorganic ions by CZE, particularly when indirect detection is used. With this mode of detection, a strongly absorbing ion is added to the running electrolyte and is monitored at a wavelength that provides constant, high background absorbance. As solute ions move into their discrete zones during the electrophoretic process, they displace the indirect detection agent; this produces a decrease in background absorbance as the zone passes through the detector.

Micellar electrokinetic chromatography (MEKC) is a hybrid of electrophoresis and chromatography but is distinct from capillary electrokinetic chromatography (CEC), where the capillary is actually filled with a solid phase. MEKC is an unusually effective electrophoretic technique because it can be used for the separation of neutral and charged solutes. Separation of neutral species is accomplished by the use of micelles formed by additives in the separation buffer (e.g., SDS). Differential interaction of analytes with micelles provides separation that is based on chromatography, whereas the application of an electrical field provides electrophoretic separation of charged analytes and flow.

Capillary gel electrophoresis (CGE) is directly comparable with traditional slab or tube gel electrophoresis because the separation mechanisms are identical.[6] Size separation is achieved with a suitable polymer that is loaded into the capillary, used for one separation, and then replaced. Separation is size-based for DNA- and SDS-saturated proteins and requires a gel because they contain mass-to-charge ratios that do not vary. A variety of polymeric matrices have been defined for both DNA (e.g., polyacrylamide and cellulosic materials) and protein analysis (e.g., dextran-based matrices). One of the requirements that often accompany this type of analysis is that electro-osmotic flow must be reduced. T is is accomplished by (1) covalently, (2) adsorptively, or (3) dynamically coating the surface.

Capillary IEF (cIEF) is comparable with tube IEF and is governed by the same principles and procedures. It differs from conventional IEF in that it is carried out using a free solution of ampholytes or a precast gel. As is expected with a CE mode, and unlike conventional IEF, the focused zones migrate past the online detector during or after the focusing process.

Microchip Electrophoresis

Microchip electrophoresis platforms were first developed in the 1990s.[7] Subsequent developments by numerous laboratories have advanced analytical microchip technology to the point where it functions as an alternative platform to CE. Similar in principle to CE, microchips differ from capillaries in that the (1) separation channels, (2) sample injection channels, and (3) reservoirs are fabricated into the same planar substrate using photolithographic processes employed by the microelectronics industry. Additionally, (1) sample preparation and/or precolumn or postcolumn reactors, (2) detectors, and (3) excitation sources have been integrated into the chips.

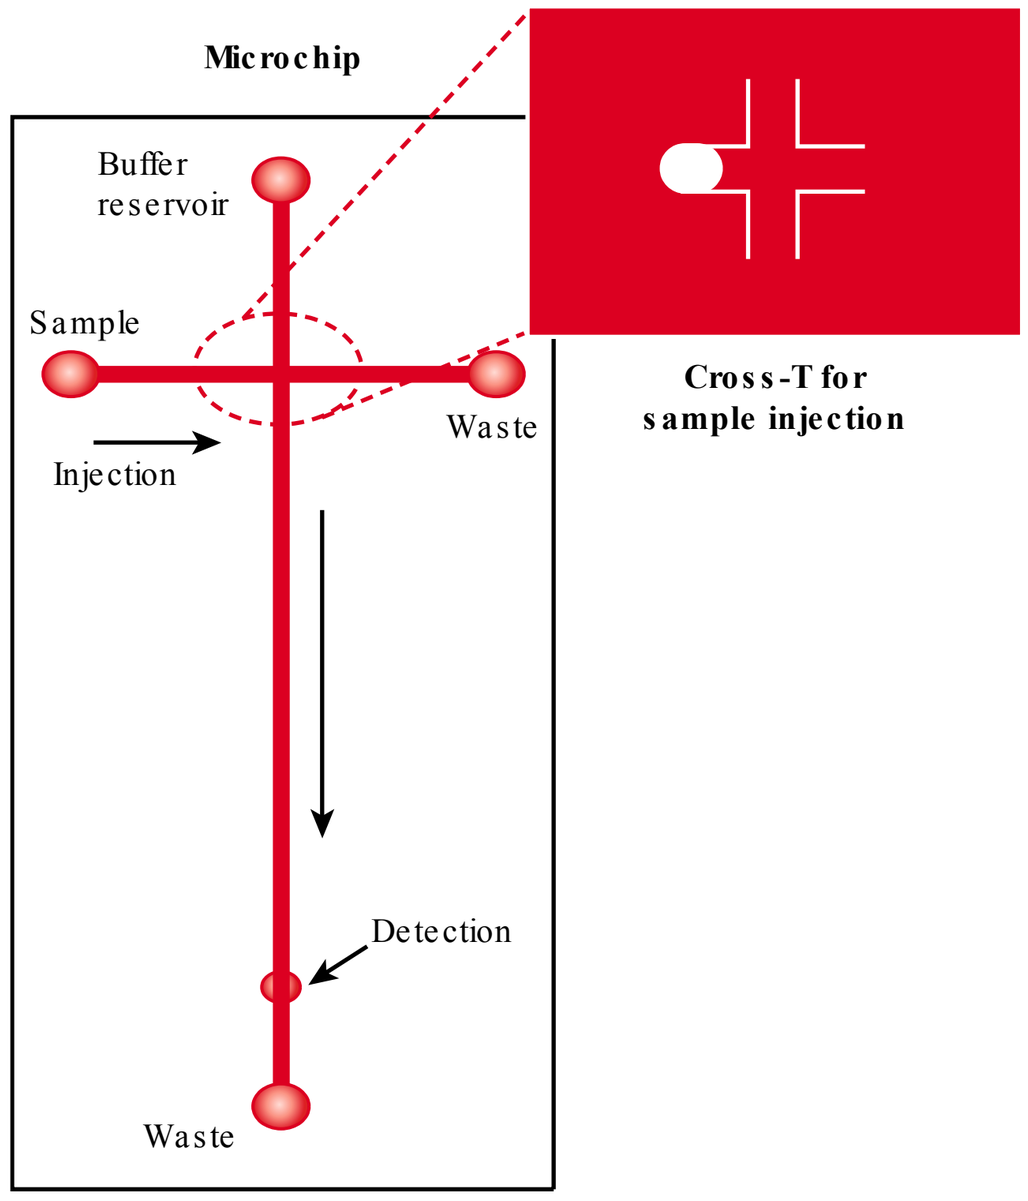

Figure 11-6 Simple cross-T microstructure design on chips used for electrophoretic separation.

T e classic cross-T design of a single-channel microchip (Figure 11-6) involves a short (injection) channel that intersects a longer (separation) channel with reservoirs at the ends of each of these channels. T e cross-T design is important for injecting sample volumes an order of magnitude smaller in the chip system than in the capillary system. T is is accomplished through EK sample injection by applying a field of several hundred volts across the sample and sample waste reservoirs, thereby inducing migration of 50 to 500 pL of sample into the injection cross. A higher voltage (1 to 4 kV) is then applied to the separation channel, which induces separation of the analyte zones before they reach the detection window downstream.

In the same manner that optical detection is conducted in a capillary system, it is accomplished on a single channel in a microchip. For example, UV-Vis absorbance detection has been used but is more dif cult than in CE because the substrates used to fabricate the chips often are not as "pure" as the fused silica used in capillaries, or they may have different spectral properties. Consequently, detection occurs primarily through LIF because this is easily implemented with the planar configuration of the microchip. Detection limits for fluorescein-like fluors have been easily demonstrated at the 10^{-11} mol/L level of detection and have been pushed as low as 10^{-13} mol/L—a mass detection limit of a few hundred molecules. T is allows for detection, for example, of polymerase chain reaction (PCR)-amplified DNA fragments at a level that competes with ^{32}P-autoradiography from Southern blots.[6] Typical microchip separation times are around 50 to 200 seconds. In the clinical diagnostic arena, the main analytes of interest for extrapolation to the microchip platform are proteins and DNA.

As a result of the large number of fluorescent intercalators that have been incorporated into double-stranded (ds) DNA and the excellent detection sensitivity that results from LIF, DNA separations on microchips have developed more rapidly than protein separations. This has accelerated the rate at which capillary and microchip electrophoresis methods have emerged as alternatives to traditional slab gel electrophoresis for DNA analysis, particularly for sequencing applications. This is signified by sequencing of the human genome using CE.

Technical Considerations

Several technical aspects of the electrophoretic process have to be considered to obtain acceptable performance. They include (1) electroendosmosis, (2) handling of buffers and stain solutions, (3) sampling considerations, and (4) a number of problems commonly encountered in performing electrophoresis.

Endosmosis or Electroendosmotic Flow

Certain electrophoretic support media in contact with water take on a negative charge as the result of adsorption of hydroxyl ions. These ions become fixed to the surface and are rendered immobile. Positive ions in solution cluster about the fixed negative charge sites, forming an ionic cloud of mostly positive ions. The number of negative ions associated with this ionic cloud increases with increasing distance from the fixed negative charge sites until eventually positive and negative ions are present in equal concentrations (Figure 11-7).

When current is applied to such a system, charges attached to the immobile support remain fixed, but the cloud of ions in solution is free to move to the electrode of opposite polarity. Because these ions are highly hydrated, their movement causes movement of the solvent as well. This phenomenon, referred to as endosmosis, causes preferential movement of water in one direction. Macromolecules in solution that would otherwise move in the opposite direction to this flow may remain immobile or may even be swept back toward the opposite pole if they are insufficiently charged. In electrophoretic media in which surface charges are minimal (starch gel, purified agarose, and polyacrylamide gel), endosmosis is also minimal. Because the inner surface of a glass capillary contains many such charged groups, endosmosis is very strong and is actually the primary driving force for migration in CE systems.

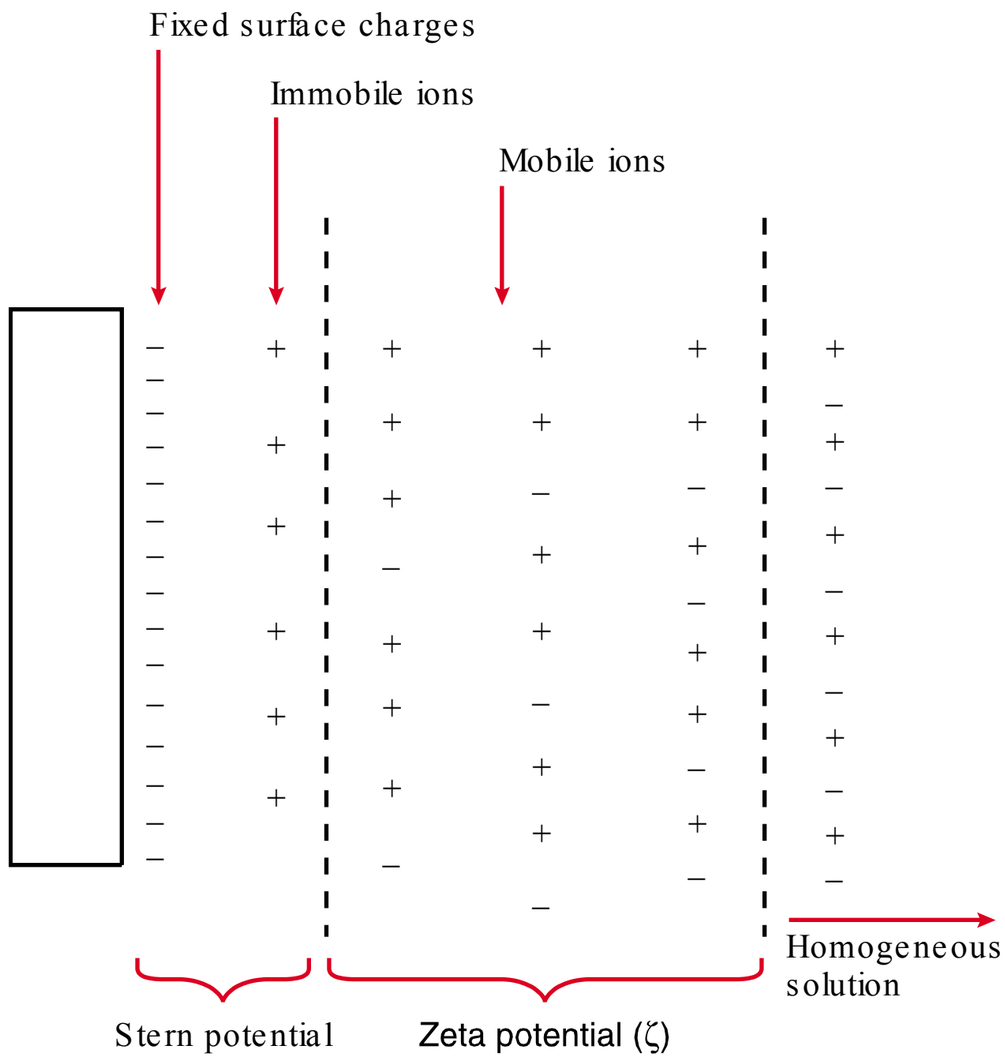

Figure 11-7 Distribution of + and − ions around the surface of an electrophoretic support. Fixed on the surface of the solid is a layer of − ions. (These may be + ions under suitable conditions.) A second layer of + ions is attracted to the surface. Extending farther from the surface of the solid is homogeneous solution.

Buffers and Stain Solutions

Buffers are good culture media for the growth of microorganisms and should be refrigerated when not in use. Moreover, a cold buffer improves resolution and reduces evaporation from the electrophoretic support. Buffer used in a small-volume apparatus should be discarded after each run because of pH changes caused by the electrolysis of water that accompanies electrophoresis. If volumes used are larger than 100 mL, buffer from both reservoirs may be combined, mixed, stored at 4 °C, and reused for four subsequent electrophoretic runs.

A typical stain solution may be used several times. The stain or substrate reagent, in the case of isoenzymes, may be considered faulty whenever protein zones appear too lightly stained. Stain solution must be stored tightly covered to prevent evaporation.

Sampling

Because albumin in serum is about 10 times more concentrated than the α_1-globulins, the amount of serum applied should avoid overloading with albumin while adequately quantifying α_1-globulin. Typical amounts of serum applied in agarose gel electrophoresis are 0.6 to 2.0 µL, depending on the test requirements. If procedures call for multiple applications, as in isoenzyme analysis, concern about albumin overloading is no longer a factor. Urine specimens require 50- to 100-fold concentration for adequate sensitivity, and CSF may or may not require concentration, depending on the staining approach used.

Maintaining a Healthy Capillary

Capillary preparation and maintenance play a critical role in attaining reproducible results with CE. When a new capillary is used or a change is made to a new separation buffer, the capillary must be adequately equilibrated with the separation buffer—a process termed conditioning. Equilibration is particularly important when a phosphate-containing buffer is involved. For acceptable reproducibility, a phosphate-containing buffer should be equilibrated in the capillary a minimum of 4 hours before use. As with any untreated silica surface, ionized silanol groups are ideal for interaction with charged analytes, particularly peptides and proteins in neutral/basic pH buffers. Hence, after each separation, the capillary surface must be "regenerated" or "reconditioned" by the cleansing of any material adsorbed onto the wall. This is accomplished by following each run with

a 3 to 5 column volume rinse with 100 mmol/L NaOH, then by flushing with 5 to 8 column volumes of fresh separation buffer.

Common Problems

The following problems may be encountered when slab gel electrophoresis is performed:

1. Discontinuities in sample application may be due to dirty applicators, which are best cleaned by agitating in water followed by gently pressing the applicators against absorbent paper. Caution must be used, and it is inadvisable to clean wires or combs by manual wiping.
2. Unequal migration of samples across the width of the gel may be due to dirty electrodes causing uneven application of the electrical field or to uneven wetting of the gel.
3. Distorted protein zones may be due to (1) bent applicators, (2) incorporation of an air bubble during sample application, (3) overapplication of sample, or (4) excessive drying of the electrophoretic support before or during electrophoresis.
4. Irregularities (other than broken zones) in sample application may be due to excessively wet agarose gels. Parts of the applied samples may look washed out.
5. Unusual bands are usually artifacts that may be easily recognized. Hemolyzed samples are frequent causes of an increased β-globulin (where free hemoglobin migrates) or an unusual band between the α_2- and β-globulins as the result of a hemoglobin-haptoglobin complex. A band at the starting point may be fibrinogen, and the sample should be verified as being serum before this band is reported as an abnormal protein. Split α_1, α_2-, and β-globulin bands are not unusual and should not be considered errors. In some samples, the α_1- and β-lipoproteins may migrate ahead of their normal positions and appear as an atypical band. Occasionally, a split albumin zone is observed in bis-albuminemia, but a grossly widened albumin zone may be due to certain medications that are albumin bound.

Atypical bands in an isoenzyme pattern may be the result of binding by an immunoglobulin. An irregular but sharp protein zone at the starting point that lacks the regular, somewhat diffuse appearance of proteins may actually be denatured protein resulting from deteriorated serum. When one is faced with an unusual band anywhere in a serum protein pattern, the possibility that it is a true paraprotein (see Chapter 18 for further details) must always be considered. Finally, it is good laboratory practice to include a control serum with each electrophoretic run to evaluate its quality and that of the densitometer.

Review Questions

1. The isoelectric point of an amino acid or protein is defined as the:
   a. ability of the amino acid or protein to carry both positive and negative charges.
   b. pH at which the amino acid or protein has a negative charge.
   c. pH at which a molecule has no net charge.
   d. point on an electrophoretic gel at which that specific protein migrates.
2. The term amphoteric means:
   a. the pH at which a protein has no net charge.
   b. that a protein will have a negative charge at a high pH.
   c. that a protein has both positive and negative charges because of its side chains.
   d. the positive electrode.
3. Unequal migration of samples down the gel in an electrophoresis assay is an interference usually caused by:
   a. dirty electrodes causing uneven application of the electrical field.
   b. dirty pipette tips or applicators.
   c. too much sample being applied.
   d. inappropriate binding of immunoglobulins to other proteins in a sample.
4. In serum protein electrophoresis, the greater the charge of a molecule:
   a. the slower it will migrate.
   b. the faster it will migrate.
   c. the less migration rate will be affected.
5. Serum protein electrophoresis is what kind of basic technique?
   a. Immunoassay
   b. Standardization
   c. Qualitative technique
   d. Separation
6. Specimens with very low protein content sometimes require preconcentration before they are loaded onto an electrophoretic gel. An electrophoretic technique that does not require this concentration step is:
   a. disc electrophoresis.
   b. capillary electrophoresis.
   c. zone electrophoresis.
   d. two-dimensional gel electrophoresis.
7. What optical measuring technique allows for the scanning and quantification of electrophoretic fractions separated on a support medium?
   a. Spectrophotometry
   b. Chromatography
   c. Densitometry
   d. Nephelometry
8. A Southern blot is used to detect fragments of:
   a. RNA.
   b. protein.
   c. agarose.
   d. DNA.
9. A 1% agarose gel is best suited for separating DNA fragments in which one of the following size ranges:
   a. 500 bp (0.5 kbp) to 20 kbp
   b. 50 to 100 kbp
   c. 100 to 500 kbp
   d. larger than 500 kbp
10. The component of an electrophoresis system in which separation takes place is the:
    a. stain.
    b. support medium.
    c. densitometer.
    d. zone.

CHAPTER 12

Chromatography*

Glen L. Hortin, M.D., Ph.D., and Carl A. Burtis, Ph.D.

Objectives

1. Define the following:
   - Chromatography
   - Column chromatography
   - Derivatization
   - Mobile phase
   - Planar chromatography
   - Resolution
   - Retention factor
   - Retention time
   - Stationary phase
2. Evaluate a chromatogram to determine resolution; list four ways to improve resolution.
3. State the need for extraction or precipitation processing of clinical specimens before chromatographic separation.
4. Describe the following types of chromatographic separation mechanisms, including the principles of separation, by stating the stationary and mobile phases and listing the clinical applications, if any, of each:
   - Ion exchange
   - Partition
   - Adsorption
   - Steric exclusion
   - Affinity
5. Explain the principle of thin-layer chromatography, including mobile and stationary phases, and its use in a clinical laboratory.
6. Calculate retention factor and identify compounds using the retention factor obtained from a planar chromatography procedure.
7. State the basic method of gas chromatography; list the mobile and stationary phases and the two gases commonly used in this technique.
8. Summarize the components of a gas chromatograph.
9. Describe the two types of chromatographic columns used for gas chromatography; state the function of the injector and the importance of temperature.
10. List and describe five detectors used in gas chromatography, including the advantages and disadvantages of each.
11. State the basic method of liquid chromatography; list the mobile and stationary phases.
12. Summarize the components of a high-pressure liquid chromatograph.
13. State the function and type of injector used in HPLC and the importance of the flow cell in detection.
14. Differentiate between the following four types of particulate column packings used in HPLC:
    - Bonded phase packings
    - Polymeric packings
    - Chiral packings
    - Restricted access packings
15. Describe three types of detectors that are used in HPLC.
16. Explain the need for sample extraction and derivatization used in sample preparation for HPLC.
17. Discuss analyte identification and quantification in chromatography, including retention time, the need for and comparison with an internal standard, and the need for increased chromatographic efficiency for low-concentration analytes.

Key Words and Definitions

Adsorption chromatography A separation mechanism based on the differential adsorption of analytes on the surface of a stationary phase and using hydrogen bonding and hydrophobic interactions as the forces behind the separation.

Affinity chromatography A separation mechanism in which one component of a specifically matched pair (such as antigen/antibody or hormone/receptor) is immobilized in a stationary phase and is used to capture the other component of the pair that is in the mobile phase.

Chromatogram A plot of detector response used in column chromatography to the presence of analyte in the mobile phase as a function of time or mobile phase volume.

*The authors gratefully acknowledge the original contributions of Drs. Larry D. Bowers, M. David Ullman, and Bruce A. Goldberger, on which portions of this chapter are based.

Key Words and Definitions—cont'd

Chromatography A group of separation techniques that separate analytes by differential distribution between a stationary phase and a mobile phase.

Column chromatography A separation method in which the stationary phase is packed into a tube or is coated onto the inner surface of the tube.

Column packing Particulate matter packed into a column used for chromatographic techniques.

Derivatization Labeling of or chemical addition to an analyte performed to increase the column retention or detectability of that analyte.

Detector A device that responds to the presence of analyte in the mobile phase, the magnitude of which is used to identify and quantify analytes; universal units detect most analytes and selective devices detect only analytes with specific properties.

Gas chromatography (GC) Column chromatography in which the mobile phase is a gas.

High-performance liquid chromatography (HPLC) Liquid chromatography that uses columns containing small particles of stationary phase and requiring high pressure to push the mobile phase past the stationary phase.

Ion-exchange chromatography A separation mechanism that is based on the exchange of ions between a charged stationary phase and oppositely charged ions in the mobile phase.

Liquid chromatography (LC) Column chromatography using a liquid mobile phase.

Mobile phase A gas or a liquid that flows in a chromatographic system and carries the sample past the stationary phase.

Partition chromatography A separation mechanism that is based on the differential distribution of solutes between two immiscible liquids.

Planar chromatography A separation technique in which the stationary phase is on a thin support such as paper or a glass plate.

Resolution A measure of the separation of two adjacent chromatographic peaks; resolution equals the difference in retention time for two components divided by the average of their peak widths.

Retention time The time interval between specimen injection and solute reaching the detector; retention time helps identify and quantify analyte.

Reversed-phase chromatography: A partitioning type of chromatography in which the mobile phase is polar relative to the nonpolar stationary phase.

Size-exclusion chromatography A separation mechanism that separates solutes on the basis of the molecular size of the solutes in a solution.

Stationary phase A solid or a liquid phase that interacts with components of the mobile phase.

Diverse forms of chromatography are used in the clinical laboratory for separating and quantifying a variety of clinically relevant analytes.[9] This chapter describes (1) basic concepts, (2) separation mechanisms, (3) specific chromatographic and detection techniques, (4) extraction techniques, and (5) qualitative and quantitative analyses.

Basic Concepts

Chromatography is a physical process whereby the components (solutes/analytes) of a sample mixture are separated as a result of their differential distribution between stationary and mobile phases.[14,15] During this process, the mobile phase carries the sample through a (1) bed, (2) layer, or (3) column containing the stationary phase. As the mobile phase flows past the stationary phase, the solutes may (1) reside only in the stationary phase (no migration), (2) reside only in the mobile phase (migration with the mobile phase), or (3) distribute between the two phases (differential migration). Those solutes with greater affinity for the stationary phase reside in the stationary phase and migrate more slowly than those with less affinity. Those with less affinity reside mostly in the mobile phase and migrate faster. Thus, the lower-affinity solutes separate from solutes having greater affinities for the stationary phase. Strongly bound solutes subsequently are displaced from the stationary phase by changing the physical or chemical nature of the mobile phase. In this chapter, the term chromatograph is used as a verb and as a noun. As a verb, it means to separate by the process of chromatography. As a noun, it refers to the assembly of components that are necessary to effect a chromatographic separation.

Forms

Planar and column are the two basic forms of chromatography (Figure 12-1). In **planar chromatography,** the **stationary phase** is coated on a sheet of paper (paper chromatography) or is bound to a solid surface (thin-layer chromatography [TLC]).

In **column chromatography,** the stationary phase may consist of a particle of pure silica or polymer, or it may be coated onto or chemically bonded to these support particles. The stationary phase may be "packed" into a tube, or it may be coated onto the inner surface of the tube. The technique is termed **gas chromatography** (GC) or **liquid chromatography** (LC), depending on whether the mobile phase involves a gas or a liquid.

Operationally the instrument used to perform a GC or LC separation is known as either a gas or liquid chromatograph. When the stationary phase in LC consists of small-diameter particles, the technique is **high-performance liquid chromatography** (HPLC). When a gas or liquid chromatograph is connected to a mass spectrometer, the combined or "hyphenated/hybrid" techniques are **gas chromatography-mass**

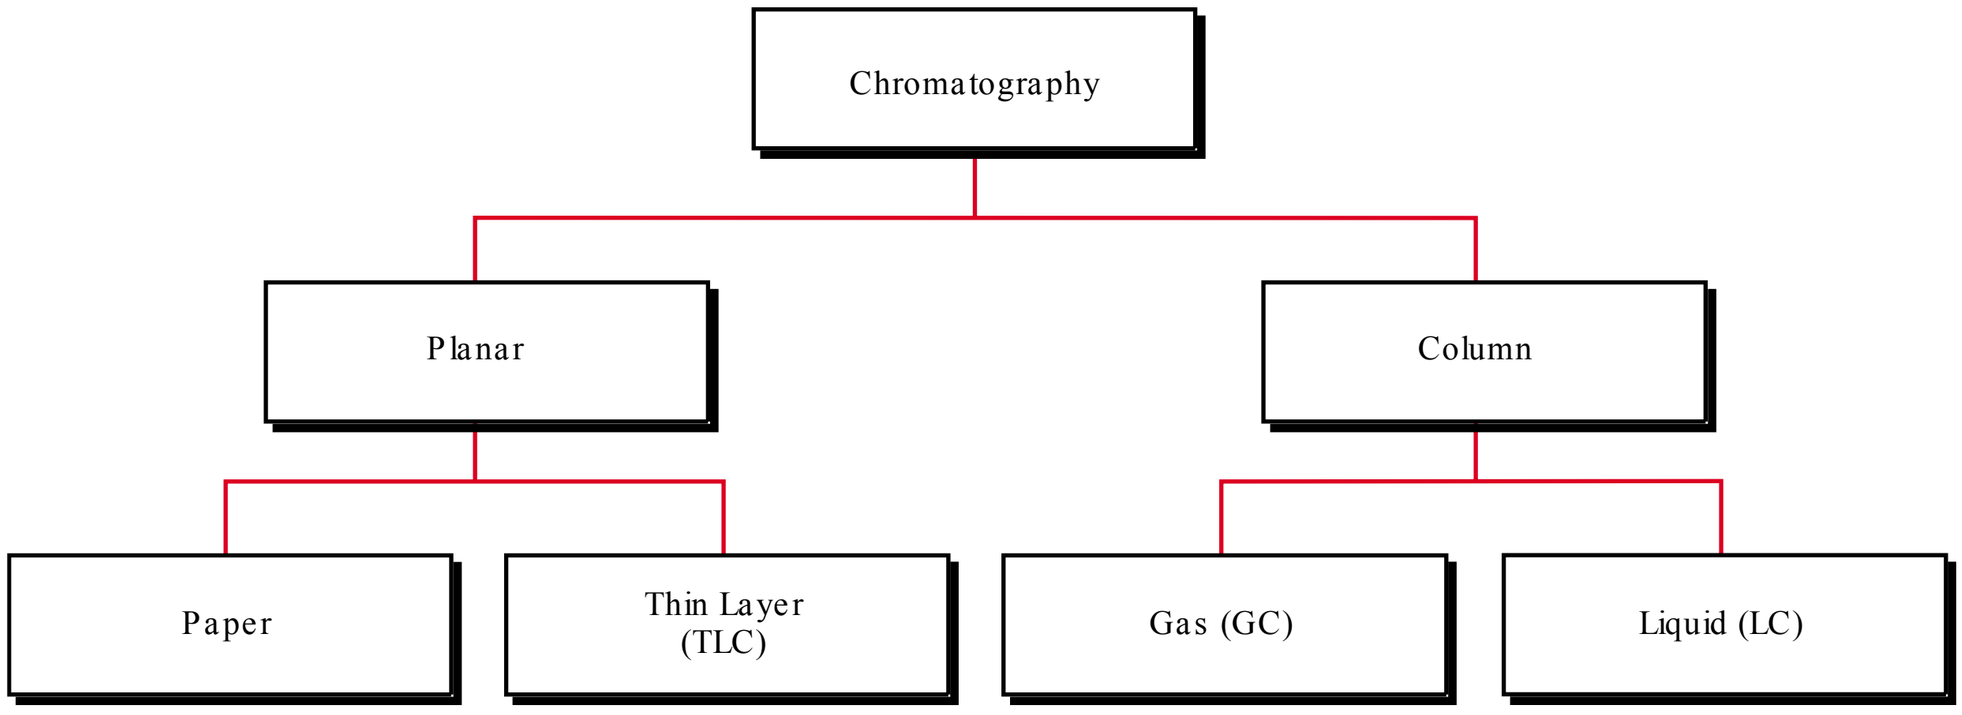

Figure 12-1 Forms of chromatography.

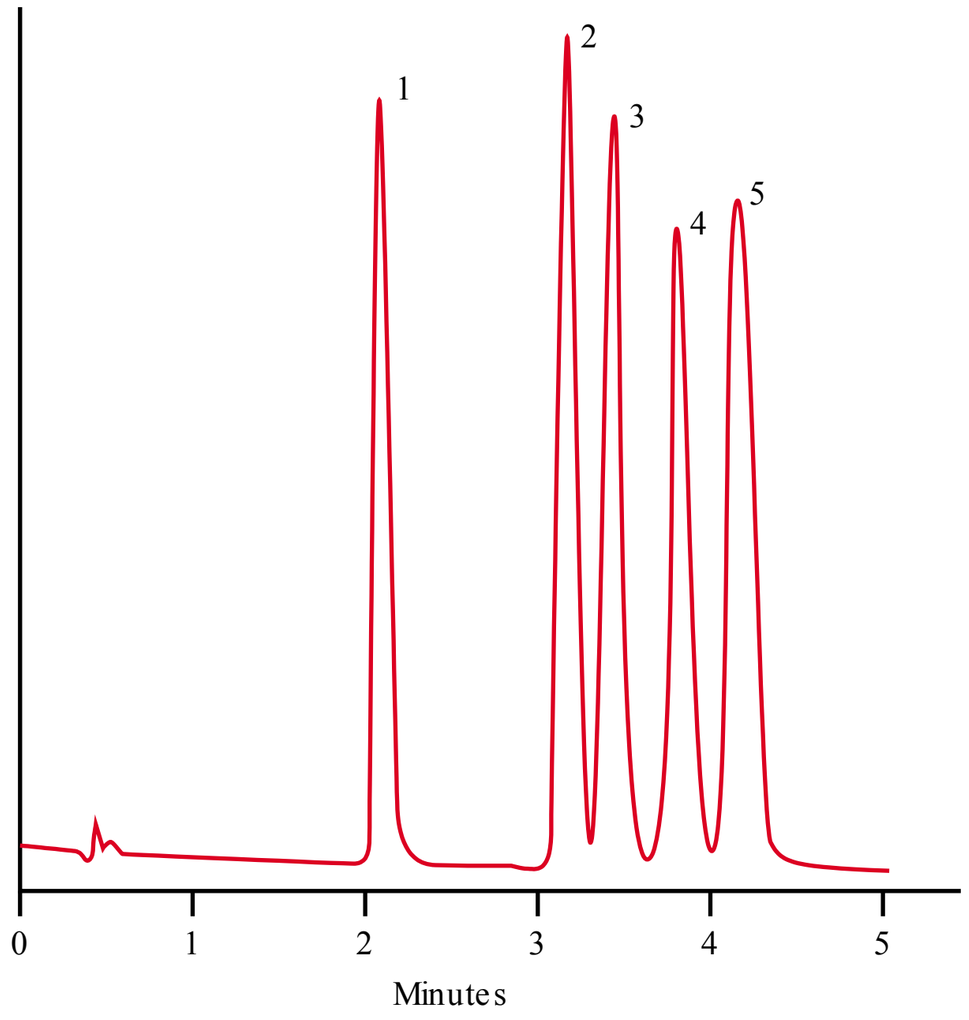
spectrometry (GCMS) and **liquid chromatography-mass spectrometry** (LCMS).

Detector Response

In analytical GC and LC, the **mobile phase**, or eluent, exits from the column and passes through a **detector** that produces an electronic signal that is plotted as a function of (1) time, (2) distance, or (3) volume. The resulting graphical display is a **chromatogram** (Figure 12-2). The **retention time** or volume is the time or volume when a solute exits the column and passes through the detector. The data represented by the chromatogram are used to help identify and quantify the solute(s). Because eluting solutes are displayed graphically as a series of peaks, they are frequently referred to as chromatographic peaks. These peaks are described in terms of peak (1) retention time or volume, (2) width, (3) height, and (4) area. In planar chromatography, the separated zones are detected by their natural colors or are visualized through chemical modification that produces colored "spots" or "bands" that are used qualitatively to identify various analytes or to quantify them.

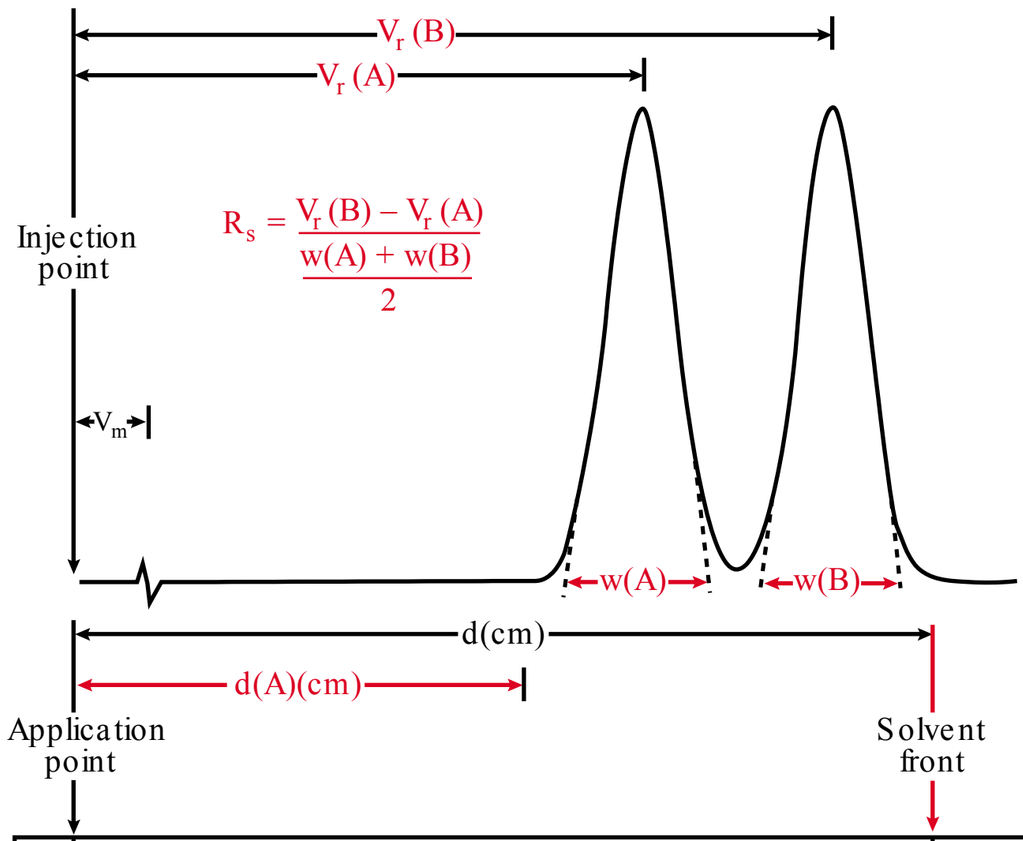


Resolution

Resolution (R_S) is a measure of chromatographic separation; it requires that two peaks have different elution times for the peak centers and sufficiently narrow bandwidth to eliminate or minimize overlap (Figure 12-3),[9] and it is expressed mathematically as follows:

$$R_S = \frac{V_r(B) - V_r(A)}{\left[\frac{w(A) + w(B)}{2}\right]} \quad (1)$$

where



Vr(A) = retention volume for solute A;
Vr(B) = retention volume for solute B;
w(A) = bandwidth (units of volume) measured at base for solute A; and
w(B) = bandwidths (units of volume) measured at base for solute B.

Column: C18, 3µ, 0.46 × 10 cm
Eluent: Isocratic, 0.025 M phosphate
Buffer: pH 3.0 in 25% acetonitrile
Flow rate: 2 mL/min
Detection: 215 nm, 0.1 AUFS

Compounds: 1. Doxepin
2. Desipramine
3. Imipramine
4. Nortriptyline
5. Amitriptyline

Figure 12-2 Chromatogram from an HPLC reversed-phase separation of tricyclic antidepressants with the use of a UV photometer detector set at 215 nm. Signal is displayed at 0.1 AUFS. AUFS, Absorbance units full scale; HPLC, high-performance liquid chromatography; UV, ultraviolet. (Courtesy Vydac/The Separations Group, Hesperia, Calif.)

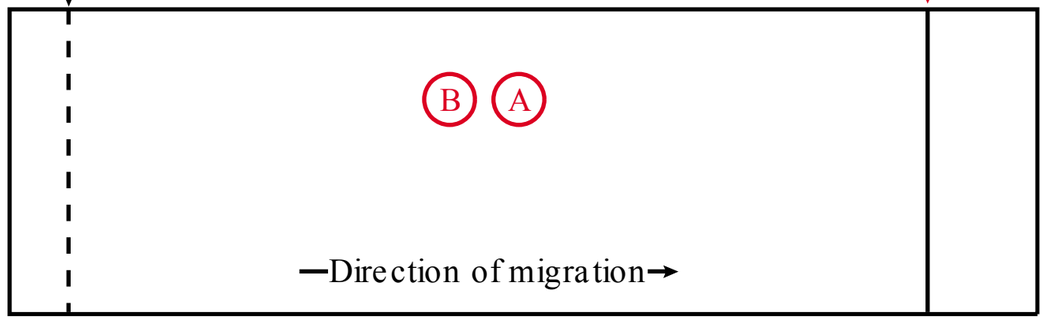


Figure 12-3 Schematic diagram of a chromatogram obtained from a column and open-bed chromatograph (planar). In open-bed chromatography (bottom), strongly retained compounds (B) move more slowly than less strongly retained compounds. In column chromatography (top), compound B is eluted later than compound A, again because of stronger retention. A, Solute A; B, solute B; d(A), distance traveled by solute A; R_S, resolution; V_m, volume between injector and detectors; V_r(A), retention volume for solute A; V_r(B), retention volume for solute B; w(A), bandwidth (units of volume) measured at base for solute A; w(B), bandwidth (units of volume) measured at base for solute B.

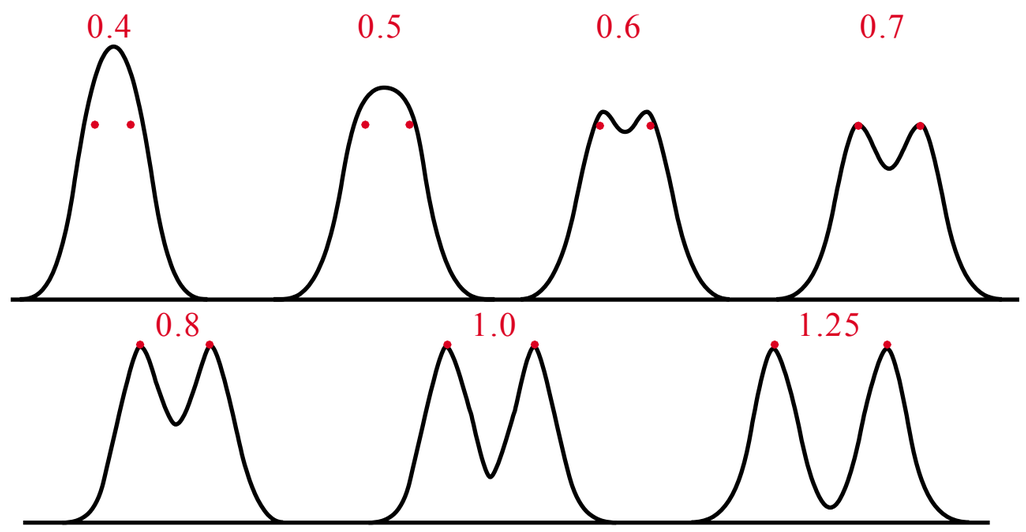

Figure 12-4 Separation of chromatographic peaks present in a 1:1 ratio as a function of resolution (R_S). (From Snyder LR. A rapid approach to selecting the best experimental conditions for high-speed liquid column chromatography. Part I. Estimating initial sample resolution required by a given problem, J Chrom Sci 1972;10:202.)

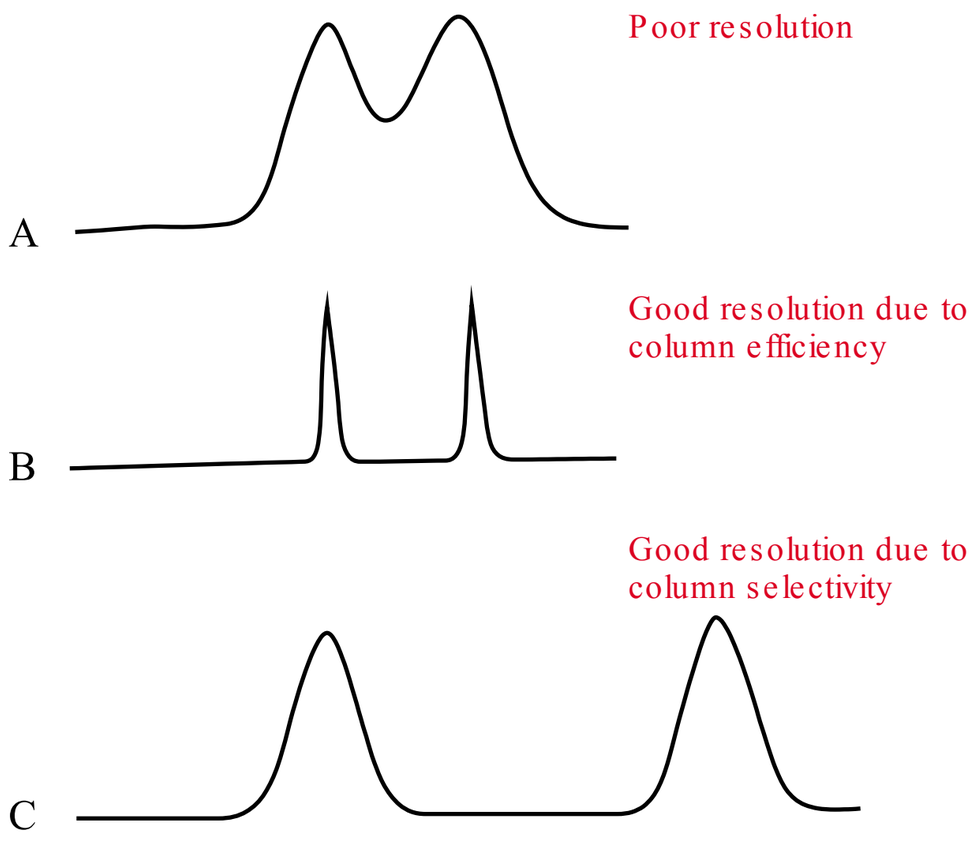

Figure 12-5 Effects of selectivity and effciency on chromatographic resolution. A, Poor resolution. B, Good resolution caused by column effciency. C, Good resolution caused by column selectivity. (From Johnson EL, Stevenson R. Basic liquid chromatography, Palo Alto, Calif: Varian Associates, 1978.)

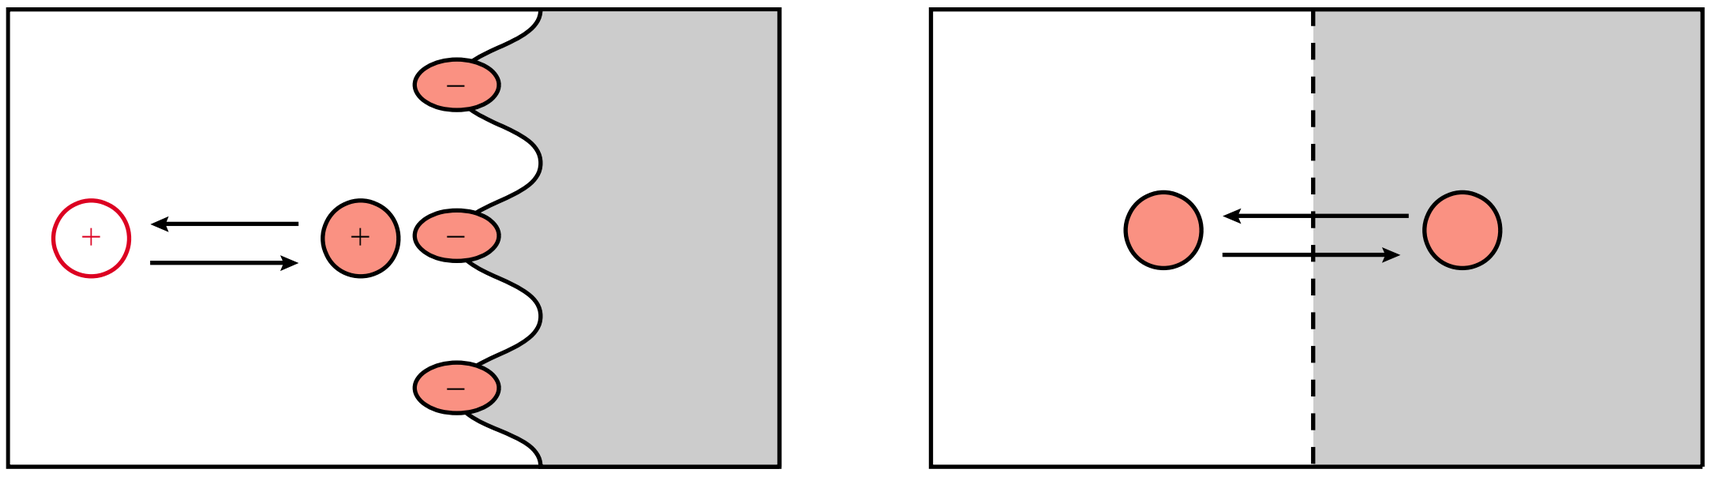
Resolution also is expressed in terms of time, with Vr(A) and Vr(B) being replaced with retention times tr(A) and tr(B), and w(A) and w(B) being expressed in units of time.



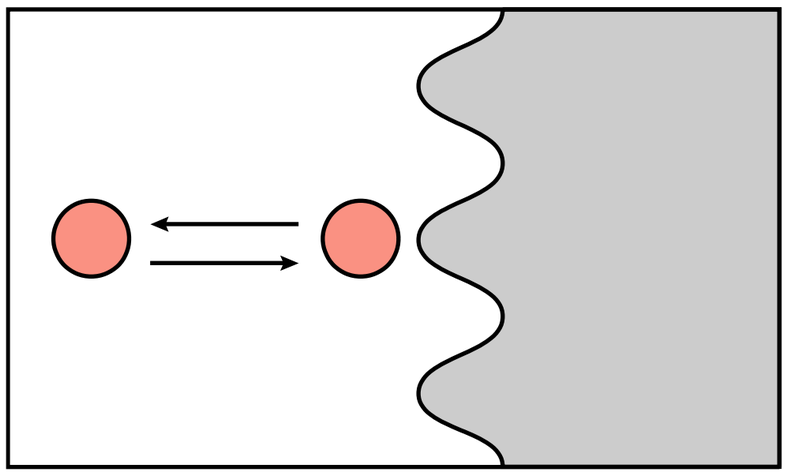
Incomplete separation occurs when the calculated value for R_S is less than 0.8, whereas baseline separation is obtained when R_S is greater than 1.25 (Figure 12-4). As demonstrated in Figure 12-5, when R_S is unacceptable for a given separation, it is improved through a change in (1) the column retention factor (k′), (2) column efficiency (N), or (3) column selectivity (a). T e retention factor describes the distribution of solutes between stationary and mobile phases. Column efficiency accounts for the ease of physical interaction between solute molecules and **column-packing** material. Selectivity characterizes the specific chemical affinity between solute molecules and column packing. T us by rearranging Equation 1 and expressing the parameters in terms of retention, efficiency, and selectivity, resolution also is expressed as:

$$R_S = \left(\frac{k'}{k'+1}\right) \times \frac{\sqrt{N}}{4} \times \left(\frac{\alpha - 1}{\alpha}\right) \qquad (2)$$

where

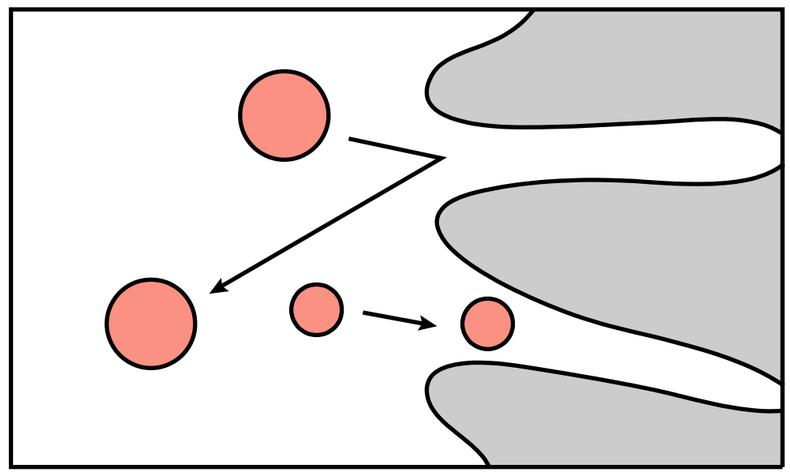
k′ = retention or capacity factor (a thermodynamic term);
N = number of theoretical plates (a kinetic term representing column efficiency); and
α = "alpha" the selectivity factor (a thermodynamic term).

Selectivity and efficiency are important chromatographic parameters that are varied to affect the degree of resolution of a given separation. For example, enhanced resolution is achieved by changing the selectivity of separation by altering factors such as (1) the composition of the mobile phase, (2) the stationary phase, or (3) temperature. Alternatively, improved resolution is achieved by enhancing column efficiency by (1) using smaller particles, (2) changing flow rate, (3) using a longer column, and (4) minimizing the so-called dead volume. T is latter term refers to the volume of tubing, connectors, and other spaces without a stationary phase packing. T e dead



Ion-exchange chromatography

Separation is based on exchange of ions between surface and eluents.



Partition chromatography

Separation is based on solute partitioning between two liquid phases.

Adsorption chromatography

Separation is due to a series of adsorption/desorption steps.

Size-exclusion chromatography

Separation is based on molecular size.

Figure 12-6 Examples of separation mechanisms used in chromatography. (Courtesy James K. Hardy, Akron, Ohio [http://ull.chemistry.uakron.edu/accessed August 6, 2013].)

volume serves as a mixing space where solute distributes into a larger volume, which degrades a separation.

Column efficiency is often described as the number of theoretical plates (N) per column length. An increase in N represents improved chromatographic efficiency and sharper peaks. Efficiency is often expressed as the number of theoretical plates per column length (N/L).*

The efficiency and the number of theoretical plates for a column are directly related to the column length, but usually a tradeoff of longer analysis times for longer columns occurs.

Separation Mechanisms

Chromatographic separations are classified by the process s used to separate the solutes. These include (1) ion-exchange, (2) partition, (3) adsorption, (4) size-exclusion, and (5) affinity mechanisms.

*Column efficiency also is expressed as the height equivalent of a theoretical plate (HETP) where HETP = L/N. In theory, a theoretical plate is equivalent to the length of a column necessary to allow one equilibration of the solute to occur between stationary and mobile phases. To increase the efficiency of a column, the number of theoretical plates is increased. In practice, this typically is accomplished by increasing the length of the column.

Ion-Exchange Chromatography

Ion-exchange chromatography is based on an exchange of ions between a charged stationary phase and ions of the opposite charge in the mobile phase (Figure 12-6). Cation-exchange particles contain negatively charged functional groups such as (1) carboxyl, (2) phosphate, or (3) sulfonate ions. These groups bind positively charged components (cations) in the mobile phase. Anion-exchange particles contain positively charged groups such as primary, tertiary, or quaternary amines that bind negatively charged components (anions) in the mobile phase. Ionic interactions are strong interactions, and displacement of ions bound to the stationary phase depends on competition by other ions in the mobile phase. The retention of components by the stationary phase is adjusted by changing the ionic strength or pH of the mobile phase. Retention is decreased by higher ionic strength (high salt concentration) or by adjustment of pH to decrease the charge of analytes or the stationary phase. Ion-exchange chromatography has several clinical applications, including the separation of (1) amino acids, (2) glycated hemoglobin, (3) hemoglobin variants, and (4) oligonucleotides.[3] Extraction with small ion-exchange columns is often used as a preparative rather than an analytical technique to isolate nucleic acids from blood or other specimens for molecular analysis. Another important application

of ion-exchange chromatography is the removal of inorganic ions from aqueous mixtures (see Chapter 8).

Partition Chromatography

The differential distribution of solutes between two immiscible liquids is the basis for separation by **partition chromatography** (see Figure 12-6). Operationally, one of the immiscible liquids serves as the stationary phase. To prepare this phase, a thin film of the liquid is adsorbed or is chemically bonded onto the surface of support particles or onto the inner wall of a capillary column. Separation is based on differences in the relative solubility of solute molecules between stationary and mobile phases. Reversed-phase chromatography is a highly versatile technique that is widely used for the analysis of analytes of clinical relevance.[9]

Partition chromatography is classified as gas-liquid chromatography (GLC) or as liquid-liquid chromatography (LLC). LLC is further categorized as normal phase or reversed phase. For normal-phase LLC, a polar liquid is used as the stationary phase and a relatively nonpolar solvent or solvent mixture is used as the mobile phase. In **reversed-phase chromatography,** the stationary phase is nonpolar, and the mobile phase is relatively polar.

Ion-suppression and ion-pair chromatography are two forms of reversed-phase chromatography that are used to separate ionic solutes. With ion-suppression chromatography, the ionic character of a weakly acidic or basic analyte is neutralized or "suppressed" through modification of the mobile phase pH. The suppressed analyte thus has the properties of a neutral species and is separated by reversed-phase chromatography. In ion-pair chromatography, a counter ion—opposite in charge to that of the analyte—is added to the mobile phase, where it forms ion pairs with ionic analytes, displaces the usual base pairs, and neutralizes the analyte ion(s). These ion pairs then are separated by reversed-phase chromatography.

Hydrophilic interaction chromatography (or hydrophilic interaction liquid **chromatography,** HILIC) is a version of partition chromatography wherein analytes elute in order of increasing polarity. This mode of separation is used extensively for separation of biological, organic, and inorganic molecules by differences in polarity. Its utility has increased because of the simplified sample preparation for biological samples.

Adsorption Chromatography

The basis of separation by **adsorption chromatography** is differential adsorption of solutes on the surface of the stationary phase (see Figure 12-6). Hydrogen bonding and hydrophobic interactions[6] are the forces that mediate separations. In this type of chromatography, retention depends on the surface area of the stationary phase and the affinity of the solutes for the stationary phase. In GC, this mode is used to separate low-molecular-weight compounds (e.g., methyl, ethyl, isopropyl alcohols) and compounds that are normally gases at room temperature.

Size-Exclusion Chromatography

Size-exclusion chromatography, also known as (1) gel-filtration, (2) gel-permeation, (3) steric-exclusion, (4) molecular-exclusion, or (5) molecular-sieve chromatography, separates solutes on the basis of their molecular size in solution (see Figure 12-6). This technique is commonly used in a preparative mode to separate large molecules such as proteins and nucleic acids from small molecules such as salts or oligonucleotides. The latter application may be performed in small spin columns where elution is driven by spinning in a centrifuge.

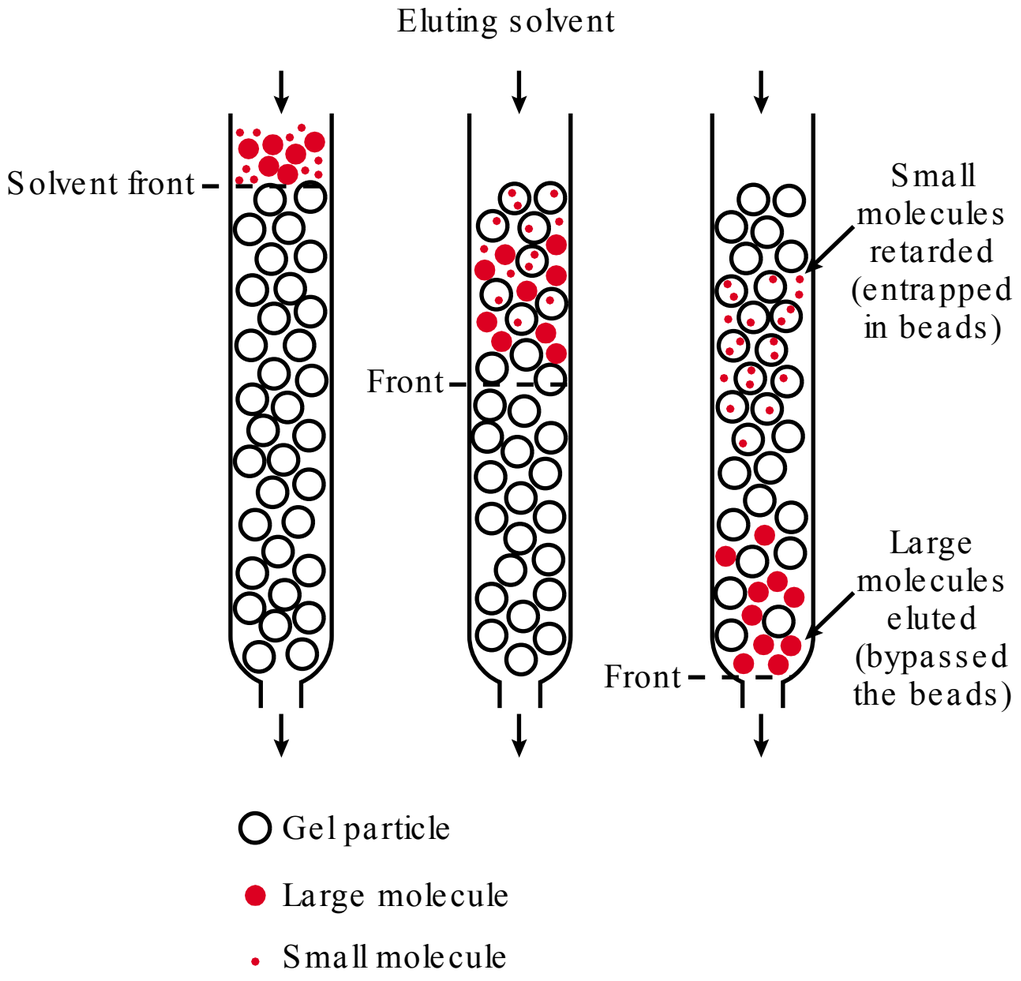


Figure 12-7 Schematic representation of gel-filtration column chromatography. (Modified from Bennett TP. Graphic biochemistry, vol 1. Chemistry of biological molecules. New York: Macmillan, 1968.)

A variety of materials are used as stationary phases for size-exclusion chromatography, including (1) cross-linked dextran, (2) polyacrylamide, (3) agarose, (4) polystyrene-divinylbenzene, and (5) porous glass. Beads of these materials have pores that allow small molecules to enter and to be retained to a greater extent than large molecules that are excluded from pores (Figure 12-7). Large molecules elute before small molecules. The goal is to select a stationary phase with minimal adsorption of analytes that acts purely by steric exclusion. All solutes should be eluted by a mobile phase volume equal to the column volume. Salt may be added to the mobile phase to suppress ionic interactions with the stationary phase. Stationary phases are available in a variety of pore sizes, and the appropriate pore size must be selected for the molecules of interest. Separations by this technique have low resolution unless there is a large difference in molecular weights—usually twofold or more.

Affinity Chromatography

In **affinity chromatography**,[18] one component of highly specific molecular interaction pairs, such as (1) enzyme-inhibitor, (2) hormone-receptor, (3) antigen-antibody, or (4) aptamer-ligand, is immobilized in a stationary phase and is used to capture molecules from the mobile phase.[8,11] The affinity interactions usually are quite strong, allowing the stationary

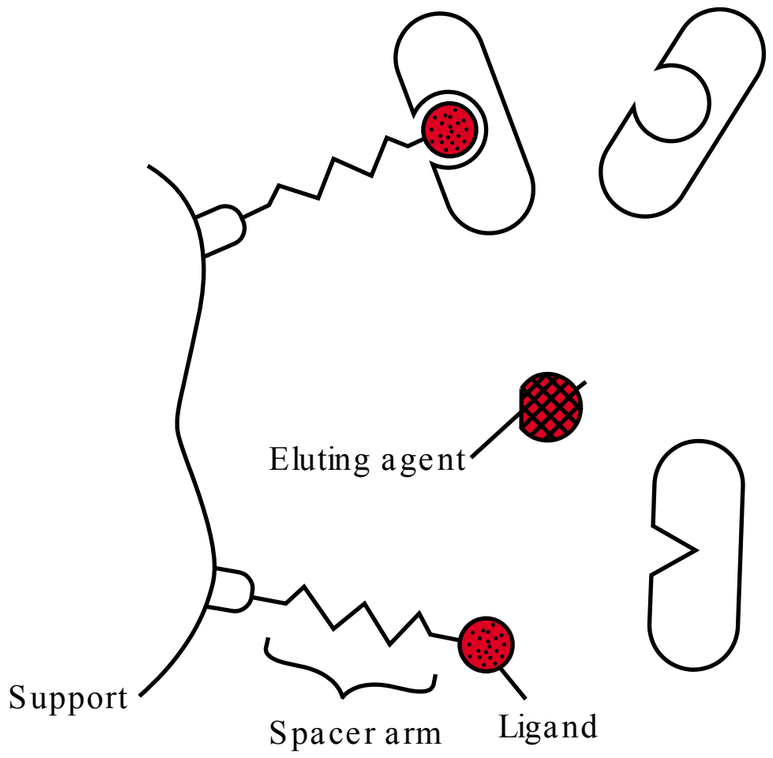

Figure 12-8 Principle of affnity chromatography. The analyte (enzyme, antibody, antigen, tissue receptor, etc.) binds to the support-bound ligand. Subsequently, it is eluted with a general eluent (such as a chaotropic agent), pH change, or a biospecifc eluent (such as an inhibitor or a substrate).

phase to be washed extensively by the mobile phase to remove all nonbound components, while bound components are retained. Some affinity separations, such as antibody-antigen interactions, offer great specificity. Immunoaffinity chromatography, often in a lateral flow format, is applied in (1) pregnancy tests, (2) rapid microbial antigen tests, and (3) a wide range of other clinical tests. Column chromatographic applications of affinity chromatography often entail a stepwise elution with a change in the composition of the mobile phase, as described in the caption of Figure 12-8. Elution is achieved by adding an excess of competing ligand or by changing the mobile phase to conditions where affinity is lost, for example, by extreme changes in pH or by addition of high concentrations of chaotropic agents, such as urea or guanidine.

Chiral chromatography is a variant of affinity chromatography in which the stationary phase contains a single enantiomer of a chiral compound.[1,17,31] In this type of chromatography, two enantiomers of a compound in the mobile phase bind with different affinity to the chiral stationary phase and therefore exit the column at different times.

Planar Chromatography

In planar chromatography, the stationary phase is coated on a sheet of paper (paper chromatography) or is bound to a solid surface (thin-layer chromatography). In TLC the stationary phase, a thin layer of particles of a material such as silica gel is spread uniformly on a glass plate or a plastic or aluminum sheet.[21] When the thin layer consists of particles of small diameter (4.5 μm), the technique is known as high-performance thin-layer chromatography (HPTLC).[19]

In paper chromatography, the stationary phase consists of a layer of water or a polar solvent coated onto the fibers of a sheet of paper. Separation is normal-phase partition chromatography between the nonpolar mobile phase and the polar stationary phase.

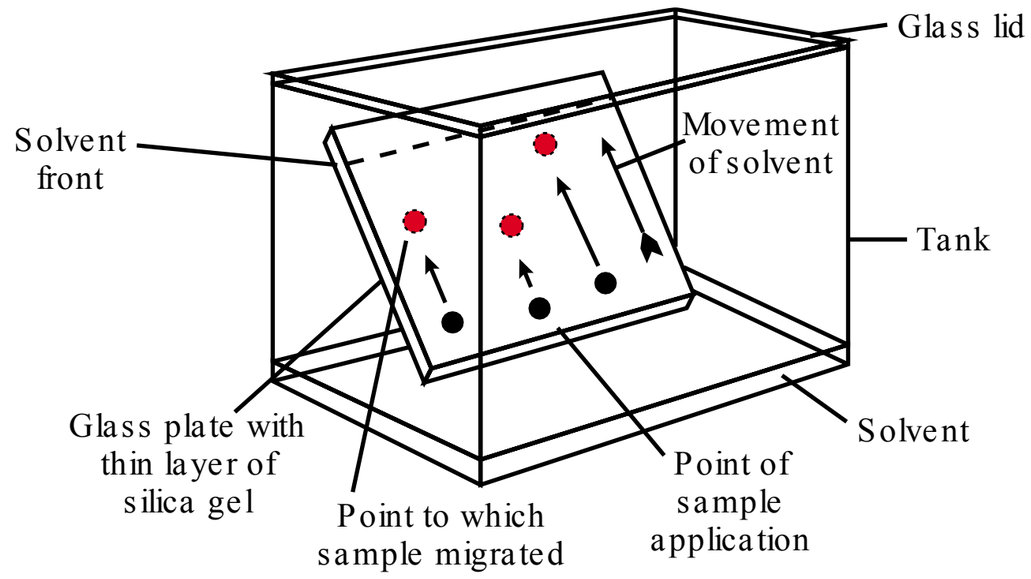

Figure 12-9 Illustration of planar chromatography (also known as thin-layer chromatography [TLC]). The solvent moves up the thin layer of adsorbent by capillary action. (Modifed *f*rom Bennett TP. Graphic biochemistry, vol 1. Chemistry o*f* biological molecules, New York: Macmillan, 1968.)

In TLC, the sample is applied as a small spot or band near the bottom edge of the plate. T en, the plate is placed in a closed tank containing the mobile phase, which migrates up the plate by capillary action (Figure 12-9). After the mobile phase travels a desired distance, the plate is removed from the tank and is dried. Solutes are visualized directly if they are colored or fluorescent by eliciting a chemical reaction to yield a visible product, or by performing autoradiography for radioactive compounds.

A solute's migration in TLC or PC is expressed as an R_f value, the ratio of solute migration to solvent front migration:

$$R_f = \frac{\text{distance from application point to solute center}}{\text{distance from application point to mobile phase front}} \quad (3)$$

Many stationary phases are available for TLC, including (1) silica, (2) cellulose, (3) alumina, and (4) alkyl-bonded silica particles for reversed-phase chromatography. TLC and PC have been used for clinical applications such as (1) identification of drugs in urine, (2) analysis of amino acids or glycosaminoglycans in urine, and (3) analysis of lipids in amniotic fluids. Use of TLC and PC in the clinical laboratory has been declining because of the introduction of more automated, reproducible, and quantitative column chromatographic methods. Manual methods for TLC tend to be less quantitative and more labor intensive and technique dependent, although TLC does offer the advantages of simplicity and low cost for equipment.

A popular type of planar chromatography used in the clinical laboratory is lateral flow affinity chromatography, which uses a membrane such as nitrocellulose as the stationary phase with one or more zones of immobilized antibody or antigen. Using a pregnancy test as an example, a urine or serum specimen is applied to one end of the membrane and serves as the mobile phase. Human chorionic gonadotropin (hCG) in the mobile phase is captured by specific antibodies immobilized in small zones on the membrane. Detection of bound hCG is achieved by binding of colored particles coupled to antibody versus hCG. If hCG is present, the antibody-conjugated

TABLE 12-1 Forms of Chromatography

Types of Chromatography	Subtypes	Stationary Phase	Mobile Phase
Gas chromatography (GC)	Gas-solid chromatography (GSC)	Solid particles or capillary wall	Gas
Performed as column chromatography	Gas-liquid chromatography (GLC)	Liquid immobilized on particles or capillary wall	Gas
Liquid chromatography (LC)	Partition chromatography	Liquid immobilized on a surface	Immiscible liquid
Is performed as planar chromatography or as column chromatography with packed or capillary columns. High-performance liquid chromatography (HPLC) uses columns at high pressures	Gel filtration	Porous solid with defined pore size	Liquid
	Ion-exchange	Solid containing charged groups on its surface	Liquid with salts
	Adsorption	Solid with a surface that adsorbs analytes	Liquid
	Affinity	Solid with immobilized capture molecules with high specificity	Liquid suitable for affinity interaction

particles forms a visible zone. If no hCG is present, the particles do not concentrate in the detection zone. T is sandwich-type format can be used to detect antigens such as proteins that are large enough to have sites for binding of two different antibodies. Detection of specific antibodies is achieved with analogous sandwich-type assays using capture and detection antigens. Small molecules, such as drugs of abuse, are too small to accommodate binding of two antibodies for a sandwich-type assay. T erefore, small antigens are detected by competitive inhibition of binding of labeled antibody to an antigen immobilized in the stationary phase.

A new type of chromatography is known as **overpressured layer chromatography (OPLC),** which is a separation technique that combines the advantages of conventional TLC/HPTLC with those of **HPLC**.[27] It employs a pressurized ultramicro (UM) chamber as a closed adsorbent layer chamber. T is enables the use of a special chromatoplate and a pump to increase and optimize the mobile phase flow velocity through an optimal development distance in an adsorbent layer. T is new system exploits the unique advantages of a planar-layer system for detection, isolation, and identification of new (1) antimicrobials, (2) antineoplastics, (3) biopesticides, and (4) other biologically active substances, as well as for the study of fundamental biochemical reactions and mechanisms.

Column Chromatography

In column chromatography, the stationary phase is coated onto or is chemically bonded to support particles that are then "packed" into a tube, or the stationary phase is coated onto the inner surface of a tube. GC and LC are two categories of column chromatography (Table 12-1). A third category, supercritical fluid chromatography,[7] which uses pressurized carbon dioxide as solvent is used only rarely for clinical applications and will not be discussed here.

Multiple factors determine which type of chromatography is best suited for a specific application. GC usually provides higher resolution as much longer columns and higher linear flow rates are used because of the lower viscosity of a gas versus a liquid. GC usually is the method of choice for volatile components. T e main factor limiting the application of GC, however, is the volatility of analytes. Because of their lack of

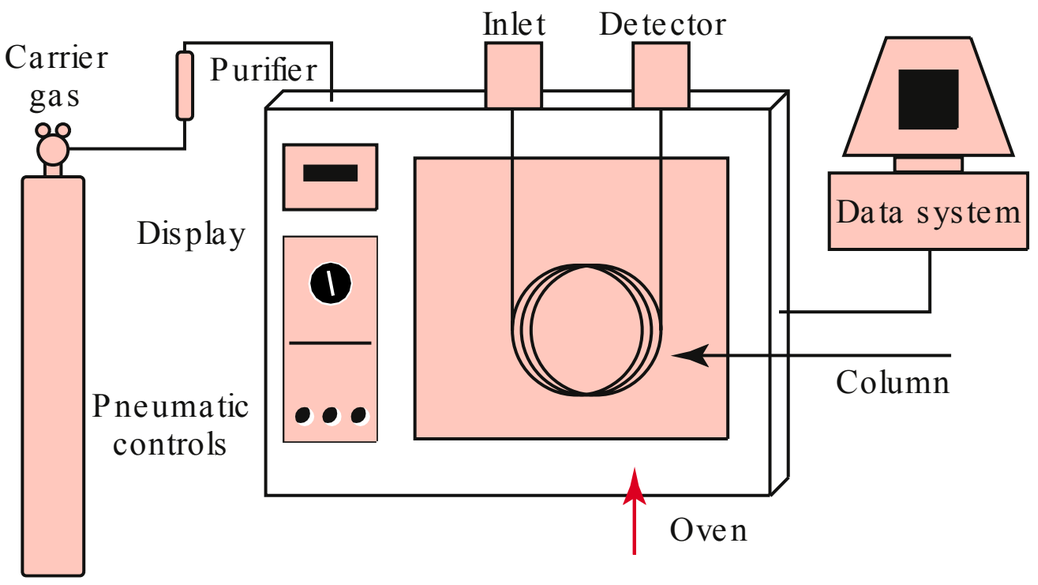

Figure 12-10 Schematic diagram of a gas chromatograph.

volatility, large molecules such as (1) peptides, (2) proteins, (3) nucleic acids, and (4) large polymers usually are analyzed by LC. Lower-molecular-weight analytes are analyzed by GC after chemical derivatization to increase their volatility.

Gas Chromatography

In GC, a gas mobile phase, or carrier gas, is used to carry a mixture of volatile solutes through a column containing the stationary phase, which usually is a nonvolatile liquid coated or bonded to particles or the inner surface of a capillary.[4,14] Less frequently, gas-solid chromatography is performed using a solid stationary phase, which directly adsorbs analytes to its surface. T e mobile phase, or carrier gas, is typically an inert gas, such as (1) nitrogen, (2) helium, or (3) argon. Separation of analytes is based on differential partitioning into the stationary phase. In general, more volatile components have a higher vapor pressure and spend more resident time in the gas phase. T e carrier gas carries analytes to a detector in the order of their elution. Analytes are identified qualitatively by their retention times or by mass spectra (see Chapter 13). T e magnitude of detector responses is used to quantify analytes.

Instrumentation

A basic gas chromatograph (Figure 12-10) consists of the following:

1. A supply of carrier gas and flow controller.
2. An injector or injection port to introduce samples into the system.

3. A chromatographic column to separate the analytes.
4. A column oven to heat the column.
5. A detector that responds to solute/analyte concentration.
6. A computer to control the system and to process data.

Carrier Gas Supply and Flow Control

A constant flow of carrier gas is required for column efficiency and reproducibility. Use of temperature gradients requires sophisticated control of the carrier gas flow rate and pressure during a chromatographic run. The pressure required to maintain a constant flow varies as carrier gas viscosity changes with temperature. The flow rate of carrier gas depends on column diameter. Packed columns require a flow rate from 10 to 60 mL/min, but smaller-diameter capillary columns use flow rates of 1 to 2 mL/min.

The carrier gas used depends on the type of column and detector. Hydrogen and helium are the carrier gases of choice with capillary columns. Only high-purity hydrogen and helium are used as carrier gas impurities (1) harm the column, (2) decrease the performance of some detectors, and (3) adversely affect quantification. For packed columns, the most frequently used carrier gas is nitrogen, which is used with (1) flame ionization (FID), (2) electron capture (ECD), or (3) thermal conductivity (TCD) detectors. Helium also is used with FIDs and TCDs, and nitrogen-argon-methane mixtures are used with ECD. Carrier gases should be pure and dry. Molecular sieve beds and specialized inline traps are used to remove water, hydrocarbon, or oxygen from the carrier gas.

Injector

Samples are injected by a manual syringe or an automated injector. To introduce an aliquot of sample into the column, an injection needle passes through a septum into an injection port in the flow path of the carrier gas. Some volatile components such as alcohols are injected as a gas phase by headspace sampling of closed specimen vials. For most methods, however, specimens are dissolved in a volatile solvent. With packed columns, specimen volumes of about 1 to 10 μL are injected. The volatile solvent and analytes are "flash-vaporized" by maintaining the injection port at a higher temperature than the column, and the vaporized specimen is swept into the column by the carrier gas. Capillary columns have low sample capacities that often require split injections, in which only a small portion of the vaporized sample enters the column, versus the splitless mode, in which all of the sample enters the column.

Injectors are a potential source of problems with GC such as septum leaks and adsorption of components from the sample onto the septum during injection. Decomposition products will form on the heated septum, yielding spurious "ghost" peaks in chromatograms. To minimize this problem, the septum usually is coated with Teflon, and the inner surface of the septum is purged continuously with the carrier gas that is vented before it passes into the column. Most commercial injectors are equipped with continuous-purge capabilities. The septum needs periodic replacement.

Temperature-programmable injectors are available that allow injection of larger volumes of specimen, up to 100 microliters or more. The sample is injected at a temperature slightly higher than the boiling point of the solvent. Most of the sample components condense on glass wool or on fused silica wool packed into the injector inlet, while the solvent is removed. Then, the injector is rapidly heated to vaporize analytes, which flow into the column. Injection of a larger volume of specimen improves the limit of detection for some analyses.

Chromatographic Column

Packed and capillary are two types of columns used in GC. Packed columns are filled with uncoated support particles (gas solid chromatography/GSC) or, more often, with particles coated or chemically bonded with a nonvolatile stationary phase (gas liquid chromatography/GLC). These particles range (1) from 1 to 4 mm in internal diameter (ID), (2) from 1 mm or more in length, and (3) are fabricated from glass or stainless steel. Longer columns are more efficient but require increased carrier gas pressures and analysis time. Although narrow columns are more efficient, wider columns have increased sample capacities. Fast GC is a type of GC in which high-speed separations are achieved using short lengths of conventional columns.

Capillary columns, also known as wall-coated open tubular columns, are fabricated by coating the inner wall of a fused-silica tube with a thin film of liquid phase. These columns range from 0.1 to 0.5 mm in ID and from 10 to 150 mm in length. The ultrapure fused silica capillary tubing used in such columns is very fragile. To physically strengthen the tubing, a thin outside coating of polyimide or aluminum is added; this improves column durability. Capillary columns are very efficient but have low sample capacities.

In addition to packed and capillary columns, progress has been made in the development of micro-GC columns on silicon chips.

Temperature Control

GC requires careful control of (1) column, (2) injector, and (3) detector temperatures. Column temperature is controlled by placing the column in an oven or directly by providing resistive heating. Injector and detector temperatures usually are controlled by resistive heaters. Depending on the application, the column temperature is maintained constant (isothermal operation) during the chromatographic run or is varied as a function of time (temperature-programmed or temperature-gradient operation, which is used for most clinical applications). With temperature programming, more volatile analytes elute first, followed by those with higher boiling points. Consequently a complex mixture of analytes with a wide range of volatility is separated into sharper chromatographic peaks and more rapidly than with isothermal operation. The upper temperature limit of operation depends on the stability of the analytes and of the column coating.

Detectors

A variety of detectors are used for GC; the most commonly used types are listed in Table 12-2. These include universal units that detect most analytes and selective devices that detect

TABLE 12-2 Examples of Detectors Used for Gas Chromatography

Type of Detector	Principle of Operation	Selectivity	Limit of Detection	Comments
Thermal conductance (TCD)	Measures thermal conductivity change in carrier gas on elution of compounds	Universal	<400 pg propane/mL He	Lower detection sensitivity
Flame ionization (FID)	CHNO + heat → $CHNO^+ + e^-$; electrons collected for detection	Hydrocarbon	10 to 100 pg CHO	Commonly used in clinical labs
Thermionic selective (TSD; NPD)	Alkaline bead selectively ionizes N- or P-containing compounds	N, P	0.4 to 10 pg N, 0.1 to 1.0 pg P	Offers higher sensitivity than FID
Electron capture (ECD)	$e^- + R + N_2 \rightarrow Re^- + N_2$; analytes capture excess electrons	Electronegative atoms such as Cl, F, Br, and I	0.05 to 1.0 pg Cl^--containing compounds	Analytes may be derivatized to add Fl or Cl
Mass spectrometer (MS)	Ionization of analytes by electrons; ions are separated according to mass/charge ratio	Highly selective, analyte must be ionizable	1 ng scanning 10 pg for selected ion monitoring (SIM)	Provides qualitative and quantitative information
Photoionization (PID)	CHNO + photon → $CHNO^+ + e^-$; detect electron	Hydrocarbon	1 to 10 pg CHO	May be seen as improvement on FID

CHNO, Carbon, hydrogen, nitrogen, and oxygen-containing compounds; CHO, carbon, hydrogen, and oxygen-containing compound; NPD, nitrogen-phosphorus detector.

only analytes with specific properties. Sometimes, two or more detectors are placed in a series to enhance analytical specificity and sensitivity. Mass spectrometers also are used as detectors for GC and are very useful for identifying analytes and increasing the specificity of analysis (see Chapter 13).

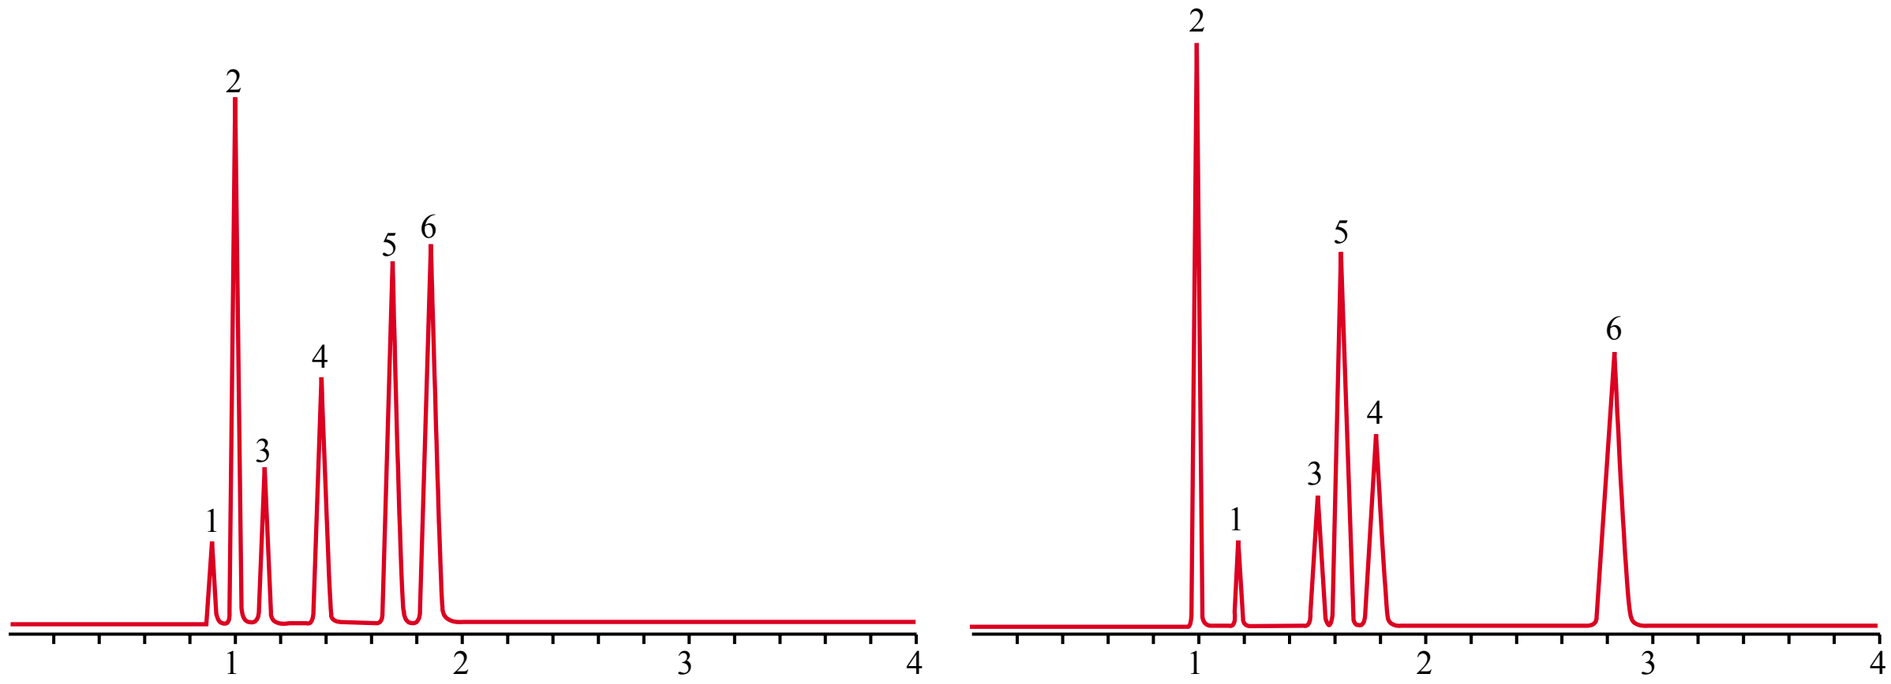
Note: When two columns or detectors are placed in series, the technique is known as two-dimensional gas chromatography.[16,26] With these systems, solutes that are insufficiently separated in the first column are introduced ("heart-cut") to a second, different column.[26] T is enables analysis with a level of separation that is not attained in conventional single-column analysis.

Flame Ionization Detector. T e FID is the most commonly used detector for clinical analysis. Its advantages include (1) simplicity, (2) reliability, (3) versatility, (4) sensitivity, and (5) ease of operation. During operation, the column ef uent is mixed with hydrogen and air, and the eluting compounds are burned by a flame. About one molecule in 10,000 releases an electron, which is detected by a collector electrode positioned above the flame. T e magnitude of the generated signal relates to the mass of carbon material delivered to the detector.

T ermionic Selective Detector. T e TSD, also known as the nitrogen-phosphorus detector (NPD), is a modification of the FID, in which an alkaline bead is heated electrically in the area above the flame. T e presence of alkaline atoms in the flame increases the signal of nitrogen-containing compounds by a factor of 15 and that of phosphorus-containing compounds by a factor of 300.

Photoionization Detector. With a PID, the energy for ionization is provided by an intense UV lamp rather than by a flame. T e PID has a lower limit of detection than the FID because it produces a more stable signal with less baseline "noise."

T ermal Conductivity Detector. T e TCD is based on the principle that addition of a compound to a gas alters its thermal conductance. TCD detects all compounds with little selectivity but is less sensitive than most other types of detectors.



Electron Capture Detector. An ECD is used for detecting electron-absorbing components such as halogenated elements —fluorine, chlorine, bromine, and iodine. It uses a radioactive beta particle (electron) emitter in conjunction with a so-called "makeup gas" flowing through the detector chamber. An ECD is often used as a detector for capillary GC. Because not all compounds contain halogenated functional groups, derivatization with reagents containing polychlorinated or polyfluorinated moieties is a common practice used with an ECD.

Computer/Controller

An automated GC is computer controlled, with the computer functioning both as a process controller and as a data processor. For example, as a process controller, the computer regulates various parameters such as (1) carrier gas composition and flow rate; (2) column backpressure; (3) column and detector temperatures; (4) sample injection, detector selection, and operation; and (5) the various timing steps that command the operation of the system. For data processing, the computer monitors signals generated by the system's detectors and commands the acquisition and storage of data at specified time intervals. T e area, or height, of each chromatographic peak is determined from the stored data, and this information is used to compute the analyte concentration represented by each peak. Available algorithms for this computation include those based on calibration curves or conversion factors from internal or external calibration (described later). If desired, a complete report is prepared and printed for each chromatographic run. Alternatively, data are stored to be recalled and reprocessed, using different integration parameters.

Practical Considerations

Two examples of separation of volatile components by GC are shown in Figure 12-11. T e figure provides examples of separation parameters that may be varied in GC. T e examples use packed columns 30 m in length with 4 minutes required to complete an analysis. HPLC columns by comparison are usually about 100 times shorter—about 30 cm in length.

Methods for sample preparation affect the practical application of GC to separate and quantify biological compounds. For example, nonvolatile compounds, such as proteins and inorganic salts, build up in a GC if injected. Extraction with an organic solvent such as dichloromethane or ethyl acetate is one means of recovering many analytes free of proteins and inorganic salts. Solid-phase extraction with small chromatographic columns is an alternative preparative step before specimen injection. T e volatility of compounds often is a limiting factor in the application of GC. Many compounds, such as amino acids and sugars, are not sufficiently volatile to be analyzed by GC. Chemical modification or **derivatization** of such compounds, however, increases their volatility for GC analysis. Chemical reactions used to increase volatility include (1) acylation, (2) silylation, (3) esterification, and (4) oximation. In addition to increasing solute volatility, derivatization enhances the specificity and sensitivity of particular assays. For example, the use of a chiral reagent to derivatize amphetamine allows separation of the d- and l-isomers with a standard GC column. In practice, enhanced detection sensitivity is achieved by preparing pentafluoropropyl derivatives for use with ECD.

Liquid Chromatography

Separation by LC is based on the differential distribution of the solutes between a liquid mobile phase and a stationary phase. As discussed earlier, when particles of small diameter are used as the stationary-phase support, the technique is referred to as high-performance liquid chromatography (HPLC).[25] Because relatively high pressures are required to pump liquids through HPLC columns, the technique also has been referred to as high-pressure liquid chromatography. In the clinical laboratory, HPLC is the most widely used form of LC.

Instrumentation

A basic liquid chromatograph (Figure 12-12) consists of the following elements[13]:

1. A solvent reservoir to hold the mobile phase.
2. One or more pumps to force the liquid mobile phase through the system.
3. An injector to introduce an aliquot of sample into the column.
4. A chromatographic column to separate the solutes.
5. A column oven to maintain constant column temperature.
6. Online detector(s) to detect analytes as they elute from the column.
7. A computer to control the system and to process data.

Solvent Reservoir

In their simplest forms, the reservoirs are glass bottles or flasks into which "feed lines" to the pump are inserted. To remove particles from solvents, inline filters are placed on the inlets of the feed lines. Prepared buffers or solutions should be filtered before they are added to solvent reservoirs. Dissolved gases are removed by vacuum degassing or purging with helium in the solvent reservoir or by use of an inline vacuum degasser that has a gas-permeable membrane. Failure to remove dissolved gases may result in the formation of bubbles in detectors, resulting in unstable baseline signals. T e components of the mobile phase are selected on the basis of the mode of chromatographic separation and the type of detector used. Methanol and acetonitrile are liquids commonly used in mobile

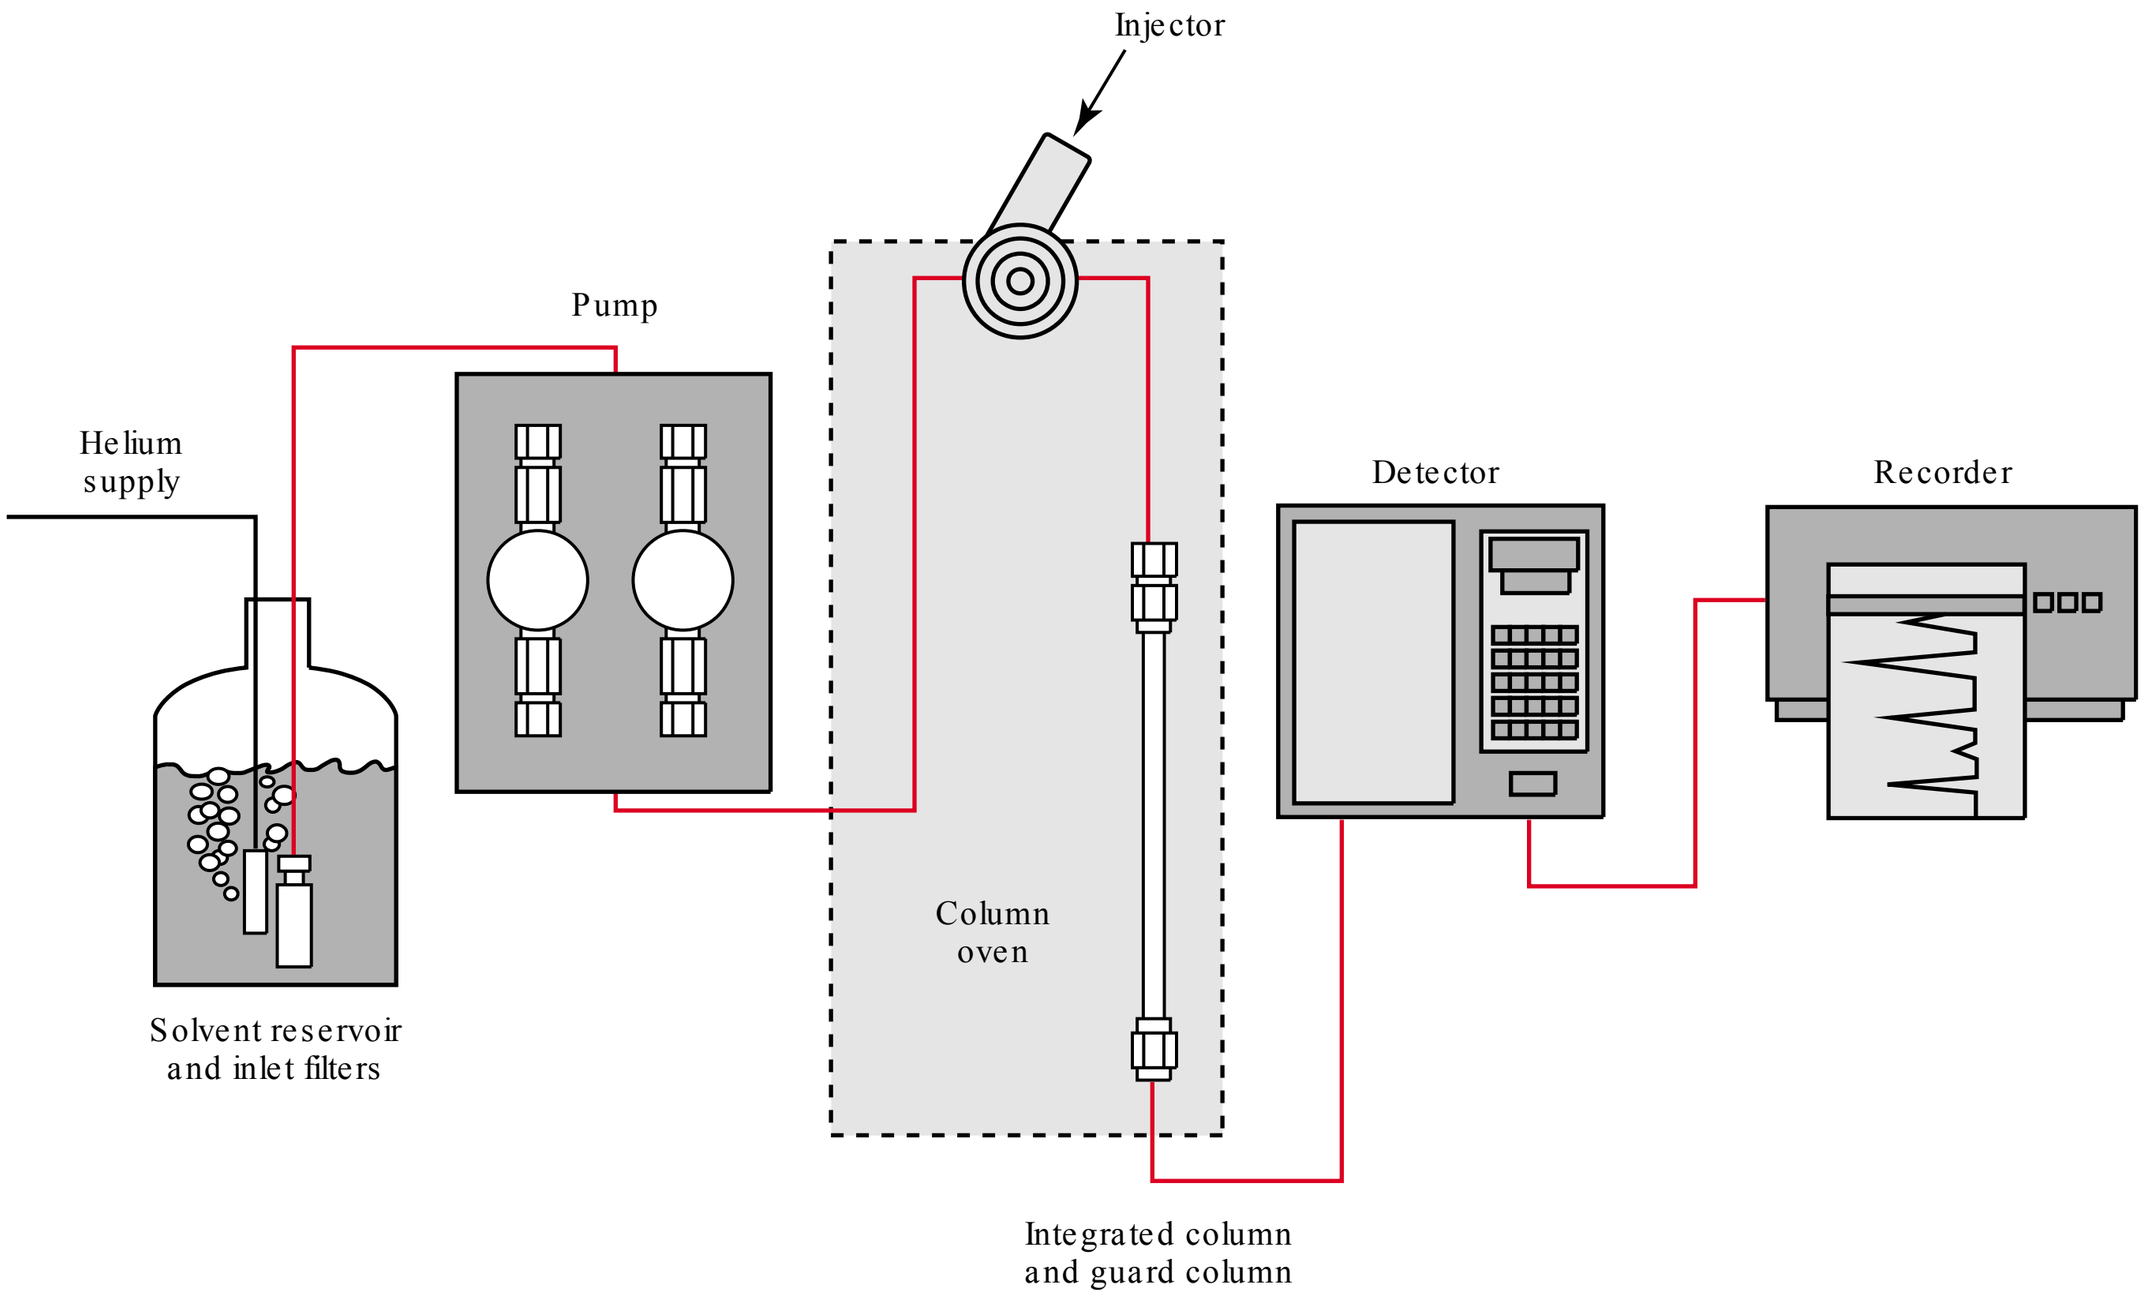

Figure 12-12 Schematic diagram of a liquid chromatograph.

phases for reversed-phase separations because of their low viscosity and low optical absorbance in the ultraviolet spectrum. High-purity solvents are required.

Pump

Pumps for HPLC must deliver a constant flow of solvent at pressures up to 6000 pounds per square inch (psi). Some applications have required higher pressures up to 15,000 psi, which have been referred to as ultrahigh-performance liquid chromatography (UHPLC or UPLC^{R}).[29,32] Operation at higher pressures requires use of (1) pumps, (2) columns, and (3) other components specifically designed for higher pressures.

In practice, pumps used with HPLC must deliver a constant flow with low pulsation. Column life and the baseline stability of detectors are often adversely affected by pulsatile flow. Pressure sensors detect excessive increases in pressure that would cause pump failure and shut down the pump before damage to the pump occurs. Dual-piston reciprocating pumps are commonly used. In operation, an asymmetrical cam drives two pistons into and out of pumping chambers. T e reciprocating action of the pump creates pulsatile flow that is smoothed by mechanical or electronic pulse dampers. For isocratic separations that use a solvent of constant composition (Figure 12-13), a single pump is needed. Gradient elution (see Figure 12-13) requires either mixing two or more solvents at low pressure using a proportioning valve before the pump inlet, or changing the flow rate of two pumps that are delivering differing solvents to a mixing chamber. In the latter case, solvent composition is controlled by changing the flow rate of the

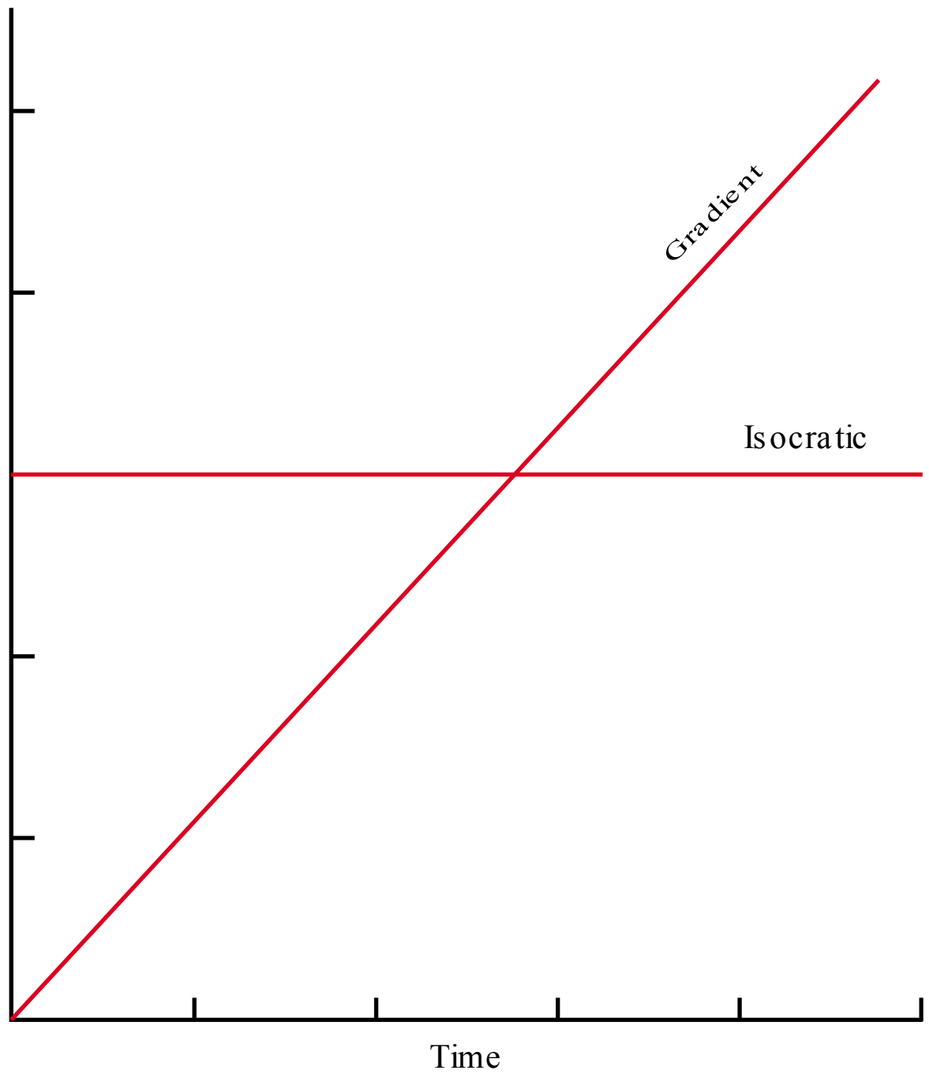

Figure 12-13 Examples of isocratic and gradient elution in LC. LC, Liquid chromatography.

two pumps. Solvent mixing is accomplished by static mixing produced by merging of two flowing solvents or by dynamic mixing with a magnetic stirrer. Solvent composition may be changed in a linear fashion or at various programmable rates. It is important for gradients to be highly reproducible. For some

TABLE 12-3 Internal Diameters (ID) of Columns Used in HPLC

Column Terminology	Column ID, mm	Optimal Flow Rate
Standard	4.6	1.25 mL/min
	4.0	1.0 mL/min
Narrow bore	3.0	0.6 mL/min
	2.0	200 µL/min
Microbore/capillary	1.0	50 µL/min
	0.5	12 µL/min
	0.1	0.5 µL/min

applications, such as amino acid analysis by cation-exchange chromatography, a step gradient is used with multiple changes in mobile phase made with a switching valve. Isocratic separations provide the advantage of simplicity. Gradient elution is useful for separating complex mixtures with widely varying affinity for the stationary phase. At the completion of a gradient, additional time is required to reequilibrate the system to initial mobile phase conditions before the next injection.

Injector

The first step of an LC separation is the introduction of an aliquot of sample into the column via an injector. The most widely used type of injector is the fixed-loop injector, which is switched into or out of the flow path by manual or automated injection. In the inject mode, the loop is switched into the flow path, and the sample is carried downstream and into the column. The loop continues as part of the flow path until it is switched back to the fill position. Important characteristics of injection systems include their (1) reproducibility, (2) amount of carryover, and (3) range of injected volumes. Some automated injectors have the capability of injecting multiple aliquots or of mixing a sample and a reagent before injection to attain derivatization reactions.

Chromatographic Columns

Both packed and capillary columns are used in LC, and there is great diversity in sizes of columns and types of column packing.[28] Advances in column technology have improved the (1) selectivity, (2) stability, and (3) reproducibility of LC analytical columns and the materials used to pack or coat the inner walls of such columns.[9]

Column Dimensions. Modern column technology has produced columns in different dimensions with the tendency toward smaller internal volumes prevailing for analytical, especially hyphenated, techniques (see Chapter 13). For use in the clinical laboratory, most analytical HPLC columns are fabricated from tubes made of 316 stainless steel that have IDs ranging from 0.3 mm to 5 mm and lengths from 50 mm to 250 mm (Table 12-3). Column end fittings, which have zero dead volume and frits to retain the support particles, are used to connect the column to the injector on the inlet end and the detector on the outlet end. Generally, lower detection limits are achieved with columns having smaller IDs. These smaller ID columns are manufactured from narrow-bore (approximately 2.1 mm ID) and microbore (approximately 1.0 mm ID) tubes. In addition to providing improved efficiency, columns with smaller IDs use decreased volumes in the mobile phase. For example, a 2-mm-ID column requires much less solvent than a 4.6-mm-ID column (see Table 12-3).

Capillary columns used in LC are constructed by coating the inner wall of a fused silica tube with a thin film of liquid phase. These columns vary from 0.1 to 0.5 mm in ID and from 10 to 50 cm in length.

A guard column commonly is placed before the analytical column. A guard column is packed with the same or similar stationary phase as the analytical column. It collects particulate matter and any strongly retained components from the sample and, thus, extends the life of the expensive analytical column. The guard column is replaced periodically because buildup of particulate matter and impurities on a column causes (1) increased back-pressure, (2) increased background, and (3) lower performance.

Column Stationary Phase. The type of stationary phase in the column is the major determinant of selectivity and resolution of LC separations.[2] The typical physical form of the stationary phase usually consists of a packed bed of small particles or a monolithic porous rod.

Particulate Column Packings. Particulate packings have diameters ranging from 1.8 to 10 µm. In general, the smaller the diameter of the particle, the more efficient is the column. Because the operating backpressure of an LC column is inversely proportional to the square of the particle diameter, relatively high pressures are required to pump liquids through HPLC columns. Historically, separations by HPLC commonly used particles about 5 µm in diameter, but a trend toward the use of progressively smaller particles of less than 2 µm in diameter has been noted. The use of columns with small-diameter particles has led to a new generation of HPLC systems with pressure limits up to about 1000 bar (15,000 psi), which is about twofold to threefold higher than in earlier HPLC systems.Most solid phases are porous, and pore size is another important parameter of particles. The pore size influences the surface area of particles and the access of analytes to the full surface area. Separation of small molecules often uses particles with small pore sizes in the range of about 6 to 12 nm (60 to 120 Å). Particles with smaller pores have a greater number of pores and a greater surface area. Larger molecules, such as (1) proteins, (2) nucleic acids, and (3) large peptides, are too large to access these small pores, and wide-pore particles (15 to 50 nm) are needed for analysis of these macromolecules. Nonporous particles also are available, but these particles have the drawbacks of low surface area and capacity. In general, retention of analytes is increased by higher surface area and higher carbon load (see next page).

Types of particulate packings include (1) bonded phase, (2) polymeric, (3) chiral, and (4) restricted access materials.

Bonded Phase Packings. With this type of packing, the stationary phase is bonded chemically to the surface of silica particles through a silica ester or a silicone polymeric linkage that is relatively chemically stable. Bonded phase packings are available for a variety of chromatographic

applications, including (1) ion-exchange, (2) normal-phase, and (3) reversed-phase chromatography. In normal-phase HPLC, the functional groups of the stationary phase are polar relative to those of the mobile phase, which usually consists of nonpolar solvents, such as hexane. Examples of polar functional groups for normal-phase HPLC packings are (1) silanol, (2) amino, and (3) nitrile groups. Reversed-phase HPLC uses a nonpolar stationary phase. The most popular reversed-phase packing is the octadecyl or C18 (a straight aliphatic chain with 18 carbons) type, also sometimes called octadecyl silica or ODS columns. Reversed-phase column retention and selectivity characteristics also are altered via attachment of other groups, such as (1) octyl, (2) phenyl, (3) butyl, or (4) cyanopropyl, to the silica. Retention is also affected by the number of immobilized groups, often identified as the percent carbon load, and by chemical blocking of silanol groups on the surface of silica particles, which is often referred to as endcapping. Blocking of the hydroxyl groups on silica increases the stability of silica and decreases the effects of the hydroxyl groups on chromatography. The hydroxyl groups have weak ion-exchange properties that cause tailing of basic compounds. For this reason, endcapping sometimes is referred to as base deactivation. Because of variations in carbon load and endcapping chemistries, packings with the same type of bound stationary phase, such as ODS, may have differing chromatographic properties.

Polymeric Packings. Carbon particles that have been converted to graphite by a process known as graphitization or mixed copolymers are routinely used as polymeric packing (e.g., polystyrene-divinylbenzene) or further derivatized with ion-exchange or C4, C8, or C18 functional groups. Columns filled with these packings feature levels of performance comparable with those of silica-based columns and are stable from pH 2 to 13. Silica particles usually have decreased stability above pH 7.

Chiral Packings. Chiral packings are used to separate enantiomers, which are mirror-image forms of the same compound.[17,20] The chiral stationary phases are prepared by attaching a suitable chiral compound to the surface of an achiral support such as silica gel, which creates a chiral stationary phase (CSP).[1] Many common chiral stationary phases are based on oligosaccharides such as cellulose or cyclodextrin (in particular with β-cyclodextrin, a seven–sugar ring molecule). As with all chromatographic methods, various stationary phases are particularly suited to specific types of analytes. In the clinical laboratory, this type of packing is used to separate and quantify drug and amino acid enantiomers.

Restricted Access Packings. With this type of packing, the outer surfaces of the support particles are protected by a hydrophilic network. Smaller solutes, such as drugs, pass through the network into the pores, which are coated with hydrophobic stationary phase. Large protein molecules are denied access to the inner core and pass through the column. Columns filled with restricted access packing allow the direct injection of biological samples with high protein concentrations, which bypasses sample preparation and improves analytical accuracy.

Monolithic Columns. A monolithic column is one that is cast as a continuous homogeneous matrix ("just like concrete in a mold"). Such columns have bimodal pore structures with large pores (approximately 2 μm in diameter) that create high pore density, and smaller ones (approximately 13 nm in diameter) that create a large internal surface area. They have been found to be capable of efficient fast separations, as they allow higher flow rates than particulate columns at reasonable backpressures. In addition, they are capable of fast mass transfer and have high binding capacity. The lower back pressure provides highly reproducible column characteristics because many of the factors that degrade particulate columns are eliminated (e.g., packing down, channeling). The monolithic rods are encased in inert polytetrafluoroethylene (PTFE) tubing and are housed in stainless steel tubes. The inert tubing eliminates void volumes at the stainless steel tube/monolithic rod interface, thus improving resolution. Two additional advantages of these columns are that they are able to be used with mobile phase flow gradients (e.g., increasing flow rate at the end of a separation), and several columns may be coupled in a series to improve resolution with little increase in flow backpressure. Capillary monolithic columns also are available.

Of clinical interest, monolithic columns are being used to perform reversed-phase separations of peptides and proteins.

Column Heaters/Chillers

Control of column temperature is a factor in the reproducibility and efficiency of LC separations However, unlike GC separations, where temperature gradients are employed, in LC separations, a constant column temperature is maintained. It is achieved using a variety of techniques such as (1) column chambers, (2) water jackets, (3) temperature-controlled blankets, or (4) heating/cooling blocks. In addition, operation at high flow rates might require a heater/exchanger, usually a coil of tubing with good heat exchange properties, placed before the column inlet.

Detectors

Many different types of detectors have been used as monitors in liquid chromatographs (Table 12-4). Examples include (1) photometric or spectrophotometric, (2) fluorometric, (3) electrochemical, and (4) mass spectrometric detectors.

A key and integral component of such detectors is the flow cell through which the eluate from the chromatographic column passes. Dissolved analytes are detected and an electronic signal generated.

Operationally, detectors are used individually or are linked in series.[5] In addition, postcolumn reactors have been interposed between the column and the detector to perform a chemical reaction such as the reaction of ninhydrin with amino acids to generate products with a stronger and more specific signal.

Photometers and Spectrophotometers. UV and visible photometers and spectrophotometers measure the radiant energy absorbed by compounds as they elute from the chromatographic column (see Chapter 9). These detectors operate in the radiant energy regions of 190 to 400 nm and 400 to 700 nm, respectively. The devices are versatile and detect many

TABLE 12-4 Examples of Detectors Used in High-Performance Liquid Chromatography

Type of Detector	Principle of Operation	Range of Application	Detection Limit	Comments
Spectrophotometer	Measures absorbance of light at a single wavelength	Diverse	<1 ng	Analytes must absorb light or must be derivatized
Spectrophotometer (diode array)	Measures absorbance of light at many wavelengths	Diverse	<1 ng	Detector provides complete spectra
Electrochemical	Measures current fow from oxidation/ reduction reactions	Selective	pg to ng	Analytes must undergo oxidation or reduction
Fluorometer	Measures fuorescence at specific excitation and emission wavelengths	Very selective	pg to ng	Analyte must fuoresce or must be derivatized
Refractometer	Measures change in refractive index	Universal	µg	Offers relatively low sensitivity
Mass spectrometer (often a tandem mass spectrometer)	Detects ions after separation according to mass. Provides qualitative information	Diverse, limited only by ability to ionize analytes	pg to ng	Analytes must form ions. Can analyze multiple analytes simultaneously

solutes because most aromatic compounds are detected in the ultraviolet region from 250 to 300 nm, and many other compounds are detectable in the ultraviolet region from 190 to 220 nm, where amide, carboxylic acids, and many other groups have substantial absorbance.

T ese detectors operate at a fixed wavelength or at variable wavelengths. Most fixed-wavelength UV instruments use the intense 254-nm resonance line produced by a mercury arc lamp. T is type of detector is extremely sensitive and is capable of operation at 0.005 absorbance unit full scale (AUFS). To provide fixed-wavelength detectors with greater flexibility, other less intense resonance lines of the mercury lamp are used. Alternatively, a phosphor is placed between the lamp and the flow cell, and the emitted fluorescence resulting from the 254-nm excitation is used as the light source. T is latter approach is used in the dual-wavelength photometers that operate at two fixed wavelengths (e.g., 254 nm and 280 nm). T e intense 214-nm or 229-nm resonance lines of a zinc or cadmium arc lamp, respectively, have been used for detection at lower wavelengths, where more compounds have strong absorbance.

T e second type of photometric instrument is the variable-wavelength detector. It operates at a wavelength selected from a given wavelength range. T us the detector is "tuned" to operate at the absorbance maximum for a given analyte or set of analytes; this greatly enhances the applicability and selectivity of the detector. Another advantage of this detector is its ability to operate at lower wavelengths (e.g., 190 nm). Because more compounds (e.g., cholesterol) absorb at lower wavelengths, this capability enhances the versatility of the detector. At lower wavelengths, however, many solvents absorb UV light and cannot be used as mobile phases. Fortunately, acetonitrile and methanol, two widely used solvents in reversed-phase chromatography, have low UV absorptions at 200 nm.

Diode arrays also are used as HPLC detectors because they rapidly yield spectral data over the entire wavelength range of 190 to 600 nanometers in about 10 milliseconds. Such detectors have been helpful in the identification of drugs in urine and serum.

In practice, when a photometric detector is used, it is necessary to use (1) solvents, (2) ion pairing agents, and (3) buffers with low absorbance at wavelengths of interest to maintain a low background signal. Solvents such as (1) water, (2) acetonitrile, (3) methanol, (4) isopropanol, and (5) hexane allow ultraviolet detection down to wavelengths of 200 nm, as do phosphate buffers. Many other solvents and buffers have substantial absorbance in the ultraviolet region that may limit ultraviolet detection. A problem with the operation of photometric detectors is the outgassing that occurs in the solvent as it exits from the high pressure of the column and into the low-pressure flow cell of the detector. Because these detectors are very sensitive, they detect these bubbles as noise that degrades the signal-to-noise ratio of the detector. Effective degassing of solvents and maintenance of some backpressure across the detector help to minimize bubble formation.

Fluorometers. As discussed in Chapter 9, fluorescence occurs when a molecule absorbs light at one wavelength and reemits light at a longer wavelength. Online fluorometers are used in liquid chromatographs to detect fluorescing compounds as they elute from the column. Fluorescence detectors generally are more sensitive than photometric ones. In addition, precolumn or postcolumn reactors have been used to chemically tag a compound with a fluorescent label for subsequent detection. For example, amino acids and other primary amines often are labeled with a dansyl or fluorescamine tag, followed by HPLC separation and fluorometric detection. Most fluorometers used with liquid chromatographs are relatively simple in design and are extremely selective and sensitive for compounds fluorescing within the detector's operating wavelength range. Deuterium and xenon arc lamps or lasers have been used as light sources in such detectors.

Electrochemical Detectors. In amperometric electrochemical detectors (see Chapter 10), an electroactive analyte enters the flow cell, where it is oxidized or reduced at an electrode surface under a constant potential. Electroactive compounds of clinical interest conveniently analyzed by HPLC with electrochemical detection include the urinary catecholamines (see Chapter 26). In addition, it is possible to add electrochemically active tags (e.g., bromine) to compounds such as unsaturated fatty acids or prostaglandins.

Coulometric detectors are also used. When placed in a series, such detectors are used to detect and quantify co-eluting

compounds that differ in their half-wave potentials (the potential at half-signal maximum) by at least 60 mV. These detectors are extremely selective and sensitive, with wide linear response ranges. They are used in the clinical laboratory for analysis of (1) metanephrines, (2) vanillylmandelic acid, (3) homovanillic acid, and (4) 5-hydroxyindoleacetic acid in human urine. The high specificity allows analysis without extensive sample preparation.

Mass Spectrometers.[30] When a gas or liquid chromatograph is connected to a mass spectrometer (see Chapter 13), the combined techniques are referred to as gas chromatography–mass spectrometry (GCMS) and liquid chromatography–mass spectrometry (LCMS).[12,23,24]

A critical element in linking an HPLC to a mass spectrometer is the interface between them. For example, the interface has the challenging task of removing solvent molecules and transferring components from a liquid solution into a charged form in vacuum for analysis by the mass spectrometer. Therefore, all buffers used for chromatography need to be volatile to avoid overloading and contaminating the interface. In addition, a switching valve often is used to divert salts and other unretained components that elute early in the HPLC separation to waste. The switching valve then directs later parts of the HPLC run to the mass spectrometer. Several different ionization techniques, including (1) electrospray, (2) chemical ionization, and (3) photoionization, are discussed in greater detail in Chapter 13

System Controller and Data System

As with GC, computers provide system control and data processing functions for HPLC.[22] For example, the system controller manages (1) sample injections, (2) solvent delivery, (3) temperature control, (4) and detectors; it also provides an auditable record of analyst, method, calibration, controls, and specimens. Data systems take the thousands of data points from an individual run and identify a set of peaks with parameters such as (1) retention times, (2) peak areas, (3) peak heights, and (4) peak widths. Comparison of these parameters with those generated from reference materials yields identification of peaks and quantitative values. Software for data analysis becomes more critical as data streams become larger, such as from diode array and mass spectrometric detection, and multiple components are analyzed in a single run; libraries of spectra or other databases are searched for identification of compounds, peptides, or nucleic acid sequences.

Practical Considerations

Several techniques affect the practical application of HPLC in the clinical laboratory, including those used to prepare samples and mobile phases.

Sample Preparation

Sample preparation is an important step in HPLC analysis and includes procedures for (1) sample concentration by extraction, (2) purification, and (3) derivatization.[24] Particulate matter should be removed from specimens by high-speed centrifugation or by filtration. Solid phase extraction also serves as a means of filtration to remove particulate matter.

Sample Extraction and Precipitation. Before chromatographic separations are performed, many clinical specimens require some processing by extraction or precipitation steps before they undergo analysis.[10] Reasons to process such specimens include (1) removal of interfering binding proteins, (2) removal of components that precipitate or decrease the efficiency of chromatography, (3) concentration of specimens to a smaller volume, and (4) removal of water and salts. Methods used to precipitate proteins from blood or serum include addition of organic solvents, acids such as trichloroacetic acid, or high concentrations of salt. Precipitated proteins are removed by centrifugation or filtration. An aliquot of the resultant supernatant or filtrate is then chromatographically analyzed. Use of an immiscible solvent such as ethyl acetate or hexane extracts hydrophobic compounds such as (1) triglycerides, (2) carotene, (3) vitamin E, or (4) hydrophobic drugs and leaves most water, salts, and proteins that may interfere with analysis or derivatization. Also, use of volatile organic solvents allows for concentration of nonvolatile components by evaporation.

Use of solid-phase extraction, which is essentially a preparative chromatographic separation with stepwise elution of components, is increasing. Solid phase extraction is performed manually or robotically in a variety of formats, including (1) short columns, (2) 96-well plates with very short chromatographic beds at the bottom of wells, and (3) pipette tips packed with chromatographic media. Online solid phase extraction has been added to some HPLC systems with direct elution of analytes from the extraction column into the analytical column. Solid phase extractions use a variety of types of stationary phases, such as (1) ion-exchange, (2) reversed-phase, (3) affinity, and (4) normal phase. Common applications of solid phase extraction include extraction of drugs from urine or fat-soluble vitamins such as 25-hydroxyvitamin D from serum for chromatographic analysis. Most methods used for analysis of nucleic acids require an extraction step to recover DNA or RNA before analysis is begun.

Sample Derivatization. Some analytes need to be chemically derivatized before or after chromatographic separation to increase their column retention or detectability. For example, in automated amino acid analyzers, eluted amino acids are reacted with ninhydrin in a postcolumn reactor; this provides greater specificity and sensitivity in detecting amino acids. Other examples include labeling of amino acids or other primary amines with dansyl or fluorescamine tags in a precolumn or postcolumn reactor followed by fluorometric detection.

Preparation of Mobile Phase. In preparing the mobile phase, dissolved gases in the solvent need to be removed, and the solvent must be free of particulate matter. Mobile phases should be prepared from HPLC-grade solvents free of particulate matter. Any solutions prepared in the laboratory should be passed through a filter with approximately 0.5 micron pore size.

Qualitative and Quantitative Analyses

Chromatography is basically a separation technique. In practice, however, it is used both for identifying analytes and for performing quantitative analyses.

Analyte Identification

The retention time or volume or the distance traveled on a plate by a compound is often used for identification by comparison versus a reference standard.

In planar chromatography, reference compounds are chromatographed simultaneously with the unknown sample. Tentative identification is made by comparison of the migration distances and the detection characteristics of reference compounds with those of unknown analytes. If the R_f (see Equation 3) of the unknown analyte and that of the reference compound do not match, the compounds are judged to be different. If they match, the compounds are presumed to be identical. More than one compound may have the same R_f in a particular chromatographic system; therefore, the presumptive identification is often confirmed by other techniques such as use of (1) specific spray reagents, (2) antibody complexation, or (3) isolation of the compound, followed by chemical and/or instrumental analysis. Software is available for compound identification by library searching of ultraviolet (UV) spectra based on corrected R_f values.[9]

In column chromatography, analytes are identified by their detector response and retention times. Usually, a set of standards is run to identify the retention times of analytes. Identification of the same analytes in patient specimens in subsequent runs then depends on maintenance of highly consistent performance by the system. An internal standard may be added to specimens to check on consistency of retention times. In GC, (1) irregular gas flow, (2) leaks in the system, (3) changes in temperature control, or (4) degradation of the stationary phase may lead to problems with stable retention times. In LC, (1) changes in solvent (such as from refilling the solvent reservoir with fresh solvent), (2) irregular flow rate, (3) variation in gradient formation, (4) liquid leaks in the system, (5) degradation of columns with extended use, (6) changing to a new column, or (7) erratic temperature control may lead to variable retention times. Multiple components often have identical retention times. This problem may be addressed by using detectors with greater specificity, such as mass spectrometers that allow identification of multiple components eluting at the same time. Multiple detectors may be connected in series that assist with identification by their different specificities.[5] In LC, fluorometric or electrochemical detection often provides considerable specificity, or postcolumn reactors may selectively detect a specific class of compounds such as amino acids. In analysis of physiological specimens by column chromatography, unexpected interfering materials occasionally may arise from (1) medications, (2) diet, (3) herbal preparations, (4) unusual physiological states, or (5) specimen contamination. The frequency of such interference depends to some degree on the specificity of the chromatography and detection methods. Use of detection methods such as tandem mass spectrometry with very high specificity tends to decrease problems with interference.

Analyte Quantification

The electronic signals generated by the detector(s) are also used to produce quantitative information. Both external and internal calibrating techniques have been used. With external calibration, reference solutions containing known quantities of analytes are analyzed in a separate run to establish detector responses per amount of analyte (Figure 12-14). A calibration curve of (1) peak height, (2) peak area, or (3) spot density versus calibrator concentration is constructed and used to calculate the concentration of the analyte in the samples. With internal calibration, also called internal standardization, reference solutions of known analyte concentrations are prepared, and a constant amount of a different compound, the internal standard, is added to each reference solution and to each sample (Figure 12-15). A calibration curve is established for the ratio of detector response of the analyte versus the internal standard, and this calibration curve is applied to ratios of signal from analyte versus internal standard in patient specimens. Use of an internal standard is particularly useful when additional steps are involved, such as extractions with incomplete recovery of specimen. The internal standard helps correct for incomplete recovery. Internal

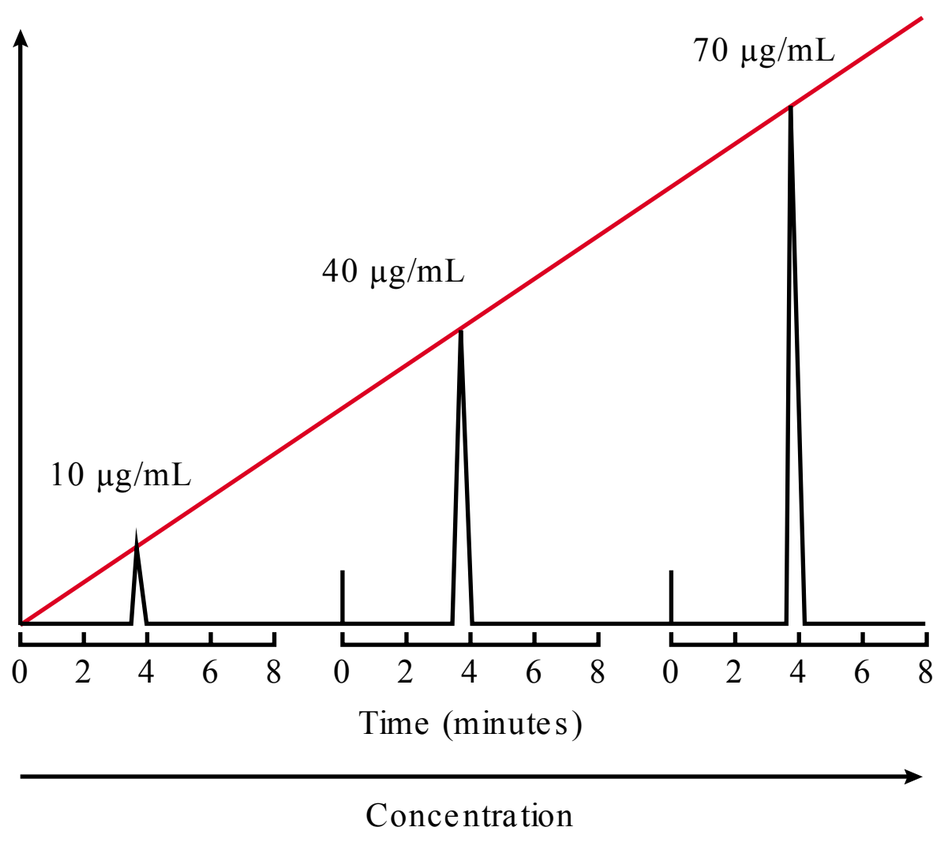

Figure 12-14 The use of external calibrators in the production of a calibration plot. (From Krull I, Swartz M. Quantitation in method validation. LC-GC 1998;16:1084-90.)

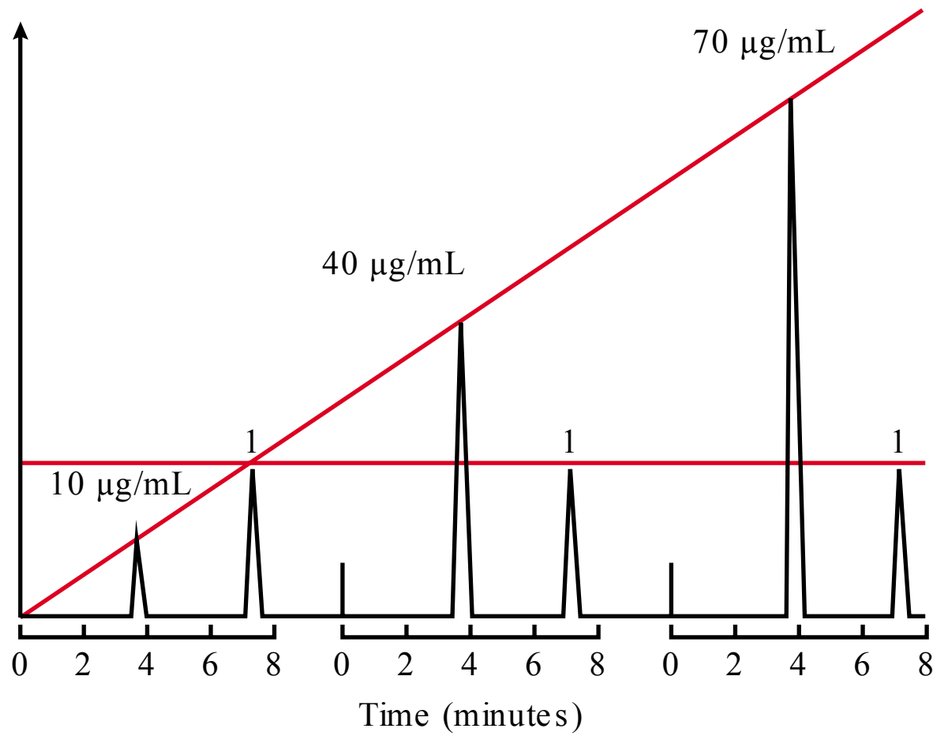

Figure 12-15 The use of internal calibrators in the production of a calibration plot (with peak 1 as the internal standard). (From Krull I, Swartz M. Quantitation in method validation. LC-GC 1998;16:1084-90.)

standards also are important in quantitation by mass spectrometry because the efficiency of ionization of analytes in the interface between HPLC and the mass spectrometer may vary. Ideally, in mass spectrometry, the internal standard has the same chromatographic retention and physical properties as the analyte. T is often may be accomplished by using internal standards that have the identical chemical structure but substitute stable isotopes for hydrogen, carbon, or nitrogen.

Some important analytical characteristics of quantitative analysis include (1) limits of detection, (2) limits of quantification, (3) precision of analysis, and (4) carryover. Another important characteristic to establish is the analytical measuring range, which usually will extend from the limit of quantification on the low end to the upper limit of the measuring range. T e response of many detectors is subject to saturation and nonlinearity of responses at very high concentrations. Also, in some cases, chromatographic systems may be overloaded by very high analyte concentrations. A range of high analyte concentrations should be tested to verify the highest concentration at which acceptable performance is achieved (the upper limit of the measuring range). Specimens with concentrations above that level should be diluted into an appropriate concentration range before analysis.

For analytes present in low concentrations, the major challenge often is to extend limits of quantification to low enough values. In general, the analytical limit of detection is improved by (1) increasing chromatographic efficiency (obtaining taller and sharper peaks), (2) increasing the amount of specimen loaded (possibly through extraction or the preconcentration step), (3) using smaller-diameter columns that elute the analytes in a smaller volume of solvent (with higher analyte concentration), and (4) appropriately selecting detectors and detector parameters such as wavelength of detection.

Review Questions

1. To be analyzed by gas chromatography, a compound must:
   a. be volatile or be made volatile.
   b. not be volatile.
   c. be water soluble.
   d. contain a nitrogen atom.
2. Which of the following statements concerning chromatography is correct?
   a. High-performance liquid chromatography (HPLC) involves the use of support particles coated on a piece of paper or glass.
   b. In affinity chromatography, a hormone can bind to its receptor that is coated on glass or resin beads.
   c. T in-layer chromatography (TLC) is considered to be a quantitative type of chromatography.
   d. Ion-exchange chromatography uses the principle that particles compete for binding sites in the stationary phase.
3. T e most commonly used detector for clinical lab analysis of analytes after gas chromatography (GC) is a:
   a. photoionization detector.
   b. thermionic selective detector.
   c. mass spectrometer.
   d. flame ionization detector.
4. Spotting a specimen on a silica-coated glass plate and calculating the retention factor (R_f) for migrated substances in a sample is referred to as TLC. What type of chromatography is this?
   a. Column chromatography
   b. Affinity chromatography
   c. Planar chromatography
   d. Liquid chromatography
5. Some point-of-care tests use chromatography as a processing step in the assay. In point-of-care pregnancy testing, for example, the stationary phase is nitrocellulose paper and the hCG antigen is present in a urine sample, which is considered the mobile phase. T e antigen in the mobile phase binds with an antibody in the stationary phase. T is is an example of planar chromatography using which of the following as the separation mechanism?
   a. Partition
   b. Ion exchange
   c. Affinity
   d. Steric exclusion (size)
6. A highly sensitive, specific, and quantatitive chromatographic method that uses pressure to push sample and solvent through a packed column is:
   a. TLC.
   b. GC.
   c. HPLC.
   d. Ion-exchange chromatography.
7. In column chromatography, unknown analytes are identified as they pass through the detector. Comparison of the _____ of unknown analytes with that of the internal standard is the method used for unknown identification.
   a. retention time
   b. retention factor
   c. resolution
   d. fluorescence
8. Which component of a gas chromatograph introduces an aliquot of sample to be analyzed into the column?
   a. Pipette
   b. Aliquotter
   c. Sample extractor
   d. Injector
9. Which phase of chromatography carries the sample?
   a. Stationary phase
   b. Mobile phase
   c. Retention phase
   d. Column phase
10. T e component of a liquid chromatograph that is integral in passing the eluate from the chromatographic column into the detector is the:
    a. injector.
    b. diode array.
    c. flow cell.
    d. retainer.

CHAPTER

13 Mass Spectrometry*

Alan L. Rockwood, Ph.D., D.A.B.C.C., Thomas M. Annesley, Ph.D., and Nicholas E. Sherman, Ph.D.

Objectives

1. Define the following terms:
   - Base peak
   - Ion trap
   - Mass analysis
   - Mass spectrometry
   - Mass-to-charge ratio (m/z)
   - Molecular ion
   - Product/Fragment ion
   - Proteomics
   - Time of flight (TOF)
2. List the applications of mass spectrometry analysis.
3. Describe a generic mass spectrometer, including principle of operation, components, and functions of these components.
4. For the following ionization methods, state the principle and specific uses of each type:
   - Electron
   - Chemical
   - Electrospray
   - Atmospheric pressure chemical
   - Inductively coupled plasma (ICP)
   - Matrix-assisted laser desorption/ionization (MALDI)
5. For the following types of mass spectrometers, state the principle of operation, and list the designs, specialized components, and laboratory uses of each:
   - Beam-type
   - Trapping-type
   - Tandem
6. List three types of electron multiplier detectors and state the principle of this type of detection.
7. Describe the instrumentation and the principles of the techniques involved and state the clinical applications of each of the following:
   - Gas chromatography-mass spectrometry
   - Liquid chromatography-mass spectrometry
   - MALDI-TOF
   - ICP-mass spectrometry
8. Explain the role of mass spectrometry in the field of proteomics.

Key Words and Definitions

Base peak The ion with the highest abundance in the mass spectrum; it is assigned a relative abundance of 100%.

Electrospray ionization A commonly used technique in which a sample is ionized at atmospheric pressure before introduction into the mass analyzer.

Extracted ion profile The sum of ions over a limited m/z ranged displayed as a function of time.

Fragment ion An ion formed by dissociation of a molecular ion, by convention often limited to fragmentation prior to mass analysis.

Gas chromatography–mass spectrometry (GC-MS) A combined technique in which a mixture of analytes is separated into individual components by gas chromatography, followed by the ionization of the separated compounds in the ion source of a mass spectrometer.

Ion An atom that has acquired an electrical charge by losing or gaining one or more electrons.

Ionization The production of an ion from a neutral atom or molecule using various techniques including but not limited to chemical ionization or electrospray ionization; ionization is required for all mass spectrometry techniques.

Ion trap A component of a trapping-type mass spectrometer where ions are held in a spatially confined region of space using, for example, a magnetic or electrostatic field; manipulation of the traps allows m/z measurements to be performed.

Isotope A variant of a chemical element; each variant differs in the number of neutrons in the nucleus and therefore in atomic weight from other isotopes of the same element.

*The authors gratefully acknowledge the original contributions by Larry D. Bowers, upon which portions of this chapter are based. We also wish to acknowledge technical assistance by Jacquelyn McCowen-Rose and Martha Fowles and helpful suggestions from N. Leigh Anderson, Julianne C. Botelho, Pierre Chaurand, David K. Crockett, Ulrich Eigner, Steven A. Hofstadler, Andrew N. Hoofnagle, Gary H. Kruppa, Mark M. Kushnir, Donald Mason, Michael Morris, Maria M. Ospina, and Hubert W. Vesper.

Key Words and Definitions—cont'd

Isotope dilution mass spectrometry (IDMS) An analytical technique used to quantify a compound relative to an isotopic species of known or fixed concentration using isotopically labeled internal standards.

Liquid chromatography–mass spectrometry (LC-MS) An analytical process that uses a liquid chromatograph coupled to a mass spectrometer.

MALDI Acronym for matrix-assisted laser desorption/ionization. It is a soft ionization technique that allows the analysis of biomolecules and large organic molecules which tend to be fragile and fragment when ionized by more conventional ionization methods.

Mass analysis The process by which a mixture of ionic species is identified according to the mass-to-charge (m/z) ratios (ions).

Mass spectrometer An analytical instrument that first ionizes a target molecule and then separates and measures the mass-to-charge (m/z) ratio of these molecules or their fragments; this instrument interfaces with other instruments including but not limited to a second mass spectrometer or a gas chromatograph.

Mass spectrometry Study of matter through the formation of gas-phase ions that are characterized using mass spectrometers by their mass, charge, structure, and/or physico-chemical properties.

Mass spectrum A plot of the relative abundance of each ion plotted as a function of its mass-to-charge (m/z) ratio.

Mass-to-charge ratio (m/z) The quantity formed by dividing the mass of an ion by its charge.

Product ion A fragment ion formed when a molecular ion breaks into smaller pieces; in a tandem mass spectrometer, the fragmentation process takes place after ions have been separated by the m/z value in a first stage of mass spectrometry.

Proteomics The identification and quantification of proteins and their posttranslational modifications in a given system or systems.

Selected ion monitoring (SIM) A MS technique where only specified ions of interest are monitored.

Skimmer A cone with a central orifice that is designed to intercept the center of a spray or jet expansion so as to sample the central portion of the expansion.

Tandem mass spectrometer A mass spectrometer capable of successive separation of ions in an ion beam according to m/z value (tandem in space) or separation of a set of trapped ions in an ion trap according to m/z value (tandem in time).

Torr A non-SI unit of pressure with the ratio of 760 to 1 standard atmosphere, chosen to be roughly equal to the fluid pressure exerted by a millimeter of mercury. For example, a pressure of 1 torr is approximately equal to 1 mm of mercury.

Total ion chromatogram (TIC) The sum of all ions produced displayed as a function of time.

Mass spectrometry (MS) is a powerful qualitative and quantitative analytical technique that is used to measure a wide variety of clinically relevant analytes. When MS is coupled with **gas** or **liquid** chromatographs (see Chapter 12), the resultant analyzers have expanded analytical capabilities and widespread clinical applications. In addition, because of its ability to identify and quantify proteins, MS is a key analytical tool that is used in the emerging field of **proteomics**. This chapter begins with a discussion of the basic concepts and definitions of MS, which is followed by discussions of MS instrumentation and clinical applications.

Basic Concepts and Definitions

A **mass spectrometer** is an analytical instrument that first ionizes a target molecule and then separates and measures the **mass-to-charge ratio** (m/z) of the molecule or its fragments. Although mass spectrometers do not measure molecular mass, for historical reasons the mass-to-charge ratio is often loosely referred to as "mass." **Mass analysis** is the process by which a mixture of ionic species is identified according to the m/z ratios of the ions.[23] This analysis may be qualitative, or it may be both qualitative and quantitative. Mass spectrometry is extremely useful for identifying compounds and determining the elemental composition and structure of both inorganic and organic compounds, as well as for performing quantitative analysis of selected compounds.

A **mass spectrum** is represented by the relative abundance of each **ion** plotted as a function of its m/z ratio (Figure 13-1). Often, each ion has a single charge (z = 1), in which case the m/z ratio is equal to the mass. The unfragmented ion of the original molecule is called the molecular ion. **Fragment ions** are formed when a molecular ion breaks into smaller pieces. The ion with the highest abundance in the mass spectrum is assigned a relative value of 100% and is called the **base peak**. The base peak may be the molecular ion or a fragment ion. When this relative abundance scale is used, instrument-dependent variability in the mass spectrum is minimized, and it is then possible to compare the mass spectrum with spectra obtained on other instruments. Because the fragmentation of ions at specific bonds depends on their chemical nature, it is often possible to determine the structure of an analyte from the pattern of fragments in the mass spectrum.

In addition, the pattern of relative abundances among the fragment ions of a given compound is often unique to that compound, much as human fingerprints are unique for each individual. Computer-based libraries of spectra take advantage of this and are available to assist in identification of the analyte(s) from mass spectra.

Fragmentation of ions also takes place in a **tandem mass spectrometer.** Unlike fragment ions produced before mass analysis (e.g., in an ion source), the fragmentation process takes place after ions have been separated by the m/z value in a first stage of mass spectrometry. These fragment ions are more commonly known as **product ions.**

The mass spectrometer is considered to be a "universal detector" because all compounds have mass, and in theory it is possible to ionize and detect all compounds in a mass spectrometer. When interfaced with a liquid or a gas chromatograph, the mass spectrometer provides structural information and/or highly specific detection of individual analytes as they elute from a chromatography column. Depending on the operating characteristics of the mass spectrometer and the chromatographic peak width, several mass spectral scans are typically acquired across the peak. The sum of all ions produced is displayed as a function of time to yield a **total ion chromatogram (TIC).** It is possible to program the data system to display the sum of ions over a restricted mass range rather than the full mass range. The resultant display is called an **extracted ion profile.** Both TICs and extracted ion profiles represent chromatograms, with signal intensity plotted as a function of time. Retention times are then measured and peak heights or peak areas integrated for use in quantitative analysis.

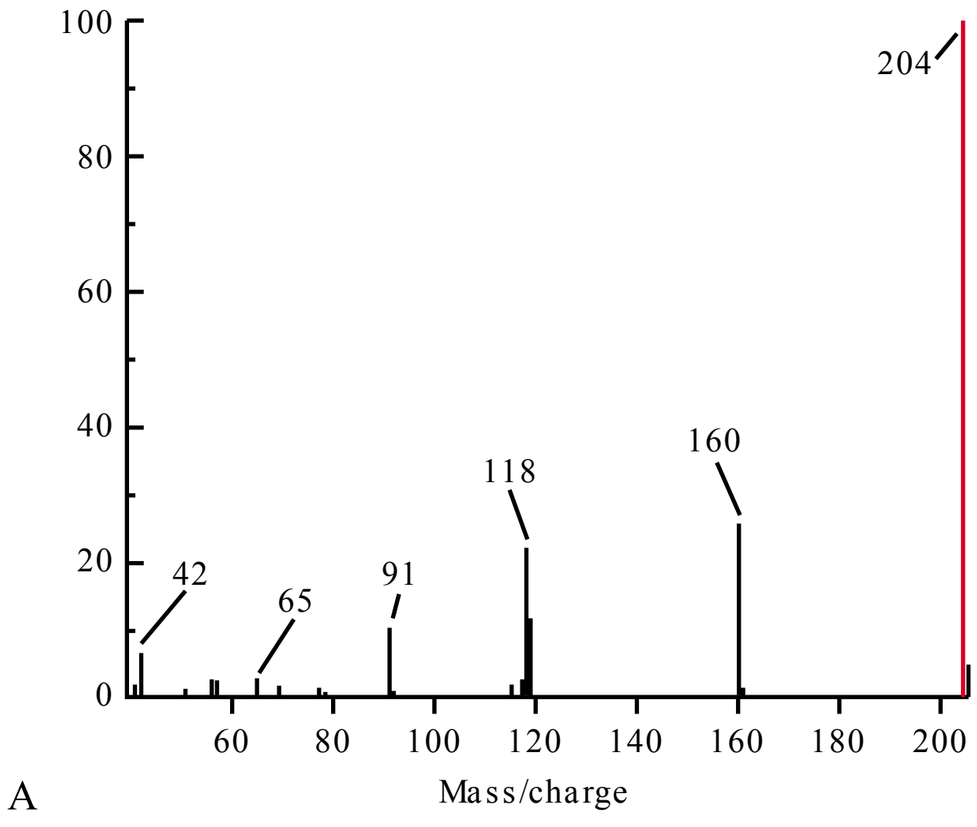

Figure 13-1 Mass spectrum of the (A) pentafluoropropionyl and (B) carbethoxyhexafluorobutyryl derivatives of d-methamphetamine.

When only a few analytes are of interest for quantitative analysis and their mass spectrum is known, the mass spectrometer is programmed to monitor only those ions of interest. This selective detection technique is known as **selected ion monitoring (SIM).** The mass spectrometer cycles repeatedly through a table of selected m/z values, monitoring the abundance of each for a short time. SIM is typically employed in chromatographic applications of mass spectrometry. The time slice for each m/z value in this multiplexing scheme is typically selected to be short compared with the chromatographic time scale. Consequently, SIM provides an approximation of continuous and simultaneous monitoring of ions of all selected m/z values. Because SIM focuses on a limited number of ions, more ion signal is collected for each selected m/z compared with scanning of the full mass spectrum. This increases the signal-to-noise ratio of the analyte and improves the lower limit of detection. In general, an unknown is considered identified if the relative abundances of three or four ions agree within ±20% of those from a reference compound.

Mass spectra of most chemical compounds contain a series of peaks, most often differing by approximately one m/z unit, with the differing masses of the peaks attributed to the presence of atoms of different elemental **isotopes** in the molecule. These peaks are commonly referred to as isotope peaks or isotopic peaks. For example, the mass spectrum of $C_2H_7O^+$ consists primarily of three isotope peaks at nominal m/z values of 47, 48, and 49 with relative abundances of 100%, 2.4%, and 0.2%, respectively. The higher isotope peaks of $C_2H_7O^+$ contain contributions from ^{12}C, ^{13}C, ^{1}H, ^{2}H, ^{16}O, ^{17}O, and ^{18}O in various combinations. For example, the m/z 48 peak of $C_2H_7O^+$ is composed of $^{12}C^{13}C^{1}H_7{}^{16}O^+$, $^{12}C_2{}^{1}H_6{}^{2}H^{16}O^+$, and $^{12}C_2{}^{1}H_7{}^{17}O^+$. Calculation of isotopic patterns is often very challenging, particularly for high-molecular-weight compounds, and various methods that are used to meet this challenge have been discussed in the literature.[19]

It is possible to isotopically label molecules by artificially substituting atoms of a selected isotope for the naturally occurring isotopic atoms in specified portions of the molecule. Because of the mass difference compared with the masses of naturally occurring isotopic peaks in a mass spectrum, a labeled molecule is separated in the mass spectrometer from an unlabeled molecule and its abundance measured separately. **Isotope dilution mass spectrometry** takes advantage of this feature by spiking a specific concentration of labeled internal standard into a sample and basing a quantitative analysis on the ratio of abundance of the analyte to abundance of the internal standard in the mass spectrum.

Instrumentation

A mass spectrometer consists of an (1) ion source, (2) vacuum system, (3) mass analyzer, (4) detector, and (5) computer (Figure 13-2). In most cases, a chromatograph is also included as a sample introduction device.

Ion Source

All MS techniques require an **ionization** step in which an ion is produced from a neutral atom or molecule. Many approaches have been used to form ions in both high-vacuum and near–atmospheric pressure conditions. Electron ionization (EI) and chemical ionization (CI) are ionization techniques that are used when gas phase molecules are introduced directly into the analyzer from a gas chromatograph. The ionization methods used most frequently when a high-performance liquid chromatograph is interfaced with a mass spectrometer (HPLC-MS) include (1) **electrospray ionization** (ESI)[7] and (2) atmospheric pressure chemical ionization (APCI). Other ionization techniques include (1) atmospheric pressure photoionization (APPI),[18] (2) inductively coupled plasma (ICP),[2] and (3) matrix-assisted laser desorption/ionization **(MALDI)**.[11]

Electron Ionization

In EI, gas phase molecules are bombarded by electrons emitted from a heated filament and attracted to a collector electrode (Figure 13-3). This process must occur in a vacuum to prevent both filament oxidation and collisional attenuation of the electron beam. Electrons are emitted from a hot filament by thermionic emission, accelerated through a potential difference of ≈70 volts, and directed toward a vaporized sample. These electrons have enough kinetic energy that the collision of an electron with most organic molecules ejects an electron from the analyte molecule and produces a radical cation, which is a chemical species that is both an ion and a radical.[23] In most cases, this radical ion then undergoes unimolecular rearrangement and fragmentation to produce a another cation and a radical:

$$AB^{+\cdot} \rightarrow A^{+} + B^{\cdot}$$

As determined by their chemical stability, the relative proportions of molecular ion and various fragment ions are reasonably reproducible. Positive ions are repelled or drawn out of the ionization chamber by an electrical field. These cations then are electrostatically focused and are introduced into the mass analyzer. The mass spectral pattern, in most cases dominated by fragment ions, is often used much like a fingerprint to identify compounds by comparison with mass spectral libraries.

Chemical Ionization

Chemical ionization (CI) is a "soft" ionization technique, meaning that relatively little fragmentation is produced during the ionization process. A proton is transferred to, or abstracted from, a gas phase analyte by a reagent gas molecule. Typical reagent gases are (1) methane, (2) ammonia, (3) isobutane, and (4) water. The reagent gas is directed into a special CI source, so the source pressure is increased to about 0.1 torr; most of this pressure is attributable to the reagent gas. An electron beam ionizes the reagent gas and produces reactive species, often as a result of a cascade of ion molecule reactions, such

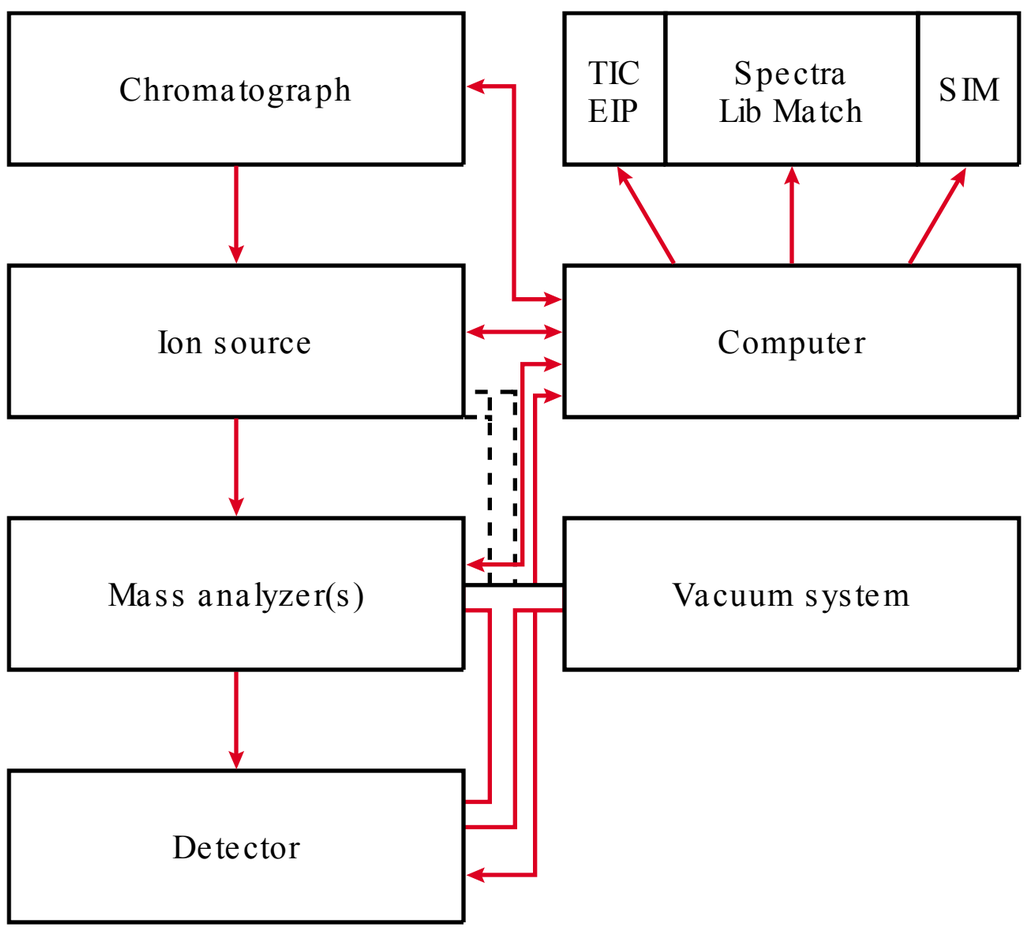

Figure 13-2 Block diagram of the components of a chromatograph-mass spectrometer system. The mass analyzer and the detector are always under vacuum. The ion source may be under vacuum or under near-atmospheric pressure conditions, depending on the ionization mode. The computer system is an integral part of data acquisition and output.

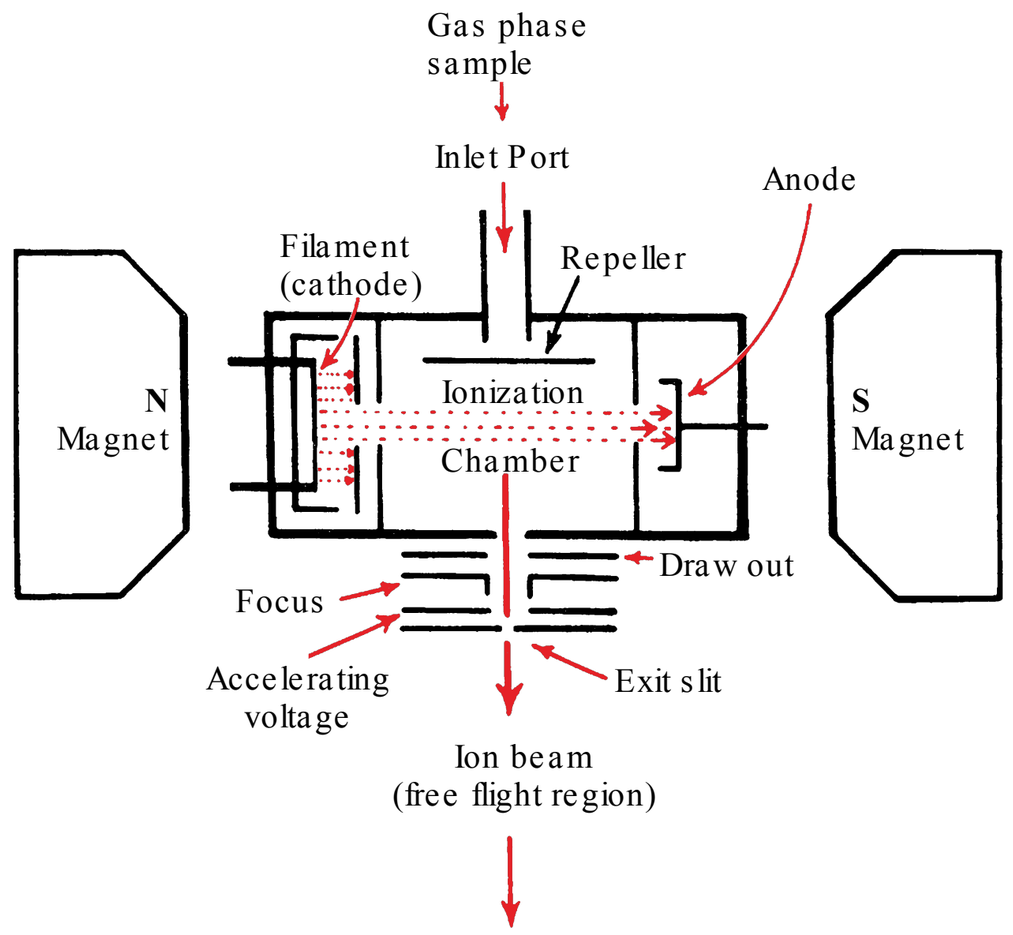

Figure 13-3 Electron impact ion source. The small magnets are used to collimate a dense electron beam, which is drawn from a heated flament placed at a negative potential. The electron beam is positioned in front of a repeller, which is at a slight positive potential compared with the ion source. The repeller sends any positively charged fragment ions toward the opening at the front of the ion source. The accelerating plates strongly attract the positively charged fragment ions.

as (in the case of methane reagent gas) proton transfer reactions to form CH_5^+, followed by proton transfer from CH_5^+ to the analyte molecule. This is a low-energy process, so relatively little fragmentation occurs. This process is advantageous for analyte molecular mass determination and for quantification.

Another variation of CI, negative ion electron capture CI, has become popular for quantification of drugs, such as benzodiazepines. Negative ion formation occurs when thermalized electrons are captured by an electronegative substituent, such as chlorine or fluorine on the analyte. Thus the number of compounds undergoing negative ionization is small, and background signal (noise) is decreased. When applicable, negative ion CI has acceptable limits of detection.

Electrospray Ionization

Electrospray ionization (ESI) is a technique in which a sample is ionized at atmospheric pressure before it is introduced into the mass analyzer.[25] The sample, typically an HPLC effluent, is passed through a narrow metal or fused silica capillary to which 1.5 to 5 kV voltage has been applied (Figure 13-4, A). Electrostatic forces on the liquid result in the expulsion of charged droplets from the tip of the capillary. In a typical electrospray ion source design, a coaxial nebulizing gas helps nebulize the liquid and direct the charged droplets toward a counter electrode. The droplets evaporate as they migrate through the atmospheric pressure region, expelling smaller droplets. The proton adduct of the molecule, which may be associated with solvent molecules, is "desolvated" to form "bare" ions, which then pass through apertures in a sampling cone and in one or more extraction **skimmers** before entering the mass analyzer. These devices are extraction cones that have a central orifice that is designed to intercept the center of a spray or jet expansion so as to sample the central portion of the expansion.

Electrospray ionization is largely dependent on solution phase chemistry. Basic compounds, because they are easily protonated, tend to be efficiently detected in positive ion mode. Less commonly, rather than being formed by proton adduction, the ion is formed by adduction of some other positively charged ion, such as an ammonium ion or an alkali metal ion. In some cases, the ion may arise from a built-in charge of the analyte, such as a quaternary ammonium compound like choline. Occasionally, ionization occurs via electrochemical reactions in the ESI ion source. Acidic compounds, which readily lose a proton to become negatively charged ions in solution, tend to be efficiently detected in negative ion mode.

One unique feature of ESI is the production of multiple charged ions from some compounds, particularly from peptides and proteins. It is common to observe approximately one charge for every ≈10 amino acid residues in a protein. For example, because a molecule of mass 20,000 yields up to 20 charges, it is detected at m/z 1000 (20,000/20) with a lower resolution and less expensive analyzer. This greatly extends the accessible molecular weight range of such an instrument. In most cases where multiple charging occurs, a series of charge states are observed in the same mass spectrum (e.g., 19 charges, 20 charges, 21 charges). These appear at a series of m/z values (e.g., 1052.6, 1000, 952.4). In most cases, charging is produced by proton adduction, and peaks are observed at $m/z = (M+n)/n$, where M is the molecular weight and n is the charge (which equals the number of protons attached).

It should be noted that Figure 13-4, A, shows the probe as it is being directed toward the sampling cone of the mass

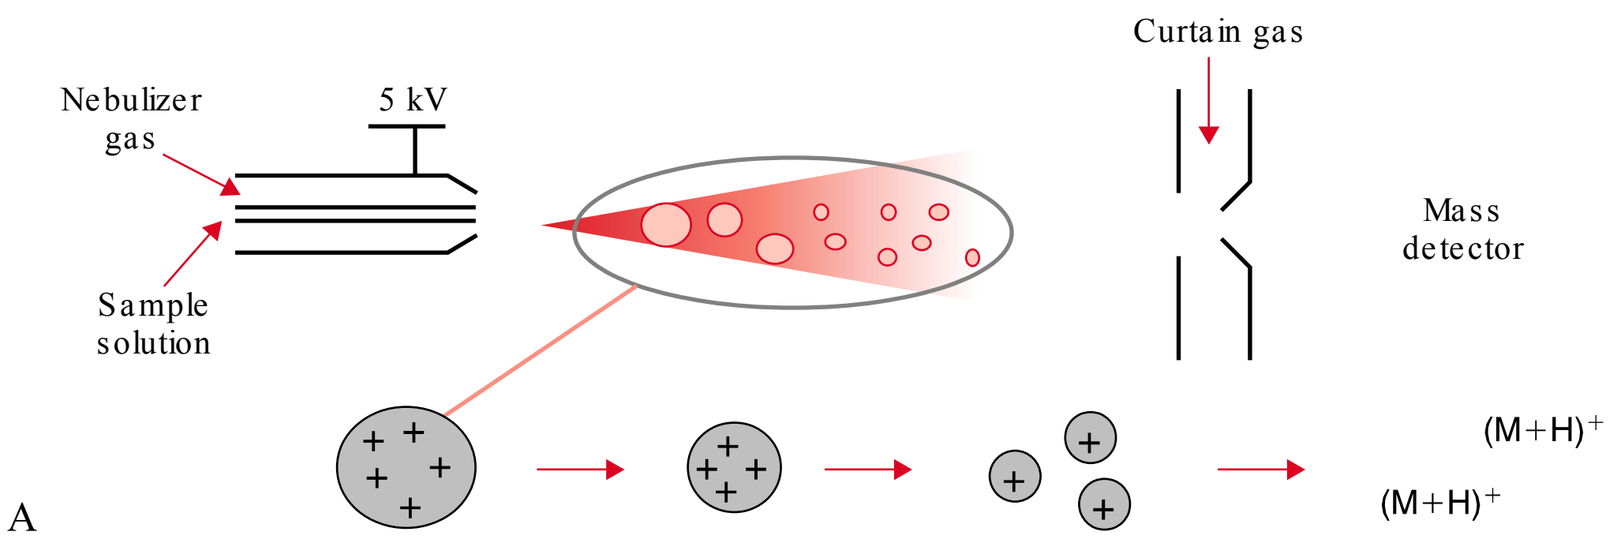

Figure 13-4 Schematics of (A) electrospray and (B) atmospheric pressure chemical ionization sources. Note the different points where ionization occurs, as described in the text.

detector. To enhance performance and minimize contamination of the mass detector, modern hardware configurations have been used to offset the probe and/or the mass detector relative to the sampling cone.

Atmospheric Pressure Chemical Ionization

APCI is similar to ESI as it (1) takes place at atmospheric pressure, (2) involves nebulization and desolvation, and (3) uses the same sample and extraction cones as ESI. Taken together, APCI and ESI represent most clinical mass spectrometry applications. The major difference between APCI and ESI lies in the mode of ionization (Figure 13-4, B). In APCI, no voltage is applied to the inlet capillary. Instead, a separate corona discharge needle is used to emit a cloud of electrons that ionize compounds after a series of ion molecule reactions, much as in CI, but with solvent molecules such as water and methanol serving as reagent molecules rather than ammonia or methane, as in CI. Products of these secondary reactions may contain clusters of solvent and analyte molecules, so a heated transfer tube or a countercurrent flow of a gas, such as nitrogen, is used to decluster the ions. As with ESI, relatively little fragmentation is seen, and APCI is used for quantitative analysis or for tandem MS.

Atmospheric Pressure Photoionization

APPI provides a complementary approach to ESI or APCI and is considered more universal across the polarity scale. It differs from APCI primarily in two respects. First, it replaces the corona discharge needle with an ultraviolet (UV) lamp (typically a 10 eV krypton discharge lamp) to generate gas phase ions via photoionization. Second, it usually includes an additional reagent gas that is easily ionized, such as toluene. As with APCI and CI, once the primary ions are produced (e.g., from toluene), they undergo a series of ion-molecule reactions that eventually result in the ionization of analyte molecules. Compared with ESI, the techniques of APPI and APCI tend to be more useful for less polar molecules, such as many steroids.

Inductively Coupled Plasma

Similar to ESI and APCI, ICP is an atmospheric pressure ionization method. However, unlike most atmospheric pressure ionization methods, which are "soft" and produce little fragmentation, ICP is the ultimate in "hard" ionization, typically leading to complete atomization of the sample during ionization. Consequently, its primary use is for elemental analysis. In the clinical laboratory, it is particularly useful for trace metal and heavy metal analysis in tissue or body fluids. ICP is extremely sensitive (e.g., parts per trillion) and is capable of extremely widedynamic ranges. The sample is typically prepared by acid digestion, and the liquid digest is introduced into the ion source via a nebulizer fed by a peristaltic pump. The nebulized sample is transmitted into hot plasma generated at atmospheric pressure by inductively coupling power into the plasma using a high-powered, radio frequency (RF) generator. A small orifice samples the plasma, and ions are transmitted to the mass analyzer through a series of differential pumping stages.

ICP-MS is comparatively free from most types of interference. However, some interferences, such as small polyatomics formed in the torch via ion-molecule reactions, cause problems. For example, ArO^+ interferes with iron at m/z 56. One solution to this problem is the dynamic reaction cell, which consists of a moderate pressure gas placed before the m/z analyzer. A reactant gas, such as NH_3, is directed into the reaction cell, where it reacts with polyatomic interferences and removes them before introduction into the mass analyzer.

Matrix-Assisted Laser Desorption/Ionization

The term matrix-assisted laser desorption/ionization (MALDI) was introduced in 1985 to describe a new soft ionization technique.[11] As currently used, the analyte is dissolved in a solution of matrix, which is a low-molecular-weight UV-absorbing compound. This solution is placed on a target that is then introduced into the mass spectrometer. The matrix-to-analyte ratio is generally around 1000 to 1. As the volatile solvents evaporate, the matrix compound crystallizes and incorporates analyte molecules. Figure 13-5 illustrates the use of a UV laser to vaporize small amounts of matrix and analyte into a plume of ions that is directed into a mass analyzer. MALDI is usually coupled with a time-of-flight (TOF) mass analyzer because MALDI produces discrete, pulsed-ion packets. This pulsed nature is well matched to the requirements of a TOF-MS analyser. Currently the most significant application of MALDI in the clinical laboratory is its use for bacterial identification.[4]

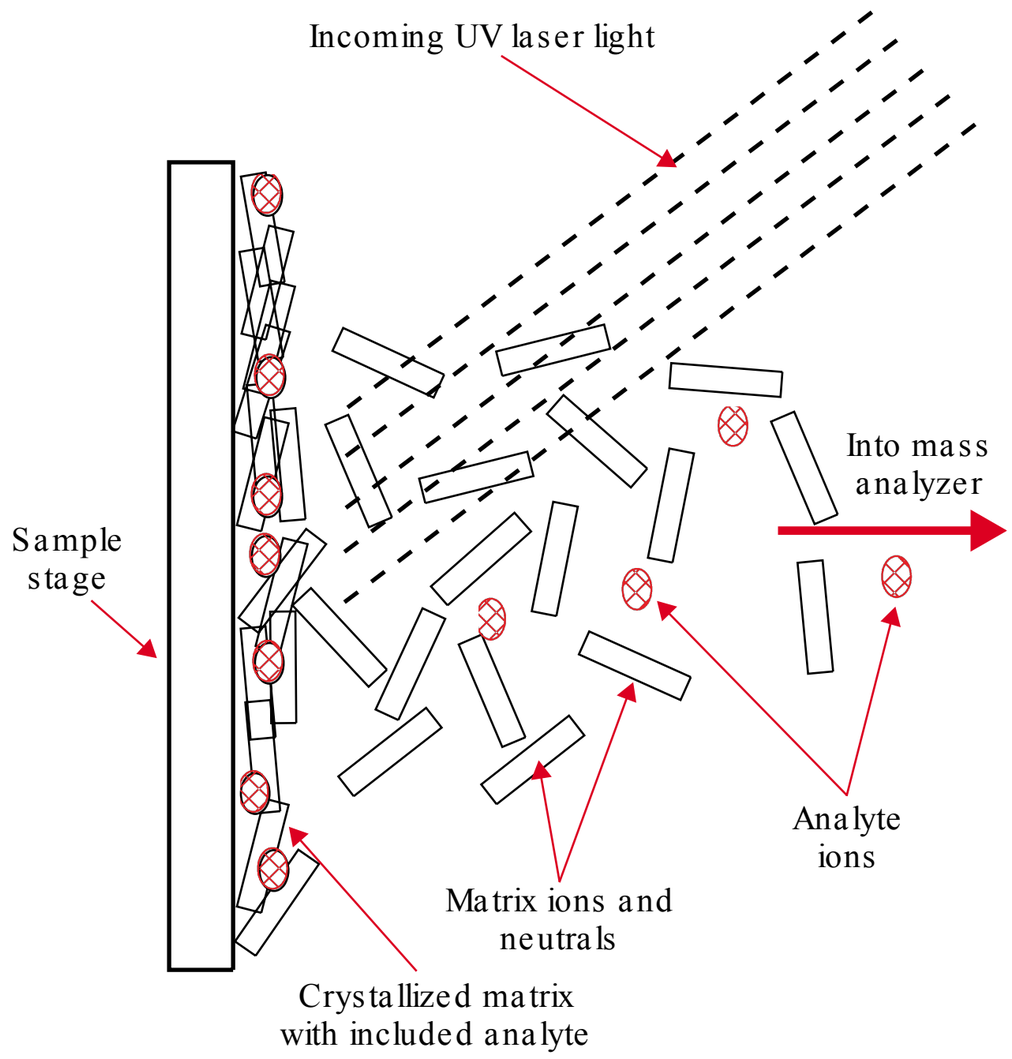

Figure 13-5 A generic view of the process of matrix-assisted laser desorption ionization. Co-crystallized matrix and analyte molecules are irradiated with an ultraviolet (UV) laser. The laser vaporizes the matrix, producing a plume of matrix ions, analyte ions, and neutrals. Gas phase ions are directed into a mass analyzer.

Vacuum System

With the exception of certain ion trap mass spectrometers, ion separation in a mass analyzer requires that the ions do not collide with any other molecules during interaction with magnetic or electrical fields. This requires the use of a vacuum from 10^{-3} to 10^{-9} **torr**, depending on the mass analyzer type. To reach this level of vacuum, a mass spectrometer uses both a mechanical vacuum and an efficient high-vacuum pump. During operation, the mechanical vacuum pump evacuates the system to a pressure at which the high-vacuum pump is then effective. A diffusion pump is the least expensive and most reliable high-vacuum pump. Turbomolecular pumps and cryopumps are also used on mass analyzers, and turbomolecular pumps have largely replaced diffusion pumps in currently marketed mass spectrometers. The high-vacuum pumps require routine maintenance for optimal operation.

Units used to express the levels of vacuum obtained include the pascal and torr. The pascal (symbol: Pa) is the SI derived unit of pressure. It is a measure of force per unit area, defined as 1 N/m^2. The torr is a unit of pressure defined as exactly 1/760 of a standard atmosphere, which in turn is defined as exactly 101325 pascals. Thus 1 torr is exactly 101325/760 ≈ 133.3 pascals.

Mass Analyzers, Ion Detectors, and Tandem Mass Spectrometers

Mass spectrometers measure m/z and not molecular mass. This has a fundamental impact on the physical operating principles of mass spectrometers and influences all aspects of (1) instrumentation design, (2) operation, and (3) interpretation of results. Most important, a peak in a mass spectrum will fall at an m/z that corresponds to a fraction of the molecular weight of the detected species if it is a multiply charged ion.

General Classes of Mass Spectrometers

Mass spectrometers are broadly classified as (1) beam-type or (2) trapping-type instruments. In a beam-type instrument, the ions make one trip through the instrument and then strike the detector, where they are destructively detected. The entire process, from the time an ion enters the analyzer until the time it is detected, generally takes microseconds to milliseconds.

In a trapping-type analyzer, ions are held in a spatially confined region of space by a combination of magnetic, electrostatic, and/or RF electrical fields. The trapping fields are manipulated in ways that allow m/z measurements to be performed. Trapping times vary from a small fraction of a second to minutes, although most clinical applications are seen at the low end of this range.

Beam-Type Designs

Beam-type mass spectrometers include (1) quadrupole, (2) magnetic sector, and (3) time-of-flight (TOF) instruments. It is convenient to categorize beam-type instruments into two broad categories: those that produce a mass spectrum by scanning the m/z range over a period of time (quadrupole and magnetic sector) and those that acquire successive instantaneous snapshots of the mass spectrum (TOF). This categorization is not definitive as certain instrument designs have been adapted to either scanning or nonscanning operation. Nevertheless, the categorization is a useful one because it covers most of the currently available instruments, and because scanning and nonscanning instruments are adapted for different optimal usages.

Quadrupole. Quadrupole mass spectrometers are sometimes known as quadrupole mass *fi*lters (QMFs). Analytically, they are currently the most widely used mass spectrometers and have displaced magnetic sector mass spectrometers as the standard instrument. Although these instruments lag behind magnetic sector instruments in terms of (1) limits of detection, (2) higher mass capabilities, (3) resolution, and (4) mass accuracy, they offer an attractive and practical mix of features, including (1) ease of use, (2) flexibility, (3) adequate performance for most applications, (4) relatively low cost, (5) noncritical site requirements, and (6) highly developed software systems.

A quadrupole mass spectrometer consists of four parallel electrically conductive rods arranged in a square array (Figure 13-6). The four rods enclose a long channel through which the ion beam passes. The beam enters near the axis at one end of the array, passes through the array in a direction generally parallel to the axis, and exits the far end of the array. The ion beam entering the quadrupole array may contain a mixture of ions of various m/z values, but only ions of a very narrow m/z range (typically $\Delta m/z < 1$) are successfully transported through the device to reach the detector. Ions outside this narrow range are ejected radially. The $\Delta m/z$ range represents a passband, analogous to the bandwidth of an interference filter in optics, which is why quadrupole mass spectrometers are often referred to as "mass filters" rather than "mass spectrometers."

Quadrupole mass spectrometers rely on a superposition of RF and direct current (DC) potentials applied to the quadrupole rods. DC voltages are applied to the electrodes in a quadrupolar pattern. For example, a positive DC potential is

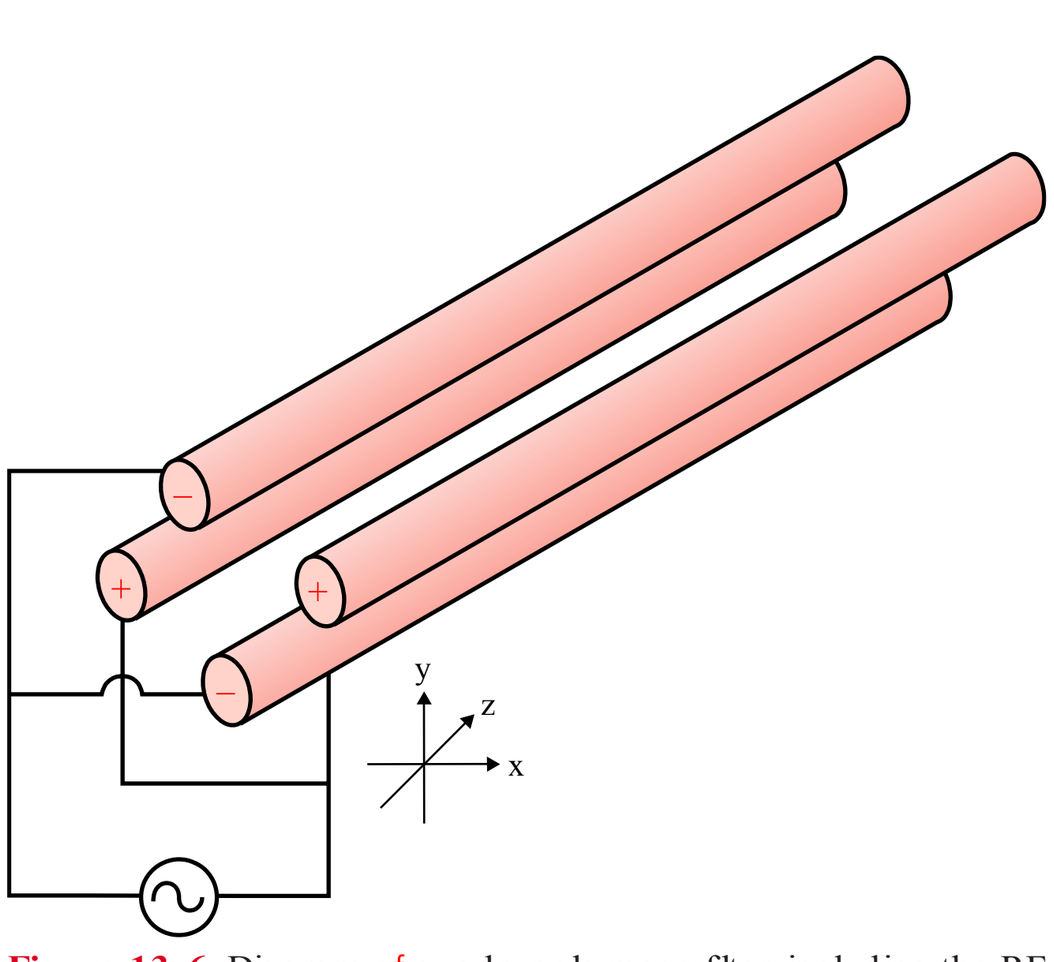

Figure 13-6 Diagram of quadrupole mass filter, including the RF part of the voltages applied to the quadrupole rods.

applied to electrodes 1 and 3, as indicated in Figure 13-7, and an equivalent negative DC potential is applied to electrodes 2 and 4. T e DC potentials are relatively small, of the order of a few volts. Superimposed on the DC potentials are the RF potentials, also applied in a quadrupolar fashion. T e RF potentials range up to the kilovolt range, and frequency is of the order of 1 MHz. T e frequency is typically fixed to a highly stable value.

T e device may be operated in a selected ion mode (SIM) mode or in a scanning mode. In an SIM mode, both DC and RF voltages are set. T is in turn sets both the center of the passband and the width of the passband. For example, the mass spectrometer may be set to pass ions of m/z 363 ± 0.5. Both the center m/z and the Δm/z are adjusted by the appropriate choice of DC and RF.

T e combination of lower and upper m/z limits establishes a passband (Δm/z) and ultimately a resolution [(m/z)/(Δm/z)]. Generally, quadrupole instruments are limited to a resolution of several thousand, which is suf cient to achieve isotopic resolution for singly charged ions of m/z as high as several thousand. However, technical advances have enabled quadrupole mass spectrometers to achieve resolutions exceeding 10,000. T e benefits of high resolution include reduction of interferences. In addition, high resolution, combined with high accuracy electronics, has enabled the measurement of "accurate masses" using quadrupole instruments. Accurate mass measurements are useful for confirmation of a chemical formula. Because of their lesser size and cost and relative simplicity of operation in comparison with magnetic sector analyzers, QMFs commonly are interfaced with both gas and liquid chromatographs.

Magnetic Sectors. Because magnetic sector mass spectrometers are rarely used in the clinical laboratory, they are mentioned here mainly for historical purposes. For a good introduction to magnetic sector technology, refer to the third edition of Tietz Textbook of Clinical Chemistry.

Time of Flight. TOF mass spectrometry (TOF-MS) is a nonscanning technique whereby a full mass spectrum is acquired as a snapshot rather than by sweeping through a sequential series of m/z values. TOF mass spectrometers are widely used and offer a number of advantages, including (1) a nearly unlimited m/z range, (2) high acquisition speed, (3) high mass accuracy, (4) moderately high resolution, (5) very sensitive, (6) absence of peak skew in the mass spectrum, and (7) reasonable cost. T ey are well adapted to pulsed ionization sources, which is an advantage in some applications, particularly with MALDI and related techniques.

Modern TOF mass spectrometers produce single-digit parts per million (ppm) mass accuracy. T is allows TOF measurements to confirm the molecular formula of a compound. TOF mass spectrometers are conceptually simple to understand as they are based on the fact that a lighter ion travels faster than a heavier ion, provided that both have the same kinetic energy. A TOF-MS resembles a long pipe. Ions are created or injected at the source end of the pipe and are then accelerated by a potential of several kilovolts. T ey travel down the flight tube and strike the detector at the far end of the flight tube. T e time it takes to traverse the tube is known as the f ight time, which is related to the m/z of the ion.

T e flight time for an ion of mass m and kinetic energy E to travel a distance L in a region free of electrical fields is given by:

$$t = L\left(\frac{m}{2E}\right)^{1/2}$$

A sample calculation for an ion of molecular weight 200 Da (3.32×10^{-25} kg) with a kinetic energy of 10 keV (1.60×10^{-15} J), traveling through a distance of 1 m, yields a flight time of 10.18 ms, and an ion of molecular weight 201 takes just 25 ns longer. To accurately capture such transitory signals, the data recording system must operate on a ≈1 ns time scale. Advances in signal processing electronics have made this practical at relatively modest cost, and this has been a major factor in the rise in popularity of TOF-MS.

TOF is inherently a pulsed technique, and it couples readily to pulsed ionization methods, with MALDI being the most common example. MALDI-TOF makes its biggest impact in the area of protein and peptide and bacterial identification. TOF is also used with continuous ion sources such as ESI with orthogonal injection from the ion source and application of a voltage pulse to a repeller to start the TOF process.

Another area where TOF-MS excels is high-mass analysis because its mass range is nearly unlimited. In MALDI-TOF, for example, it is not unusual to detect proteins with molecular weights exceeding 100,000 Da. TOF is also employed with ESI and EI ion sources. For technical reasons, ESI-TOF and EI-TOF instruments differ considerably in design from MALDI-TOF instruments, so TOF instruments are generally single-purpose instruments, as ion sources generally are not interchangeable between the different types of TOF instruments. Capability for high-mass analysis is expected to increase in importance as clinical laboratories gradually embrace proteomic-based diagnostic methods.

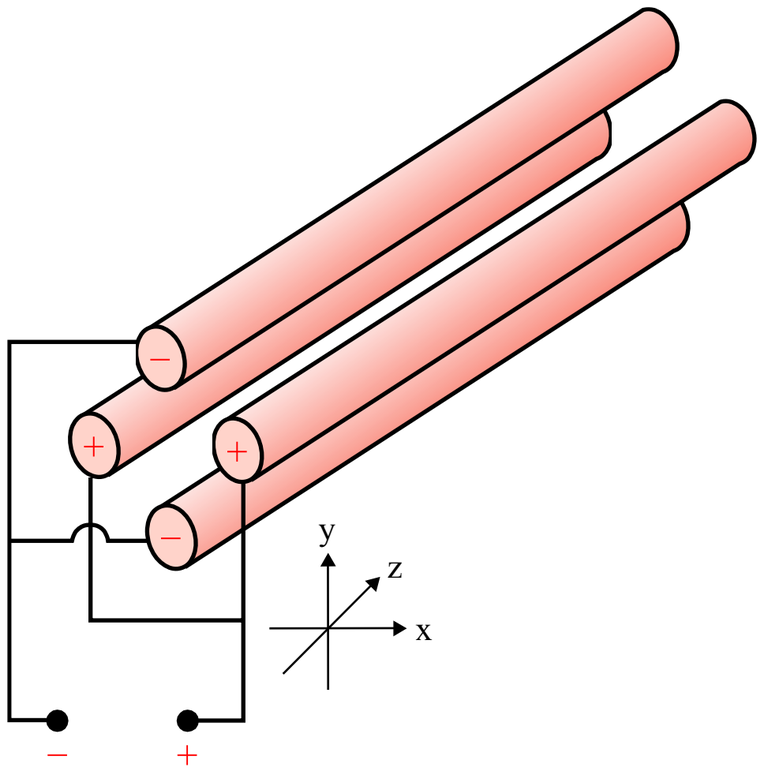

Figure 13-7 Direct current (DC) voltages applied to quadrupole rod assembly.

Absence of peak skew is another advantage of TOF-MS when it is used as a chromatographic detector. Peak skew is a distortion of the relative abundances of peaks in different parts of a mass spectrum, and this in turn distorts the shape of chromatograms derived from the mass spectral data. It arises from an interaction between the scanning function of the instrument and the changing concentrations of analytes over the chromatographic peak. TOF-MS instruments are essentially free of this artefact.

Trapping-Mass Spectrometers

In contrast to beam-type designs, these mass spectrometers are based on the trapping of ions to capture and hold ions for an extended time in a small region of space. Trapping times vary from a fraction of a second to minutes. T e division between scanning and nonscanning instruments has less meaning for ion-trapping instruments than for beam-type instruments. T e main practical difference between scanning and nonscanning instruments is related to peak skew, as discussed in the previous section on TOF. In terms of producing skewed spectra, trapping devices are more similar to nonscanning instruments, such as TOF (no skew), than to scanning instruments. T is is so because the sample is captured in an instant and then is analyzed at leisure. Because the sample is captured in an instant, no skewing of the spectra occurs, regardless of whether the m/z analysis is performed by a scanning procedure or by a nonscanning procedure.

Classes of ion traps include (1) quadrupole **ion traps** (QITs), which rely on RF fields to provide ion trapping; (2) linear ion traps, which are closely related to QITs in their operating principles; (3) ion cyclotron resonance (ICR) mass spectrometers, which rely on a combination of magnetic fields and electrostatic fields for trapping; and (4) orbitrap mass spectrometers, which use a static electrical field and rely on orbital dynamics for trapping. Of these, we will briefly describe quadrupole and linear ion traps.

Quadrupole Ion Trap. QITs are used primarily as gas chromatography (GC) or HPLC detectors. T ey are (1) relatively compact, (2) inexpensive, (3) versatile, (4) excellent for exploratory studies, (5) useful for structural characterization and (6) useful for sample identification.

Operation of the QIT is based on the same physical principle that serves as the basis for the quadrupole mass spectrometer, as described previously. Both devices make use of the ability of RF fields to confine ions. However, the RF field of an ion trap is designed to trap ions in three dimensions rather than to allow the ions to pass through as in a QMF, which confines ions in only two dimensions.

A diagram of an ion trap mass spectrometer is shown in Figure 13-8. T e trap is quite small—only a few centimeters in length. In practice, ions are trapped to be manipulated so they are dissociated into characteristic fragments and ejected to generate a mass spectrum.

Although QITs and QMFs were described at approximately the same time, the QMF initially achieved greater popularity as an analytical device. Later, two major discoveries changed the usage of the QIT. First, it was found that inclusion in the trap of a higher pressure (10^{-3} torr) of low-molecular-weight gas improved mass resolution and lowered detection limits. Second, the development of the mass-selective ejection, or mass instability scan function, improved QIT scanning. With no DC voltage and low RF voltage, ions of all m/z are stored in the QIT field. When the RF voltage is increased, ions of increasing m/z become axially unstable and leave the QIT sequentially by m/z. Ions leaving the QIT through one end cap are detected by an external electron multiplier. In addition, a lower limit of detection is obtained with QIT with the use of an axial modulation waveform to the end cap electrodes. T is oscillating voltage improves the ef ciency of ion ejection from the trap and improves mass resolution.

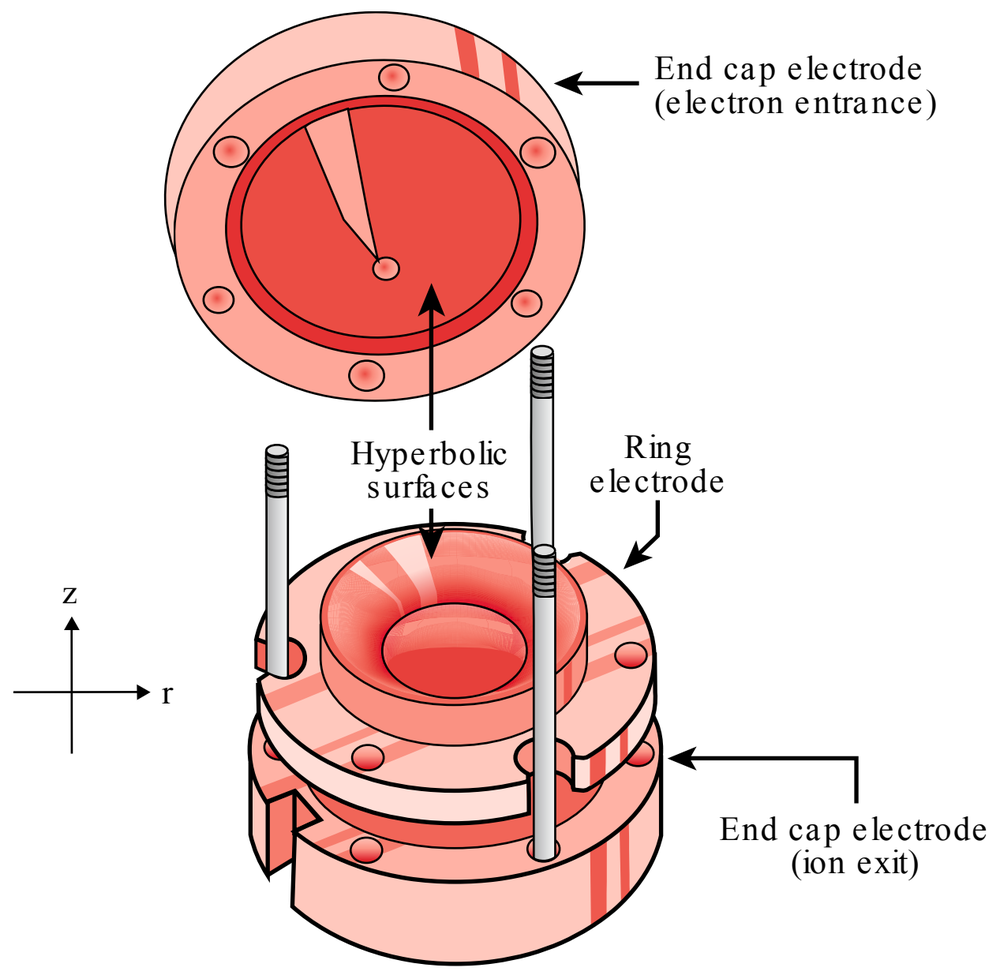

Figure 13-8 Diagram of quadrupole ion trap.

In addition to the oscillating voltage mode of operation, the QIT is capable of operation in other modes. For example, the QIT is also operated in a mass-selective storage mode that involves selecting RF and DC conditions such that only ions of one mass are stored in the QIT at any time.

T e ability to apply customized waveforms to the QIT makes it one of the most versatile of mass spectrometers, rivaled only by the ICR mass spectrometer. T is is most strongly evident in tandem mass spectrometry (MS/MS and related techniques), which will be discussed separately. It should be noted here, however, that multiple-stage MS/MS experiments (MS/MS/MS…, or MS^n) are readily performed in ion traps.

T e ability to store ions also provides other distinct advantages. When the mass-selective ejection scan approach is used, mass resolution on the QIT is inversely proportional to the scan rate. With slowing of the scan rate, mass resolution similar to that achieved in magnetic sector instruments has been accomplished. For example, this technique has been used to determine the charge state of multiply charged protein ions generated by ESI.

T e QIT also shares some advantages with TOF-MS. In particular, ion trap mass spectrometry is very sensitive.

Furthermore, sampling is decoupled from scanning, so no mass spectral peak skewing is seen in GC-MS and HPLC-MS.

Linear Ion Trap. The linear ion trap is an RF ion trap that is based on a modified linear QMF. Rather than serving as a pass-through device, as in a normal linear QMF, electrostatic fields are applied to the ends to prevent ions from exiting the device. After they are trapped, ions are manipulated in many of the same ways as in a QIT. An advantage of the linear quadrupole trap is that it generally has a higher dynamic range than a QIT. Commercial triple quadrupole mass spectrometers are available in which the third quadrupole is modified so it can function either as a QMF or as a linear trap.

Tandem Mass Spectrometers

Tandem mass spectrometry, or mass spectrometry/mass spectrometry (MS/MS), has become an important technique in clinical and analytical laboratories because it is a highly selective detection technique used for quantitative analysis of routine samples. However, it is also excellent for structural characterization and compound identification and therefore is useful for exploratory work, even when a final assay may be based on a different technology, such as an immunoassay. When coupled with the added selectivity of an HPLC, interferences in a well-designed MS/MS assay (and particularly an HPLC-MS/MS assay) are relatively uncommon. Because of its (1) low interference rate, (2) low consumable cost (as with most MS methods), and (3) high sample throughput rates, more and more clinical laboratories are purchasing and using tandem mass spectrometers.

The physical principle of tandem mass spectrometers is best understood by considering beam-type instruments—magnetic sectors and quadrupole mass spectrometers. Two mass spectrometers are arranged sequentially, with a "collision cell" placed between the two instruments. The first instrument is used to select ions of a particular m/z, called precursor ions or parent ions. The precursor ion is directed into the collision cell, where ions collide with background gas molecules and are broken into smaller ions, called product ions or daughter ions. The second mass spectrometer acquires the mass spectrum of the product ions.

The key to the high selectivity of MS/MS is that it characterizes a compound by two physical properties—precursor ion mass and product ion mass—rather than by a single property. If combined with chromatographic separation, the retention time is then added to the characterization, and the analytes are characterized by three physical properties; this eliminates most potential interferences.

As illustrated in Figure 13-9, a variety of scan functions are possible with tandem mass spectrometers. A product ion scan involves setting the first mass spectrometer, MS1, to select a given m/z and scanning through the full mass spectrum of product ions. This scan function is often used for structural characterization. A precursor ion scan reverses this relationship, with the second mass spectrometer, MS2, set to select a specific product ion, and MS1 is scanned through the spectrum. Peaks in the precursor ion scan are indicative of which parent ions produce a specific product ion—a capability that is often used to analyze for specific classes of compounds. A constant neutral loss scan consists of scanning both mass spectrometers synchronously, with a constant offset between the two mass analyzers. This scan function is selective for ions that lose a neutral fragment of a specific mass corresponding to the constant offset between the two mass spectrometers. A multiple reaction monitoring (MRM) scan is not actually a scan function but is rather a method of jumping cyclically through a table of precursor/product ion pairs. It is the tandem mass spectrometry analogue to SIM in single-stage mass spectrometry.

As with single-stage mass spectrometers, tandem mass spectrometers are roughly categorized as beam-type and trapping instruments. The most popular beam-type instrument is the triple quadrupole. In this instrument, the first quadrupole (Q1) functions as MS1, and the third quadrupole (Q3) functions as MS2. Between these two quadrupoles is another quadrupole, Q2, which functions as the collision cell rather than as a QMF.

Another technological development in tandem mass spectrometry is the combination of two TOF mass spectrometers, TOF/TOF. These instruments are highly sensitive, have excellent throughput for MALDI-MS/MS, and are especially well suited for proteomics research. However, they are unable to perform true precursor ion scans or constant neutral loss scans.

So-called hybrid mass spectrometers include a combination of two different types of mass spectrometers in a tandem arrangement. One popular approach is the combination of a quadrupole for MS1 and a TOF for MS2. As with TOF/TOF, these instruments are presently used mainly for proteomics research. They are unable to perform true precursor ion scans or constant neutral loss scans.

Detectors

With the exception of an ICR-MS, nearly all mass spectrometers use electron multipliers for ion detection. Classes of electron multipliers include (1) discrete dynode multipliers; (2) continuous dynode electron multipliers (CDEMs), also known as channel electron multipliers (CEMs); and (3) microchannel plate (MCP) electron multipliers, also known as multichannel plate electron multipliers. Although they are different in detail, all three work by using a similar multiplication process—sometimes referred to as an avalanche or cascade process—that is repeated through a chain of dynodes, numbering between 12 and 24 for most designs. The multiplication process typically produces a gain of 10^4 to 10^8, where the generation of one electron at the first dynode produces a pulse of 10^4 to 10^8 electrons at the end of the cascade. The duration of the pulse is very short—typically less than 10 nanoseconds.

An additional detector used in mass spectrometers is the Faraday cup. This is detector collects the ion current directly without going through a multiplication step. The Faraday cup is used when the ion abundance is so high that it would saturate the output of an electron multiplier. The Faraday cup is most commonly used with ICP-MS when signals are high enough to saturate an electron multiplier.

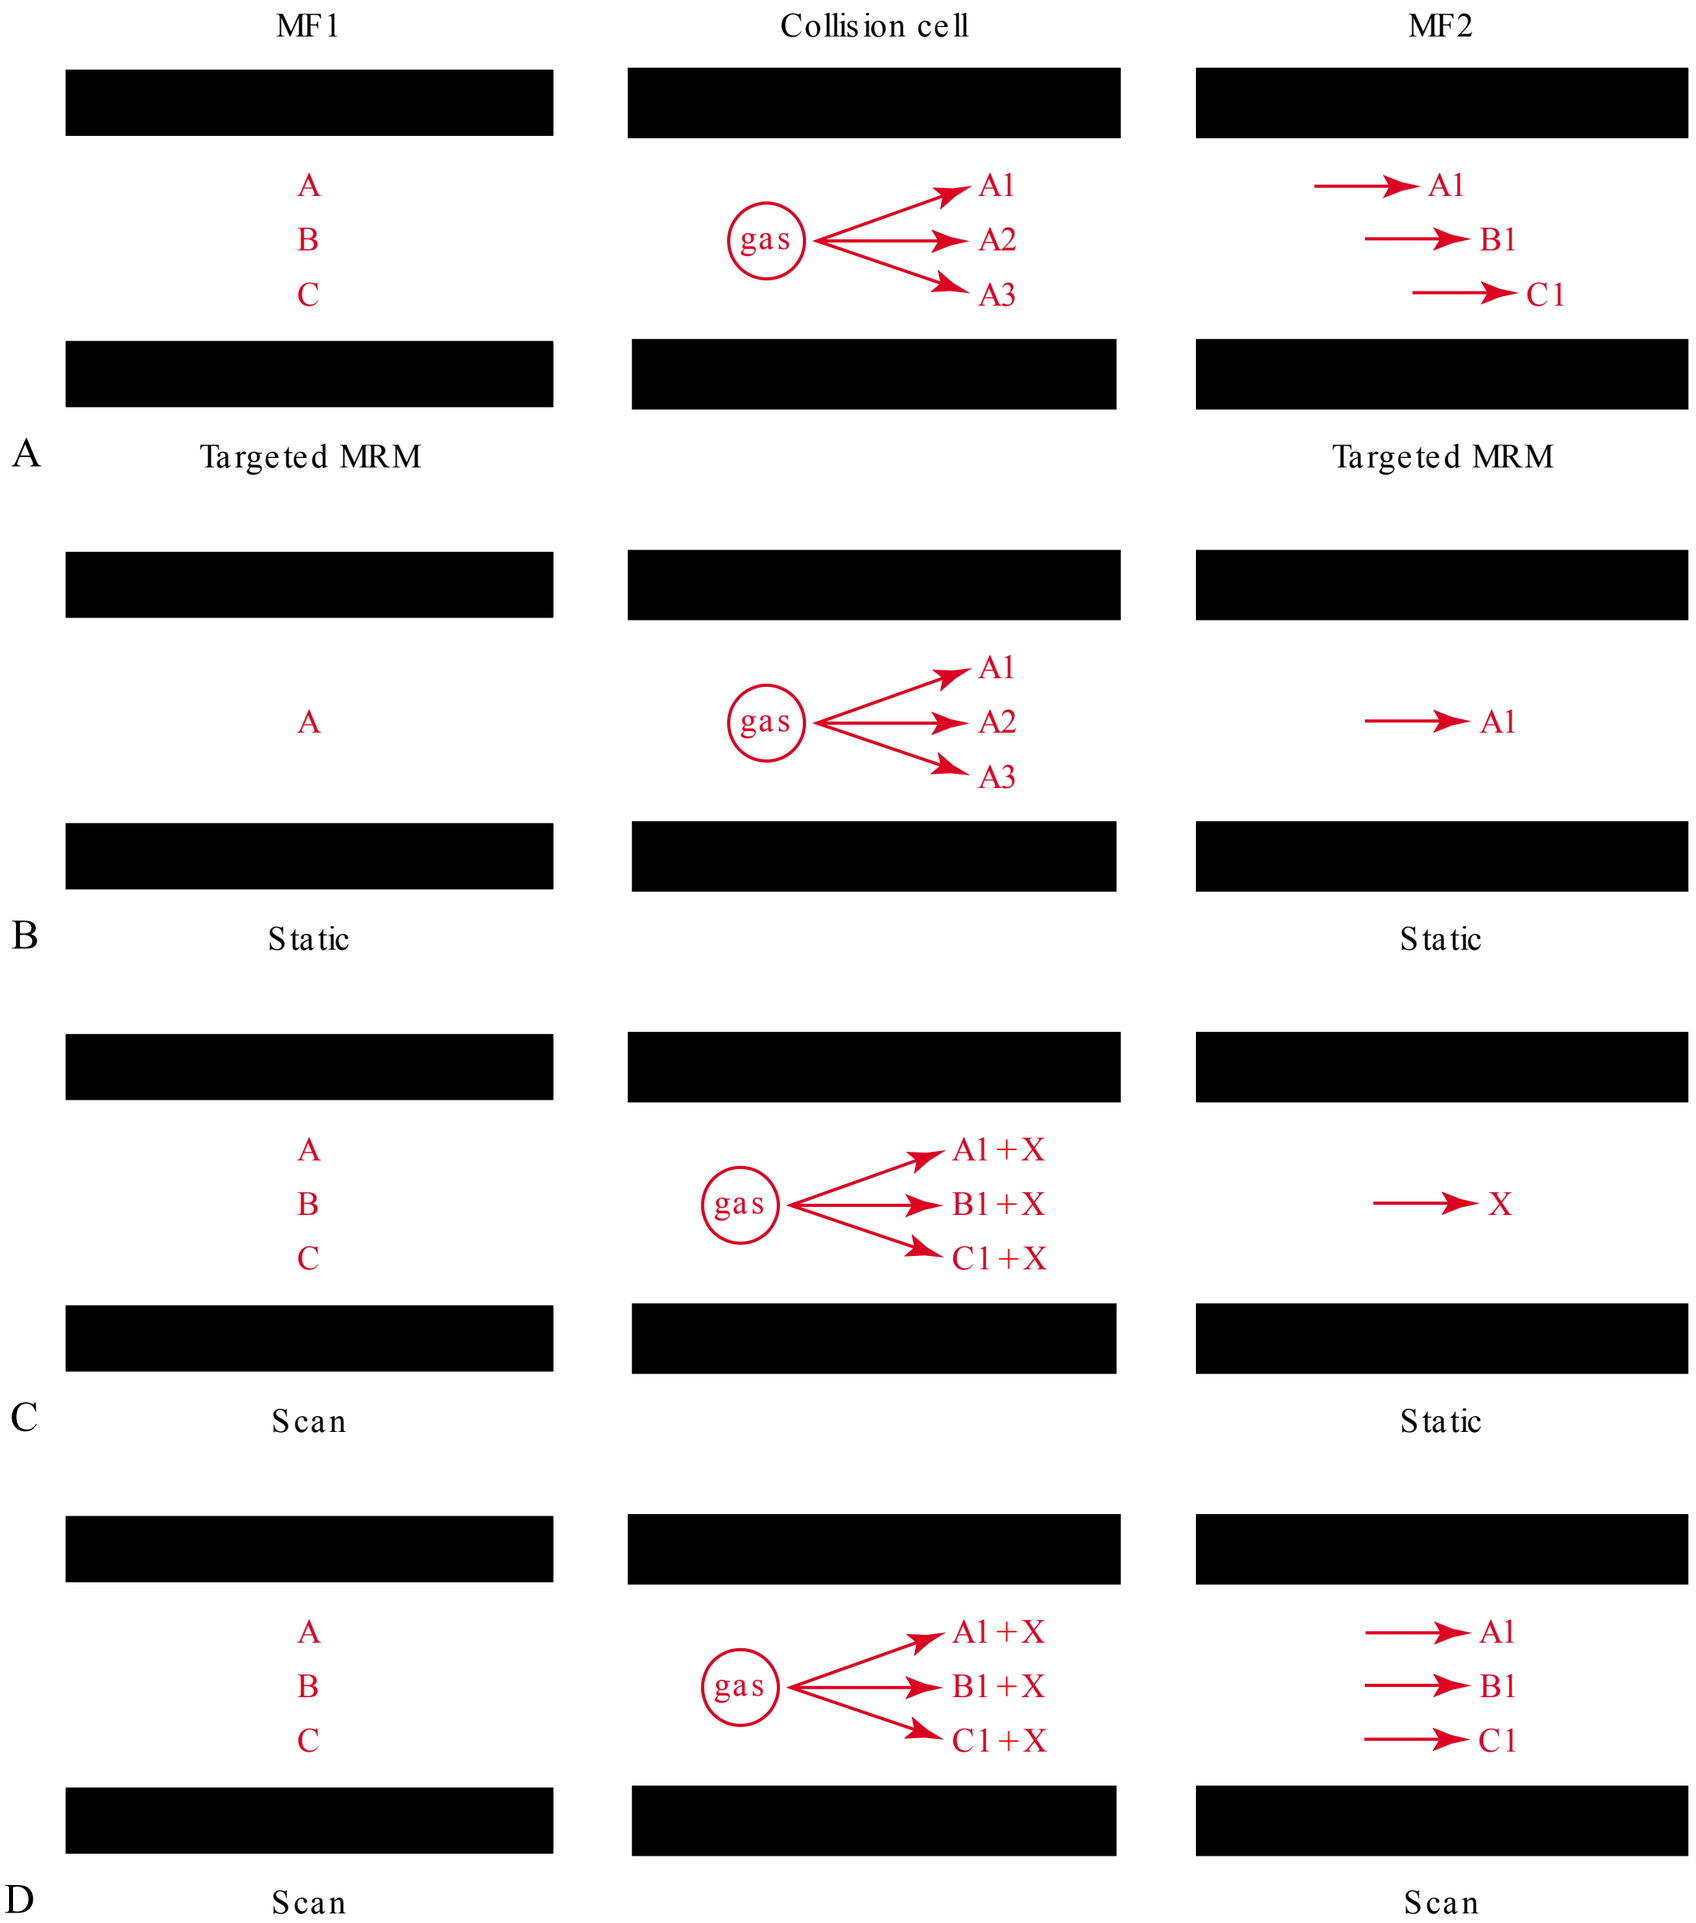

Figure 13-9 Scan modes in mass spectrometry/mass spectrometry (MS/MS). A, Multiple reaction monitoring (MRM), where A, B, C, A1, B1, and C1 are ions. Monitoring of MS/MS transitions A →A1, B →B1, and B →C1 is multiplexed. For simplicity, only the dissociation of A is shown in a collision cell in the fgure. B, MRM of a single compound, where only one MS/MS transition is monitored. C, Precursor ion scan, where A, B, C, and X are all ions. The second mass fter (MF2) is fxed to monitor the mass-to-charge ratio (m/z) corresponding to ionic species X, and the frst mass fter (MF1) is scanned through a range of m/z values. D, Constant neutral loss scan, where X is uncharged and A, B, C, A1, B1, and C1 are ions. The two mass fters are scanned with a constant m/z offset between the two, corresponding to the mass of X.

Computer and Software

In modern mass spectrometers, the raw signal produced by the instrument is digitized, and the digital signal is recorded and processed by computers and their resident software. Because of their (1) mass resolution capabilities, (2) scanning functions, (3) ability to automatically switch from positive to negative ionization modes, and (4) speed with which multiple m/z signals are monitored, modern MS instruments generate immense quantities of raw data. T us, their operation requires the use sophisticated computers and software programs.

For example, in toxicology laboratories, one important function of the data system is library searching to assist in compound identification. Several commercial libraries are available, including the (1) Wiley Registry of Mass Spectral Data (http://www.wiley.com/WileyCDA/; accessed on August 9, 2013), (2) the U.S. National Institute of Standards and

Technology (NIST) Mass Spectral Database (http://www.nist.gov/srd/nist1a.cfm/; accessed on August 9, 2013), and the (3) Pfleger, Maurer, Weber drug libraries.[1] In addition, many institutions and laboratories generate their own libraries. Important factors in the utility of using such libraries include (1) the quality and quantity of available spectra, (2) the search algorithm, and (3) whether condensed or full spectra are searched. Several library search algorithms are available; the most popular are probability-based matching and the dot product matching approach modified by the NIST. Both approaches allow assessment of match quality between observed spectra and library spectra.

The computer and software are also used to (1) integrate the signal from the mass spectrometer (usually in the form of integrated mass chromatograms), (2) generate calibration curves, (3) calculate concentration from calibration curves, (4) generate reports, and (5) perform other functions.

Clinical Applications

Mass spectrometers coupled with gas and liquid chromatographs (GC-MS and LC-MS) result in versatile analytical instruments that combine the separation power of chromatographs with the exquisite specificity and low detection limits of a mass spectrometer. Such instruments are powerful analytical tools that are used by clinical laboratories to identify and quantify organic analytes. For example, they provide structural and quantitative information on individual analytes as they elute from a chromatographic column. These coupled techniques are very sensitive, requiring only (1) nanogram, (2) pictogram, or (3) even lower quantities of an analyte for analysis. For example, one method used for analysis of estradiol using 250 μL of sample has a limit of quantitation of 1 pg/mL, corresponding to quantitation of 0.25 pg absolute.[15]

MALDI-TOF mass spectrometers and ICP ionization techniques have also enhanced the analytical capabilities of mass spectrometers. MALDI-TOF mass spectrometers have been used mainly for discovery rather than for routine analysis of patient samples. An important application of MS is its use as the primary analytical tool for discovery in the rapidly developing and expanding field of proteomics. In addition, MALDI is being used to identify bacteria.[4]

Gas Chromatography-Mass Spectrometry

Gas chromatography-mass spectrometry (GC-MS) has been used for several decades for the analysis of biological compounds. For example, it is used by the NIST as a definitive method of qualifying standard reference materials and assigning certified values to many clinical analytes (see Chapter 8). One of the most common applications of GC-MS consists of drug testing for clinical or forensic purposes. Many drugs have relatively small molecular weights and are sufficiently volatile for analysis by GC. Electron ionization with full-scan mass detection is the most widely used approach for comprehensive drug screening. Identification of unknown compounds is achieved by comparison of their full mass spectrum with a mass spectral library or database. Numerous state and federal agencies mandate that only GC-MS be used to confirm the presence of drugs in samples presumptively found to be positive by immunochemical analyses.

GC-MS has many applications beyond drug testing. For example, (1) xenobiotic compounds, (2) anabolic steroids, (3) pesticides, (4) pollutants, and (5) inborn errors of metabolism all have been analyzed by GC-MS.[13]

An important limitation of GC-MS is the requirement that compounds be sufficiently volatile to allow transfer from the solid phase to the mobile carrier gas and thus elution from the analytical column to the detector, which in this case is a mass spectrometer. Thus, many biological compounds need to be derivatized before they are amenable to analysis by GC-MS.

Liquid Chromatography-Mass Spectrometry

Compared with gas chromatographs, it is more difficult to interface liquid chromatographs with mass spectrometers because the analytes are dissolved in a liquid rather than a gas. This causes difficulties for the vacuum pumping system of the mass spectrometer. As discussed previously, several interface techniques have been developed for coupling a liquid chromatograph to a mass spectrometer, which has allowed HPLC-MS and HPLC-MS/MS to be successfully applied to a wide variety of compounds. In theory, as long as a compound is dissolved in a liquid, it is possible to introduce it into an HPLC-MS system. Thus, polar and nonpolar analytes and large molecular weight compounds, such as proteins, are analyzed using this technique.

An important area in which HPLC-MS/MS is used clinically is screening and confirmation of genetic disorders and inborn errors of metabolism.[8] Also, the ability to analyze multiple compounds in a single analytical run makes this technique an efficient tool for screening purposes. For example, electrospray tandem MS has become the recognized reference method for carnitine and acylcarnitine analysis to identify organic acidemias and fatty acid oxidation defects. It is also an excellent tool for analysis of amino acids, which then is used to diagnose various inborn errors of metabolism. In the case of carnitine and amino acid analysis, these compounds vary in their polarity, which creates problems with consistency of response factors. To address this, some procedures employ a butyl ester derivatization of the carboxyl group to force cationic character upon the amino acids, thus yielding similar ionization efficiencies for these compounds. Assays for acylcarnitines and amino acids that do not require derivatization have been described.[9,26] Other clinically relevant compounds that are amenable to HPLC-MS analysis include (1) immunosuppressants, (2) antiretrovirals, (3) biogenic amines, (4) methylmalonic acid, and (5) many steroid hormones.[3,5,14,21]

An important class of clinical applications relies on tandem mass spectrometry alone, without chromatographic separation. One method of expanded newborn screening uses butyl derivatization of acylcarnitines and amino acids, which subsequently are detected by tandem mass spectrometry. Acylcarnitines are selectively detected using an m/z 85 precursor ion scan, and amino acids are selectively detected using a 102 Da neutral loss scan.

MALDI-TOF Mass Spectrometry

MALDI-TOF has been used to analyze a large number of different classes of compounds. Its use generally falls into one of three broad categories: (1) detection of a specific compound(s), (2) identification of a protein(s) (Figure 13-10), or (3) identification of an organism. A requirement for small molecule detection by MALDI is that the molecule must (1) co-crystallize with the matrix (and not react), (2) be able to be desorbed back out of the matrix, and (3) form an ion or an adduct that is then detected.

MALDI-TOF also has been used to identify organisms such as bacteria.[4] A method has been described that attempts to identify bacteria by fingerprinting proteins that were extracted using gentle conditions.[24] The basis of this technique is that different bacteria should express unique proteins in the 2 to 20 kDa mass range, allowing classification according to the protein mass fingerprint. Historically, major problems included lack of actual protein mass information for various bacteria and lack of investigation into different strains of the same bacteria.[17] The protein mass fingerprints must be catalogued for each bacterium and determined to be completely reproducible for a given extraction method.

ICP Mass Spectrometry

ICP-MS is used for the determination of trace elements in many types of samples. However, it is known that the toxicity of an element may depend on the organic or inorganic state in which the element is present. In these cases it is more important to ascertain the concentrations of toxic species rather than the total concentration of the element. To extend the utility of this technique, GC and HPLC systems are now being coupled with ICP-MS to separate individual elemental species before ICP-MS analysis.[17]

Proteomics

The past 20 years has seen tremendous progress in genomics, with hundreds of genomes sequenced. However, this information has often failed to provide vast new understanding into cellular function—mainly because of the myriad changes that occur in the proteins produced from the genome throughout the life cycle of a cell. In the mid-1990s, MS came to the forefront of analytical techniques used to study proteins, and the term proteomics was coined. Proteomics encompasses knowledge of the (1) structure (identification), (2) function, and (3) quantitative expression of all proteins in the biochemical or biological contexts of all organisms.[12] Obtaining this knowledge is a challenging task, as every gene has potentially 100 or more distinct chemical protein isoforms. In addition, many other molecules (metals, lipids, etc.) interact with proteins in a noncovalent fashion. Therefore in a genome, such as human, a repertoire of millions of "proteins" may require identification and quantification.

Increasingly, much proteomic research has been devoted to analysis of complex mixtures of proteins from clinical samples. Currently, both instrumentation and analysis software are not sufficiently advanced to easily identify/quantify all of the proteins, including modifications, in these truly complex mixtures. As a result, much emphasis has been placed on separation methods for proteins and/or peptides, including (1) subcellular fractionation, (2) multidimensional chromatography, and (3) affinity labeling and/or purification. Through combinations of these approaches and with analysis by mass spectrometry many thousand "protein species" have been identified in a complex mixture.[10] In practice, MS/MS is used to obtain partial sequence information, followed by matching of this information with protein databases. The current state of proteomics is addressed in numerous papers every month in journals ranging from Proteomics to Clinical Chemistry. Although an exhaustive listing is impossible, several review or opinion references can serve as good starting points for exploration into the rapidly changing world of proteomics.[6,16,20,22]

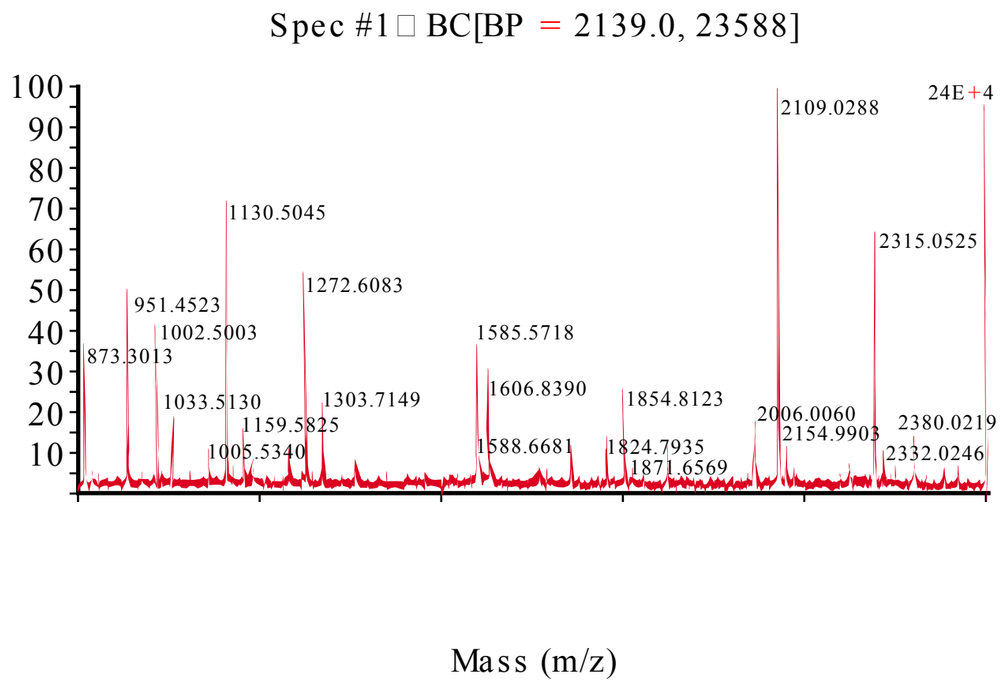

Figure 13-10 An example of a matrix-assisted laser desorption/ionization–time of flight (MALDI-TOF) spectrum showing peptides generated in a tryptic digest of a spot cored from a two-dimensional (2D) sodium dodecyl sulfate (SDS)-polyacrylamide gel electrophoresis (PAGE) gel.

Review Questions

1. Which of the following classes of mass spectrometers involves ions making a single trip through the instrument and then striking a detector where they are destructively detected?
   a. Trapping type
   b. Beam type
   c. Mass-selective ejection type
   d. Ion-cyclotron resonance type
2. In mass spectrometry, the sum of all ions produced is displayed as a function of time to yield a(n):
   a. product ion.
   b. extracted ion profile.
   c. mass spectrum.
   d. total ion chromatogram.
3. Which type of ionization technique uses an electron beam to ionize the reagent gas and produce a reactive species as a result of ion-molecule reactions?
   a. Electron
   b. Chemical
   c. Electrospray
   d. Inductively coupled plasma

4. Inductively coupled plasma mass spectrometry is typically used for:
   a. determination of trace elements.
   b. identification of a protein.
   c. drug identification.
   d. isotopic labeling of molecules.
5. T e most widely used ionization approach coupled with gas chromatography and used for comprehensive drug screening is:
   a. electrospray ionization.
   b. chemical ionization.
   c. MALDI.
   d. electron ionization.
6. Currently, the most widely used mass spectrometer, which is flexible, easy to use, and of relatively low cost, is the:
   a. quadrupole mass spectrometer.
   b. time-of-flight instrument.
   c. magnetic sector mass spectrometer.
   d. linear ion trap mass spectrometer.

CHAPTER

14 Enzyme and Rate Analyses*

Renze Bais, Ph.D., F.F.Sc. (R.C.P.A.), and Mauro Panteghini, M.D.

Objectives

1. Define the following terms:
   - Activator
   - Active site
   - Apoenzyme
   - Catalyst
   - Coenzyme
   - Denaturation
   - Enzyme
   - First- and zero-order kinetics
   - Holoenzyme
   - Inhibition (reversible/irreversible/antibody)
   - International unit
   - Isoenzyme
   - Isoform
   - Katal
   - K_m
   - Substrate
   - V_{max}
2. State how enzymes are classified in the IUB system.
3. List and describe the four components of enzyme structure.
4. Describe completely the active site of an enzyme, including the size of the site, the location within the enzyme structure, the binding involved between site and substrate, and the specificity of the site for the substrate.
5. Explain the genetic origins of isoenzymes, including the difference between the formation of allozymes and the formation of hybrid isoenzymes, isoenzyme tissue localization, and changes in isoenzyme distribution in relation to development and disease.
6. List six nongenetic changes that produce enzyme isoforms.
7. State how enzyme activity is described with international units and SI-derived units.
8. Describe the effects that the following factors have on an enzyme-catalyzed reaction:
   - Enzyme concentration
   - Substrate concentration in single- and two-substrate reactions
   - pH
   - Reaction temperature
   - Inhibitors
   - Activators
   - Coenzymes
9. Compare first-order with zero-order enzyme reaction kinetics with regard to dependence on substrate or enzyme concentration and how the reaction rate and kinetics vary with time.
10. Express the Michaelis-Menten curve using an equation; describe each component of the equation, and draw and label a Michaelis-Menten curve.
11. Express how V_{max} is calculated using a reciprocal form of the Michaelis-Menten equation; draw and label a Lineweaver-Burk plot.
12. Describe a consecutive enzymatic reaction and its analytical use; state the need for the primary reaction in this assay to be rate limiting.
13. Compare competitive, noncompetitive, and uncompetitive inhibitors, including the effect on reaction velocity and the location of attachment to the enzyme; using a Lineweaver-Burk plot, illustrate how each of the three types affects enzymatic reaction rate.
14. Compare fixed-time and continuous-monitoring methods of enzyme reaction rate measurement, including advantages and limitations.
15. Describe the self-indicating reaction used for substrate measurement.
16. Define optimization and standardization of enzyme reaction rates, including how these are performed in the laboratory and issues associated with each.
17. List the uses and advantages of immunoassays to measure enzyme mass concentration.
18. Describe the following enzyme methods used to measure metabolites, give examples of enzymes used in this measurement, and state the limitations, if any, of each method:
    - Equilibrium method
    - Kinetic method
    - Two-point kinetic method
    - Bisubstrate reaction
    - Enzyme immunoassay
19. Give an example of how an immobilized enzyme is used in measurement techniques such as potentiometry and polarography.
20. List and describe five analytical techniques used to measure isoenzymes or isoforms; state the principle of selective chemical inactivation.

*The authors gratefully acknowledge the original contributions by Drs. A. Ralph Henderson and Donald W. Moss, upon which portions of this chapter are based.

Key Words and Definitions

Activator Small molecule or ion that increases the rate of an enzyme-catalyzed reaction by promoting formation of the most active state of the enzyme or of other reactants such as the substrate.

Active center/Active site That part of an enzyme formed by the tertiary structure at which the noncovalent binding of substrate occurs to form the intermediate enzyme/substrate complex.

Biomarker In medicine, a biomarker is a biological compound that is used as an indicator of a particular disease state or some other physiological state of an organism.

Catalyst A substance that modifes and increases the rate of a chemical reaction without being permanently changed or consumed; an enzyme is a protein catalyst of biological origin.

Clinical enzymology The branch of medical science that deals with the biochemical nature and activity of enzymes of clinical relevance.

Coenzyme A small molecule (some contain structures derived from vitamins) that is required for some enzyme-catalyzed reactions to occur; is temporarily or permanently bound to the enzyme.

Enzyme A protein with catalytic properties.

First-order kinetics In an enzymatic reaction, as more substrate is consumed, the reaction rate declines and becomes dependent on substrate concentration; this is a phase of frst-order dependence on substrate concentration when the rate of the reaction is proportional to the concentration of substrate or when the enzyme concentration is fxed and the substrate concentration is varied.

Inhibitor A substance that reduces the rate of an enzymatic reaction and is classifed as reversible or irreversible.

International unit The quantity of enzyme that catalyzes one micromole of substrate per minute.

Isoenzyme A form of an enzyme that originates at the level of the gene that encodes the structure of the enzyme protein and that is distinguished by certain physical properties.

Isoform A form of an enzyme that is modifed by post-translational processing.

Katal The quantity of an enzyme that catalyzes a reaction rate of one mole of substrate per second.

Lineweaver-Burk plot A plot of the reciprocal of the velocity of an enzyme catalyzed reaction (ordinate; y-axis) against the reciprocal of the substrate concentration (abscissa; x-axis).

Michaelis-Menten constant (K_m) A constant for a given enzyme acting under given conditions; the experimentally determined substrate concentration at which the enzymatic reaction velocity equals ½ of the maximum velocity of the enzymatic reaction.

Product The substance produced by the enzyme catalyzed conversion of a substrate

Substrate A reactant in an enzyme-catalyzed reaction that binds to the active center of an enzyme

Zero-order kinetics In an enzymatic reaction, when the reaction rate is constant at maximum value, the reaction rate depends only on enzyme concentration and is independent of substrate concentration; the rate of reaction is proportional to the zero power of the substrate concentration.

Enzymes are proteins with catalytic properties; **clinical enzymology** is the application of the science of enzymes to the diagnosis and treatment of disease. In medicine, a **biomarker** is a biological compound that is used as an indicator of a particular disease state or some other physiological state of an organism. As such, enzymes are the original clinical biomarkers.[28] The principles of clinical enzymology will be introduced and discussed in this chapter, as will information on how enzymes are measured and how they are used as analytical reagents in various types of rate analysis. Individual topics include (1) basic principles, (2) enzyme kinetics, (3) analytical enzymology, and (4) rate analyses.

Basic Principles

This section begins with a presentation of enzyme nomenclature, which is followed by a discussion of enzymes as proteins and **catalysts**.

Enzyme Nomenclature

Historically, individual enzymes were identifed using the name of the substrate or group upon which they act and then adding the suffix -ase. For example, the enzyme hydrolyzing urea was urease. Later, the type of reaction involved was also identifed, as in (1) carbonic anhydrase, (2) d-amino acid oxidase, and (3) succinate dehydrogenase. In addition, some enzymes had been given empirical names such as trypsin.

Because this combination of trivial common names and semi-systematic names was found to be inadequate, in 1955 the International Union of Biochemistry (IUB) appointed an Enzyme Commission (EC) to study the problem of enzyme nomenclature. Its subsequent recommendations, with periodic updating, provide a rational and practical basis for identifying all enzymes now known and enzymes that will be discovered in the future (http://www.chem.qmw.ac.uk/iubmb/enzyme/; accessed August 6. 2013).[14]

With the IUB system, a systematic and trivial name is provided for each enzyme. The systematic name describes the nature of the reaction catalyzed and is associated with a unique numerical code. The trivial or practical name, which may be identical to the systematic name but is often a simplifcation of it, is suitable for everyday use. The unique numerical designation for each enzyme consists of four numbers, separated by periods (e.g., 2.2.8.11), and is prefixed by the letters EC, denoting Enzyme Commission. The first number defines the class to which the enzyme belongs. All enzymes are assigned to one of six classes, characterized by the type of reaction they catalyze: they are (1) oxidoreductases, (2) transferases, (3) hydrolases,

(4) lyases, (5) isomerases, and (6) ligases. The next two numbers indicate the subclass and the sub-subclass to which the enzyme is assigned. For example, these may differentiate the amino-transferring subclass from the phosphate-transferring category, or the ethanol acceptor sub-subclass from that accepting acyl groups. The last number is the specific serial number given to each enzyme within its sub-subclass.

Several readily accessible databases contain comprehensive lists of enzymes, their classification, and other information. These include BRENDA (http://www.brenda-enzymes.org/index.php4; accessed August 6, 2013), ExPASy (http://www.expasy.org/; accessed August 6, 2013), and ExplorEnz (http://www.enzyme-database.org/; accessed August 6, 2013). Table 14-1 lists some selected enzymes of clinical interest, identified by (1) trivial, (2) abbreviated, and (3) systematic names and (4) code numbers.

Although it is not recommended by the EC, it is a common and convenient practice to use capital letter abbreviations for the names of certain enzymes, such as ALT (formerly GPT) for alanine aminotransferase, AST for aspartate aminotransferase, LD for lactate dehydrogenase, and CK for creatine kinase (see Table 14-1).

Enzymes as Proteins

All enzyme molecules have (1) primary, (2) secondary, (3) tertiary, and (4) quaternary structures. The primary structure, the linear sequence of amino acids linked through their α-carboxyl and α-amino groups by peptide bonds, is specific for each type of enzyme molecule (see Chapter 18). Secondary structure refers to the conformation of limited segments of the polypeptide chain such as (1) α-helices, (2) β-pleated sheets, (3) random coils, and (4) β-turns. The arrangement of secondary structural elements and amino acid side chain interactions that defines the three-dimensional structure of the folded protein is referred to as its tertiary structure. In many cases, biological activity, such as the catalytic activity of enzymes, requires two or more folded polypeptide chains (subunits) to associate to form a functional molecule. The arrangement of these subunits defines the quaternary structure. The subunits may be copies of the same polypeptide chain, or they may represent distinct polypeptides.

The application of physical methods, such as X-ray crystallography and multidimensional nuclear magnetic resonance (NMR), has provided structural insights upon which enzyme mechanisms have been built. Furthermore, the tools of molecular biology, such as molecular cloning, have enabled the purification and characterization of enzymes that previously were available only in minute amounts. Molecular biology also enables the (1) manipulation of the amino acid sequence of enzymes, (2) site-directed mutagenesis (substituting one amino acid residue for another) and (3) deletion mutagenesis (eliminating sections of the primary structure). This has enabled the identification of chemical groups that participate in ligand binding and in specific chemical steps during catalysis.

In general, no feature of primary structures, such as repetition of particular amino acid sequences, is common to all enzyme molecules. However, considerable homologies of sequence are found between enzymes that appear to share a common evolutionary origin, such as the proteases trypsin and chymotrypsin, and similarities of sequence are even more marked among the members of a family of isoenzymes. The amino acid sequence in the immediate neighborhood of the **active center** of the enzyme (discussed later) is often closely similar in enzymes of related function (e.g., the serine proteases are so called because all of them have this amino acid in the active center).

Enzyme molecules differ in the proportions of secondary structures they contain. Regarding tertiary structure, different

TABLE 14-1 Enzyme Commission (EC) Numbers, Systematic and Trivial Names, and Frequently Adopted Abbreviations of Enzymes of Major Clinical Importance

EC Number	Systematic Name	Trivial Name	Abbreviation
1.1.1.27	L-Lactate: NAD^+ oxidoreductase	Lactate dehydrogenase	LD
1.1.1.49	D-Glucose-6-phosphate: $NADP^+$ oxidoreductase	Glucose-6-phosphate dehydrogenase	
1.4.1.3	L-Glutamate: $NAD(P)^+$ oxidoreductase (deaminating)	Glutamate dehydrogenase	GLD
2.3.2.2	(γ-Glutamyl)-peptide: amino acid γ-glutamyltransferase	γ-Glutamyltransferase	GGT
2.6.1.1	L-Aspartate: 2-oxoglutarate aminotransferase	Aspartate aminotransferase (transaminase)	AST
2.6.1.2	L-Alanine: 2-oxoglutarate aminotransferase	Alanine aminotransferase (transaminase)	ALT
2.7.3.2	ATP: creatine N-phosphotransferase	Creatine kinase	CK
3.1.1.3	Triacylglycerol acylhydrolase	Lipase	LPS
3.1.1.7	Acetylcholine acetylhydrolase	Acetylcholinesterase, true cholinesterase, choline esterase I	—
3.1.1.8	Acylcholine acylhydrolase	Pseudocholinesterase, butyryl cholinesterase, choline esterase II (serum cholinesterase)	CHE
3.1.3.1	Orthophosphoric-monoester phosphohydrolase (alkaline optimum)	Alkaline phosphatase	ALP
3.1.3.2	Orthophosphoric-monoester phosphohydrolase (acid optimum)	Acid phosphatase	ACP
3.1.3.5	5′-Ribonucleotide phosphohydrolase	5′-Nucleotidase	NTP
3.2.1.1	1,4-α-D-Glucan glucanohydrolase	Amylase	AMY
3.4.21.4		Trypsin	TRY
4.1.2.13	D-Fructose-1,6-bisphosphate D-glyceraldehyde-3-phosphate-lyase	Aldolase	ALD

types of enzyme molecules are as individually characteristic as their primary structures; however, some common features can be seen. For example, enzyme molecules are roughly globular in overall shape, with a preponderance of polar amino acid side chains on the outside of the molecule and nonpolar side chains in the interior. These ionizable residues in contact with the surrounding medium are responsible for many of the properties of the enzyme. In addition, covalent disulfide bridges link different parts of the polypeptide chains in some enzyme molecules. The biological activity of a protein molecule depends generally on the integrity of its structure, and any condition that changes the shape of the protein is generally accompanied by loss of activity through a process known as denaturation. If the process of denaturation is minimal, it may be reversed with the recovery of enzyme activity upon removal of the denaturing agent. However, prolonged or severe denaturing conditions typically results in irreversible loss of activity. Denaturing conditions include (1) elevated temperatures, (2) extremes of pH, (3) changes in ionic strength, and (4) chemical additions. Heat inactivation of most enzymes takes place at an appreciable rate at room temperature and in most cases becomes almost instantaneous above 60 °C. The polymerases are an exception; they retain activity at temperatures as high as 90 °C—a property that has been used in the polymerase chain reaction (see Chapter 48). Low temperatures are used to preserve enzyme activity, especially in aqueous solutions such as serum. Extremes of pH also cause unfolding of enzyme molecular structures and, except for a few exceptions, should be avoided when enzyme samples are preserved. Addition of chemicals, such as urea and detergents, disrupts hydrogen bonds and hydrophobic interactions so that exposure of enzymes to strong solutions of these reagents results in inactivation.

Specifcity and the Active Center

With the exception of enzymes such as (1) proteases, (2) nucleases, (3) amylases and (4) polymersases which act on macromolecular substrates, enzyme molecules are considerably larger than the molecules of their substrates. Consideration of the structure of an enzyme's active site and of its relationship to the structures of the enzyme's substrate(s) in its ground and transition states is necessary to understand the rate enhancement and specificity of the chemical reactions performed by the enzyme. The active site of an enzyme will vary between enzymes, but some general conditions apply[5]:

1. The active site of an enzyme is relatively small compared with the total volume of the enzyme molecule because its structure may involve less than 5% of the total amino acids in the molecule.
2. Active sites of enzymes are three-dimensional structures that are formed as a result of the overall tertiary structure of the protein. This occurs when the amino acids and cofactors in the active site of an enzyme are spatially structured in an exact three-dimensional relationship with respect to one another and to the structure of the substrate molecule.
3. Typically, the attraction between the molecules of the enzyme and its substrate molecules is noncovalent binding. Physical forces used in this type of binding include (1) hydrogen bonding, (2) electrostatic and hydrophobic interactions, and (3) van der Waals forces.
4. Active sites of enzymes typically are noted in clefts and crevices in the protein. This is excludes bulk solvent and reduces the catalytic activity of the enzyme.
5. The specificity of substrate binding is a function of the exact special arrangement of atoms in the enzyme active site, which complements the structure of the substrate molecule.

Isoenzymes and Other Multiple Forms of Enzymes

An **isoenzyme** is defined as "one of a group of related enzymes catalyzing the same reaction but having different molecular structures and characterized by varying physical, biochemical, and immunologic properties." However, the IUB recommends that use of the term isoenzyme be restricted to forms that originate at the level of the genes that encode the structures of the enzyme proteins in question.[4]

Isoenzymes may occur within a single organ or even within a single type of cell. These forms are distinguished on the basis of differences in various physical properties, such as electrophoretic mobility and resistance to chemical or thermal inactivation. They often have significant quantifiable differences in catalytic properties, but all forms of a particular enzyme retain the ability to catalyze its characteristic reaction.

The existence of multiple forms of enzymes in human tissue has important implications in the study of human disease. Identifying the presence in different organs of isoenzymes with distinctive properties facilitates our understanding of organ-specific patterns of metabolism, but genetically determined variations in enzyme structure between individuals account for such characteristics as differences in sensitivity to drugs and differences in metabolism (see Chapter 48), which manifest as hereditary metabolic diseases. For diagnostic enzymology, the existence of multiple forms of enzymes, whether as the result of genetic or nongenetic causes, provides opportunities to increase the diagnostic specificity and sensitivity of enzyme assays in body fluid samples.

Similar to other proteins, enzymes usually elicit the production of antibodies when they are injected into animals of a species other than those in which they originate. Even small structural differences between closely similar molecules, such as the members of a family of isoenzymes, are often sufficient to render them antigenically distinct, allowing antibodies to be produced that are specific to a single type of molecule. The availability of enzyme-specific antisera is responsible for a wide range of methods in enzyme analysis, some of which—such as immunoassay—do not depend on the catalytic activity of the enzyme molecules. The availability of immunochemical methods has been particularly important in the analysis of isoenzyme mixtures. Many commercial immunoassays now use monoclonal antibodies to increase specificity.

Genetic Origins of Enzyme Variants

True isoenzymes result from the existence of more than one gene locus coding for the structure of the enzyme protein.

Many human enzymes (perhaps more than one-third) are known to be determined by more than one structural gene locus. Genes at different loci have undergone differential modifications during the course of evolution, so that enzyme proteins coded by them no longer have identical structures but are considered isoenzymes.

The multiple genes that determine a particular group of isoenzymes are not necessarily closely linked on one chromosome. For example, the structural genes that code for human salivary and pancreatic amylases are located on chromosome 1, whereas the genes that code for cytoplasmic and mitochondrial malate dehydrogenase are carried on chromosomes 2 and 7, respectively. Among the enzymes of clinical importance that exist as isoenzymes because of the presence of multiple-gene loci are lactate dehydrogenase, creatine kinase, α-amylase, and some forms of alkaline phosphatase.

Biochemically, some enzymes are present in molecular forms that differ from one individual to another because of the existence of alternative alleles that are inherited according to mendelian laws. These give rise to gene products with the same function, and isoenzymes that result from the existence of allelic genes are termed allozymes. The proportion of human gene loci subject to allelic variation is considerable, and the probability that individual human beings will differ to some degree in their isoenzyme patterns is correspondingly high.

The number of allelic variants and the frequency with which particular variants occur within the population vary considerably from one enzyme to another. For example, mutations at either of the two principal loci that determine human lactate dehydrogenase are extremely rare, but a high incidence of mutant alleles occurs at the single locus that determines the structure of placental alkaline phosphatase. More than 400 mutations in the glucose-6-phosphate dehydrogenase gene have now been identified on the X chromosome (up-to-date genetic information on this and other enzymes is available from the Online Mendelian Inheritance in Man [OMIM] database at http://www.ncbi.nlm.nih.gov/Omim/; accessed August 6, 2013). Some of these alleles are extremely rare, whereas others occur with appreciable frequency in particular populations or geographical locations. When isoenzymes, because of variation at a single locus, occur with appreciable frequency in a human population, the population is said to be polymorphic with respect to the isoenzymes in question.

Another category of multiple molecular forms arises when enzymes are oligomeric and consists of molecules made up of subunits. The association of different types of subunits in various combinations gives rise to a range of active enzyme molecules. When the subunits are derived from different structural genes—multiple loci or multiple alleles—the hybrid molecules so formed are called hybrid isoenzymes. The ability to form hybrid isoenzymes is evidence of considerable structural similarities between the different subunits. Hybrid isoenzymes are formed in vitro, but they are also formed in vivo in cells in which different types of constituent subunits are present in the same subcellular compartment.

The number of different hybrid isoenzymes that are formed from two nonidentical protomers depends on the number of subunits in the complete enzyme molecule. For a dimeric enzyme, one mixed dimer (hybrid isoenzyme) is formed. If the enzyme is a tetramer, three heteropolymeric isoenzymes may be formed (Figure 14-1). Examples of hybrid isoenzymes include the mixed MB dimer of creatine kinase and the three hybrid isoenzymes—LD-2, LD-3, and LD-4—of lactate dehydrogenase.

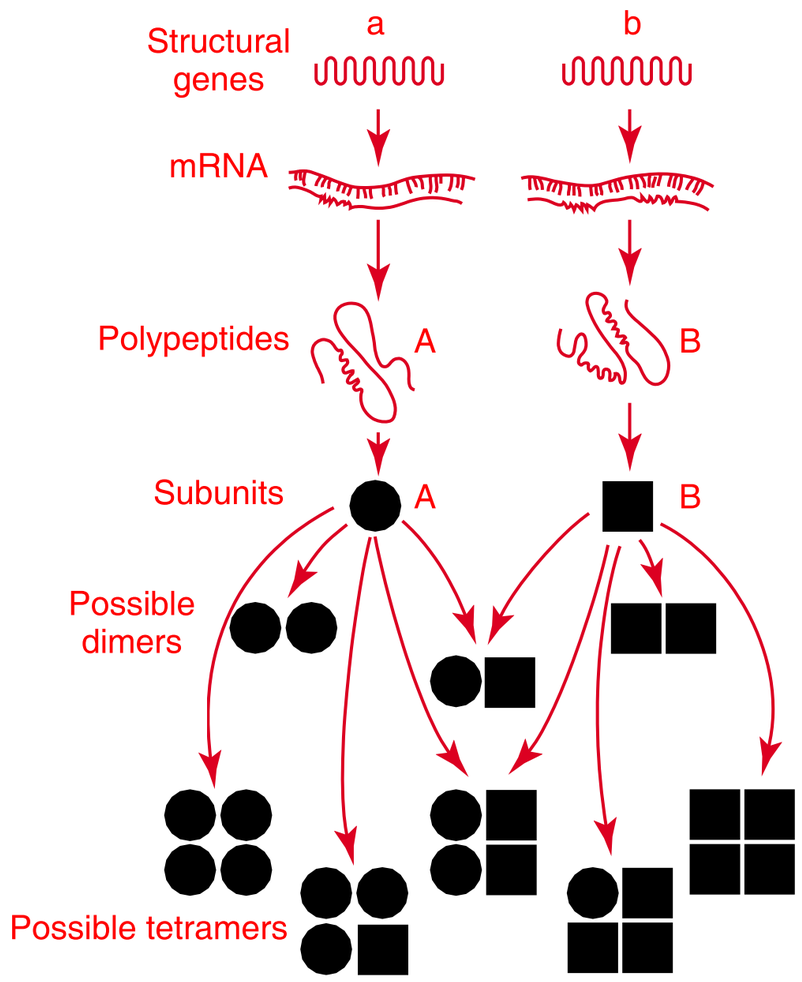

Figure 14-1 Diagram showing the origin of isoenzymes, assuming the existence of two distinct gene loci. When the active enzymes are polymers that contain more than one subunit, hybrid isoenzymes consisting of mixtures of different subunits may be formed. One such isoenzyme can be formed in the case of a dimeric enzyme, such as creatine kinase, and three if the enzyme is a tetramer (e.g., lactate dehydrogenase). In both cases, two homopolymeric isoenzymes can also exist. (From Moss DW. Isoenzyme analysis. London: The Chemical Society, 1979. Reprinted by permission of The Royal Society of Chemistry.)

Nongenetic Causes of Multiple Forms of Enzymes

Post-translational modifications of enzyme molecules give rise to multiple forms known as **isoforms** (Figure 14-2). For example, serum isoforms of creatine kinase are formed as part of the normal clearance process of the cell. Human myocardial and skeletal muscle tissues have the CK-MM and CK-MB isoenzymes, which are modified upon release into the circulation. This modification is due to sequential removal of the C-terminal amino acid, lysine, by the action of carboxypeptidase (see Chapter 19 for additional details).

Modifications that affect nonprotein components of enzyme molecules may lead to molecular heterogeneity. Many enzymes are glycoproteins, and variations in carbohydrate side chains are a common cause of nonhomogeneity of preparations of these enzymes. Some carbohydrate moieties, notably N-acetylneuraminic acid (sialic acid), are strongly ionized and consequently have a profound effect on some properties of enzyme molecules. For example, removal of terminal sialic

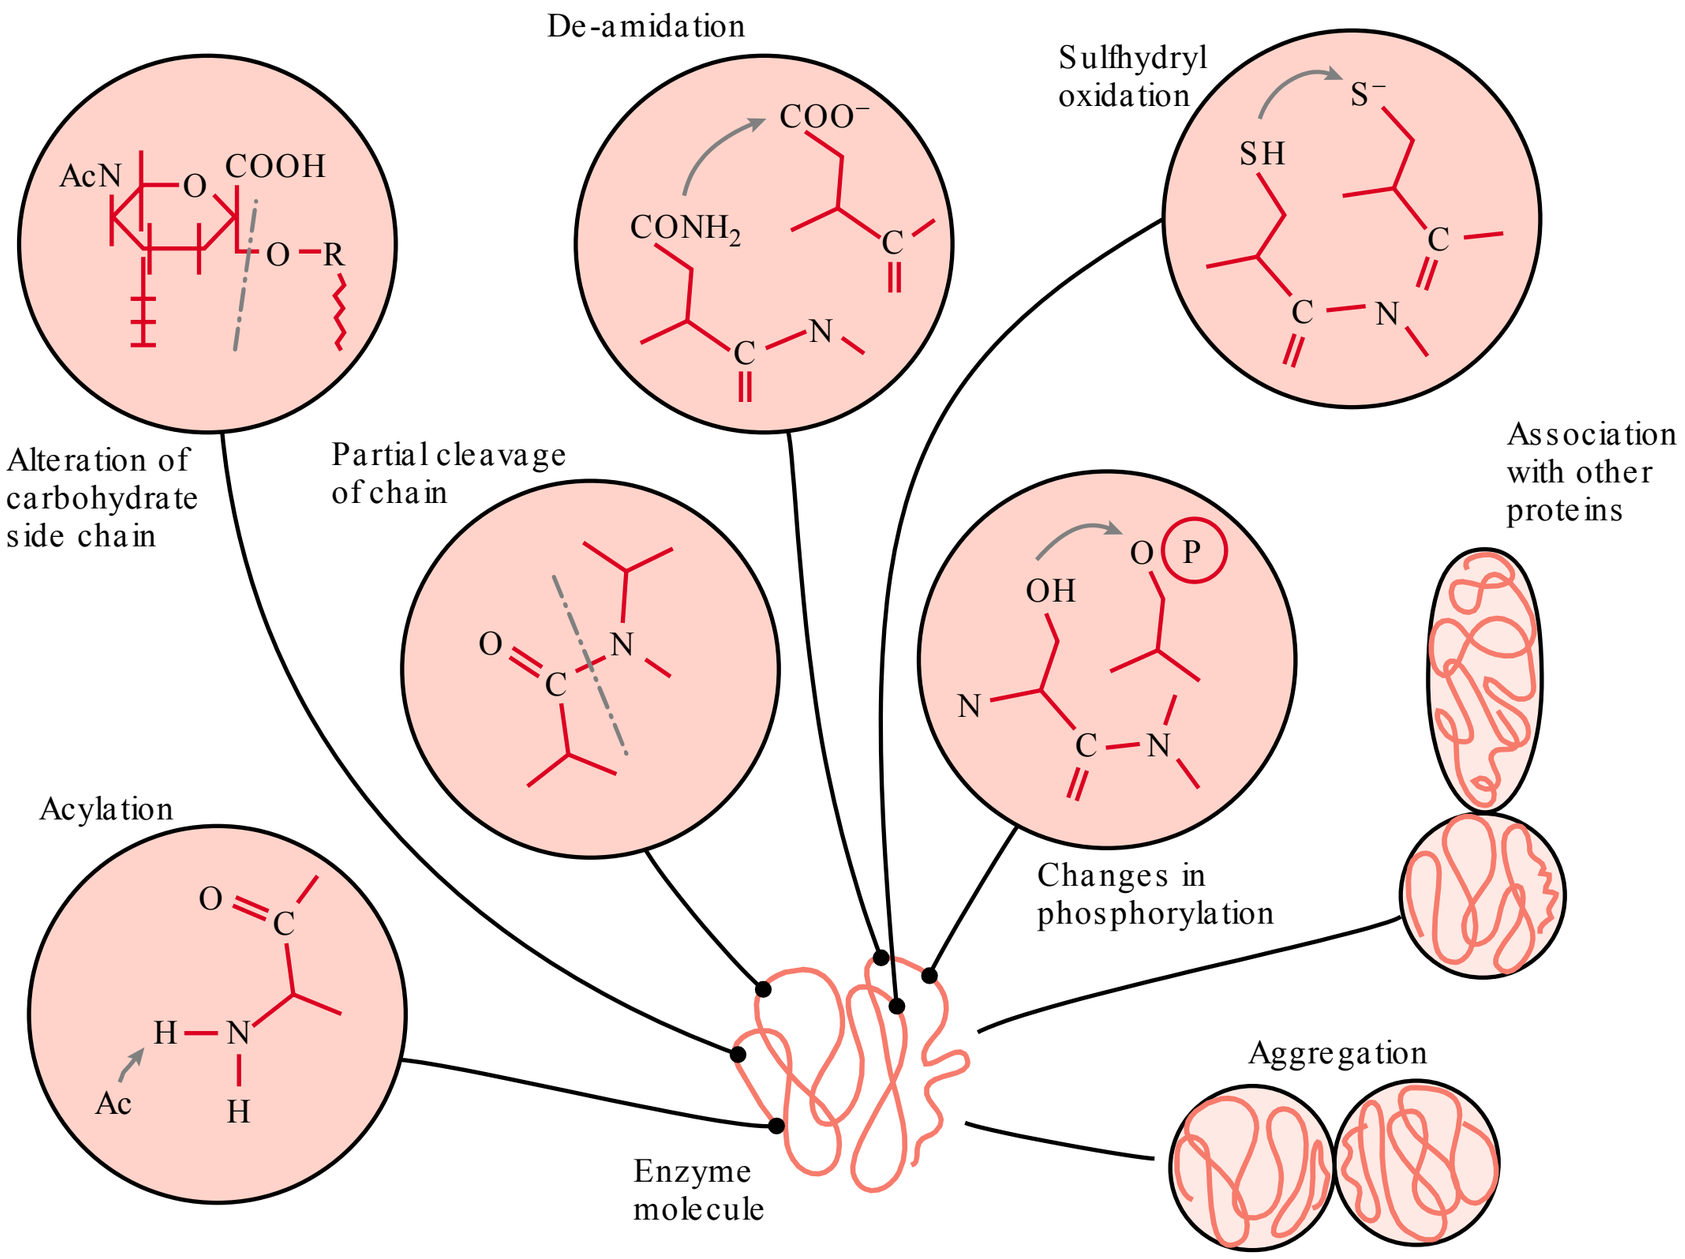

Figure 14-2 Nongenetic modifcations that may give rise to multiple forms of enzymes. (From Moss DW. Isoenzymes. London: Chapman & Hall, 1982.)

acid groups from human liver and/or bone alkaline phosphatase with neuraminidase greatly reduces the electrophoretic heterogeneity of the enzyme.

Aggregation of enzyme molecules with each other or with nonenzymatic proteins may give rise to multiple forms that are separated by techniques that depend on differences in molecular size. For example, four catalytically active cholinesterase components with molecular weights ranging from about 80,000 to 340,000 are found in most sera, with the heaviest component, C_4, contributing most of the enzyme activity. Other enzyme forms are also occasionally present, but it appears that the principal serum cholinesterase fraction is attributed to different states of aggregation of a single monomer.

A specific form of interaction between enzymatic and nonenzymatic proteins is the cause of unusual enzyme components noted when some samples of human plasma are fractionated by electrophoresis or chromatography. T ese components are the result of the combination of apparently normal enzyme or isoenzyme molecules with plasma immunoglobulins. T e enzyme/protein complexes (macrocomplexes) thus formed may themselves be heterogeneous. Since the identification of macroamylase, the first such enzyme/immunoglobulin complex to be identified, similar complexes have been observed involving (1) lactate dehydrogenase, (2) creatine kinase, (3) alkaline phosphatase, and (4) other enzymes.

A single polypeptide chain in theory exists in an infinite number of different conformations. However, one specific conformation generally appears to be the most stable for any given sequence of amino acids, and this conformation is assumed by the chain as it is synthesized within the cell. T us, the primary structure of the polypeptide chain also determines its three-dimensional secondary and tertiary structures. It is conceivable that in some cases, several alternative conformations ("conformers") of a single chain that are almost equally stable may be present, and therefore these alternative forms may coexist. T is possibility was first suggested to account for the heterogeneity noted in preparations of cytoplasmic and mitochondrial isoenzymes of malate dehydrogenase and has also been proposed as an explanation for the multiple electrophoretic zones of erythrocyte acid phosphatase. However, no multiple-enzyme forms have been shown unequivocally to be due to conformational isomerism.

Distribution of Isoenzymes and Other Multiple Forms of Enzymes

T e existence of multiple-gene loci and the isoenzymes derived from them has presumably conferred an evolutionary advantage on the species and has thus become part of its normal metabolic pattern. Some of these adaptations are related to the division of function between and within different types of specialized cells and tissues. T us, the distribution of isoenzymes is not uniform throughout the body, and wide variations in the activities of different isoenzymes are found at the organ, cellular, and subcellular levels. Tissue-specific differences are also found in the distributions of some multiple forms of enzymes that are not due to the existence of multiple-gene loci. T e tissue-specific distribution of isoenzymes and other multiple

forms of enzymes serves as the basis for organ-specific diagnosis through isoenzyme measurements.

A particularly striking example of local expression of multiple-gene loci is provided by distinct isoenzymes that occur exclusively in specific subcellular organelles. Differences between mitochondrial isoenzymes and their functionally analogous counterparts in the cytoplasm have been demonstrated in several cases (e.g., for aspartate aminotransferase and malate dehydrogenase).

Changes in Isoenzyme Distribution During Development and Disease

The patterns of several sets of isoenzymes change during normal development in tissues from many species. For example, during the embryonic development of skeletal muscle, the proportions of the electrophoretically more cathodal isoenzymes—both LD and CK—progressively increase in this tissue until approximately the sixth month of intrauterine life, when the pattern resembles that of differentiated muscle.

The liver also shows characteristic changes in the patterns of several isoenzymes during embryogenesis. In early fetal development, three aldolase isoenzymes—A, B, and C— together with various hybrid tetramers, are detected in extracts of liver. However, at birth, as in the adult liver, aldolase B is the predominant isoenzyme. Striking changes in the distribution of isoenzymes of alcohol dehydrogenase also occur in human liver during prenatal development.

Changes in isoenzyme patterns during development result from changes in the relative activities of gene loci within developing cells of a particular type (e.g., muscle cells). Other alterations in the balance of isoenzymes within the whole organism may derive from changes in the number or activity of cells that contain large amounts of a characteristic isoenzyme. An example of this is the increased number and activity of the osteoblasts, which are responsible for mineralization of the skeleton between the early postnatal period and the beginning of the third decade of life. An excess of ALP from active osteoblasts enters the circulation, where its presence is recognized by its characteristic properties, and where it elevates the total serum ALP activity of young people to above that of skeletally mature adults. ALP from the liver also contributes to the total activity of this enzyme in the plasma of healthy people, and the amount of this isoenzyme in plasma shows a small, progressive increase with age. The reason for the latter age-dependent change is not known, but it may result from increased synthesis of the isoenzyme by hepatocytes in response to continuing exposure to inducing factors.

Certain diseases, such as the progressive muscular dystrophies, appear to involve failure of the affected tissues to mature normally or to maintain a normal state. Cancer cells show progressive loss of the structure and metabolism of the healthy cells from which they arise. Therefore, the pattern of isoenzymes of mature, differentiated tissue may be lost or modified if normal differentiation is arrested or reversed, and many examples of isoenzyme changes accompanying such processes have been reported.

Reemergence of fetal patterns of isoenzyme distribution is a feature of malignant transformation in many tissues. This phenomenon was first studied extensively in the case of lactate dehydrogenase isoenzymes. Malignant tumors in general show a significant shift in the balance of isoenzymes toward electrophoretically more cathodal forms such as LD-4 and LD-5. The decline in activity of the LD-1 and LD-2 isoenzymes results in patterns that are reminiscent of those occurring in embryonic tissues. Tumors of (1) prostate, (2) cervix, (3) breast, (4) brain, (5) stomach, (6) colon, (7) rectum, (8) bronchus, and (9) lymph nodes are among those that show this transformation. In contrast, comparatively benign gliomas show a relative increase in anionic isoenzymes. A relative increase in the proportion of cathodal isoenzymes of LD has also been observed in tissue adjacent to malignant tumors (e.g., the colon), although the cells in these regions are morphologically normal.

Differences in Properties Between Multiple Forms of Enzymes

Structural differences between multiple forms of an enzyme give rise to greater or lesser differences in (1) physicochemical properties, such as electrophoretic mobility, resistance to inactivation, and solubility, or (2) catalytic characteristics, such as the ratio of reaction with substrate analogs or response to **inhibitors**. Methods of isoenzyme analysis have therefore been designed to investigate a wide range of catalytic and structural properties of enzyme molecules.[12,27]

Techniques of molecular biology, such as gene cloning and sequencing, have revolutionized the investigation of the primary structures of isoenzymes. Differences in primary structures between isoenzymes, whether derived from multiple-gene loci or from different alleles, are now known to exist in a growing number of cases. Furthermore, many questions have been answered about whether multiple-enzyme forms represented true (genetically determined) isoenzymes or arose from post-translational modification.

Isoenzymes caused by the existence of multiple-gene loci usually differ quantitatively in catalytic properties. These differences may be manifested in such characteristics as (1) molecular activity, (2) Km values for substrates, (3) sensitivity to various inhibitors, and (4) relative rates of activity with substrate analogs underscoring the biological importance of isoenzymatic variation. In contrast, multiple-enzyme forms that arise by such post-translational modifications as aggregation usually have similar catalytic properties.

Multilocus isoenzymes usually differ in terms of antigenic specificity, although these differences may be less pronounced among isoenzymes that have emerged relatively recently in evolutionary history and are still closely related in structure. Immunological cross-reaction is not uncommon among multilocus isoenzymes. Multiple-enzyme forms caused by post-synthetic modification frequently have common antigenic determinants. Isoenzymes derived from allelic genes (allozymes) are often antigenically similar, even to the extent that they may cross-react with antisera to the common isoenzyme even when a mutation has abolished enzyme activity altogether. The capacity for detecting differences between antigenically similar isoenzyme molecules depends on the extent of monoclonal antibody specificity.

Differences in resistance to denaturation by treatment with (1) heat, (2) concentrated urea solutions, and (3) detergents are commonly found between true isoenzymes, whether these are the products of multiple loci or multiple alleles. Other multiple forms of enzymes often do not differ or differ only slightly in this respect. The most commonly exploited difference between isoenzymes is the difference in net molecular charge that results from altered amino acid compositions of the molecules; this forms the basis of separation by (1) zone electrophoresis, (2) ion-exchange chromatography, and (3) isoelectric focusing. Separation methods that depend on differences in molecular size, such as gel filtration, do not distinguish between the small size differences that often exist between true isoenzyme molecules but are important in the detection of multiple forms that involve aggregation or association of enzyme molecules with other proteins.

Enzymes as Catalysts

A catalyst is a substance that modifies and increases the rate of a particular chemical reaction without being consumed or permanently altered. Enzymes are protein catalysts of biological origin. Metabolism is a coordinated series of chemical reactions that occur within a living cell to provide energy and accomplish biosynthesis. The process is regarded as an integrated series of enzymatic reactions and some diseases as a derangement of the normal pattern of metabolism. Apart from these fundamental considerations, it is the remarkable properties of enzymes that make them such sensitive indicators of pathological change.

Because of their catalytic activity, a given number of enzyme molecules convert an enormous number of substrate molecules to products within a short time. This property is used to measure changes in quantities of enzymes in the bloodstream, although the amount of enzyme protein released from damaged cells is small compared with the total quantity of nonenzymatic proteins in blood. Thus a change in the quantity of a particular enzyme is recognized by its characteristic effect on a given chemical reaction.

Units for Expressing Enzyme Activity

When enzymes are measured by their catalytic activities, the results of such determinations are expressed in terms of the concentration of the number of activity units present in a convenient volume or mass of specimen. The unit of activity is the measure of the rate at which the reaction proceeds (e.g., the quantity of **substrate** consumed or **product** formed in a chosen unit of time). In clinical enzymology, the activity of an enzyme is generally reported in terms of unit of volume, such as activity per 100 mL or per liter of serum or per 1.0 mL of packed erythrocytes. Because the rate of the reaction depends on experimental parameters, such as (1) pH, (2) type of buffer, (3) temperature, (4) nature of substrate, (5) ionic strength, (6) concentration of **activators**, and (7) other variables, these parameters must be specified in the definition of the unit.

To standardize how enzyme activities are expressed, the EC proposed that the unit of enzyme activity should be defined as the quantity of enzyme that catalyzes the reaction of 1 μmol of substrate per minute, and that this unit should be termed the **international unit** (U). Catalytic concentration is to be expressed in terms of U/L or kU/L, whichever gives the more convenient numerical value. In this chapter, the symbol U is used to denote the international unit. In those instances in which some uncertainty exists as to the exact nature of the substrate, or when difficulty is encountered in calculating the number of micromoles that are reacting (as with macromolecules such as starch, protein, and complex lipids), the unit is expressed in terms of the chemical group or residue measured in the following reaction (e.g., glucose units, amino acid units formed).

The International System of Units (SI)-derived unit for catalytic activity is the **katal**, defined as moles converted per second. The name katal became the official SI-derived unit in 1999, with Resolution 12 of the 21st French Conférence Général des Poids et Mesures (CGPM), on the recommendation of the International Federation of Clinical Chemistry and Laboratory Medicine (IFCC). Both the International Union of Pure and Applied Chemistry (IUPAC) and the IUB now recommend that enzyme activity be expressed in moles per second, and that the enzyme concentration be expressed in terms of katals per liter (kat/L).[9] Thus, 1 U = 10^{-6} mol/60 s = 16.7 × 10^{-9} mol/s, or 1.0 nkat/L = 0.06 U/L.

Enzyme Kinetics

The Enzyme/Substrate Complex

Enzymes act through the formation of an enzyme/substrate (ES) complex, in which a molecule of substrate is bound to the active center of the enzyme molecule. The binding process transforms the substrate molecule to its activated state, with the energy required for this transformation provided by the free energy of binding of S to E. Therefore, activation takes place without the addition of external energy, so that the energy barrier to the reaction is lowered and the breakdown to products is accelerated (Figure 14-3). The ES complex breaks down to give the reaction products (P) and the free enzyme (E):

$$E + S \rightleftarrows ES \rightarrow P + E \quad (1)$$

All reactions catalyzed by enzymes are in theory reversible. However, in practice, the reaction is usually found to be more rapid in one direction than in another, so that an equilibrium is reached in which the product of the forward or the backward reaction predominates, sometimes so markedly that the reaction is virtually irreversible.

If the product of the reaction in one direction is removed as it is formed (e.g., because it is the substrate of a second enzyme present in the reaction mixture), the equilibrium of the first enzymatic process will be displaced, so that the reaction will proceed to completion in that direction. Reaction sequences in which the product of one enzyme-catalyzed reaction becomes the substrate of the next enzyme and so on, often through many stages, are characteristic of biological processes. In the laboratory also, several enzymatic reactions may be linked

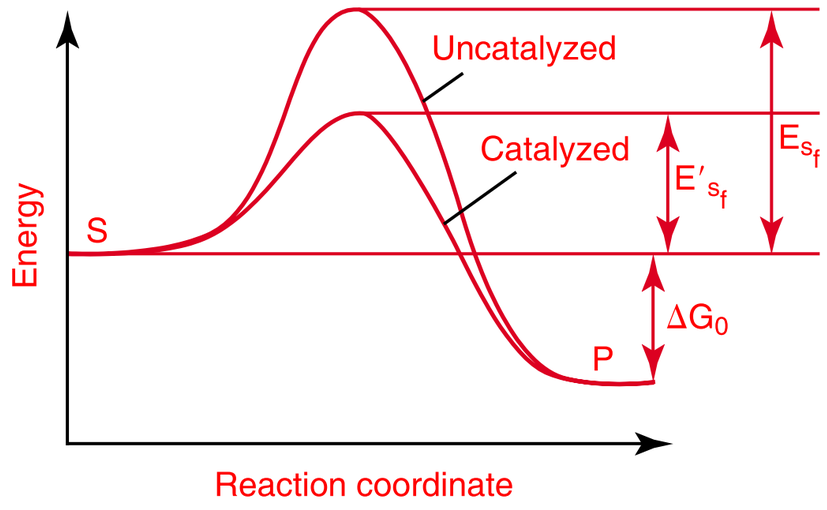

Figure 14-3 Activation energy barrier and reaction course, with and without enzyme catalysis. E_{Sf} is the activation energy for the forward reaction (S →P) in the absence of a catalyst, and E'_{Sf} is the activation energy in the presence of a catalyst. ΔG_0 is the change in free energy for the reaction.

together to provide a means of measuring the activity of the first enzyme or the concentration of the initial substrate in the chain. For example, the activity of CK is usually measured by a series of linked reactions, and the concentration of glucose is determined by consecutive reactions catalyzed by hexokinase and glucose-6-phosphate dehydrogenase.

When a secondary enzyme-catalyzed reaction, known as an indicator reaction, is used to determine the activity of a different enzyme, the primary reaction catalyzed by the enzyme to be determined must be the rate-limiting step. Conditions are chosen to ensure that the rate of reaction catalyzed by the indicator enzyme is directly proportional to the rate of product formation in the first reaction.

Factors Governing the Rate of Enzyme-Catalyzed Reactions

Factors that affect the rate of enzyme-catalyzed reactions include enzyme and substrate concentration, pH, temperature, and the presence of inhibitors, activators, coenzymes, and prosthetic groups.

Enzyme Concentration

The simplest enzymatically catalyzed reaction for converting substrate S into product P with the intermediate formation of an ES complex is as follows:

$$E_f + S \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} ES \xrightarrow{k_2} E_f + P \qquad (2)$$

where

E_f = free enzyme;
k_1 = rate constant for the association of the complex;
k_1 = rate constant for the dissociation of the complex;
ES = enzyme/substrate complex;
k_2 = rate constant for breakdown of ES to E_f and P; and
P = product.

Michaelis and Menten assumed that equilibrium is attained rapidly among E, S, and ES, with the effect of product formation (ES →P) on the concentration of ES being negligible. In addition, the formation of product is written as an irreversible process because no product is present in the solution under initial conditions. Therefore the overall rate of the reaction under otherwise constant conditions is proportional to the concentration of the ES complex.

Provided that an excess of free substrate molecules is present, addition of more enzyme molecules to the reaction system increases the concentration of the ES complex and thus the overall rate of reaction. This is accounts for the observation that the rate of reaction is generally proportional to the amount of enzyme present in the system and is the basis for the quantitative determination of enzymes by measurement of reaction rates. Reaction conditions are selected to ensure that the observed reaction rate (enzyme activity) is proportional to enzyme concentration over as wide a range as possible.

Substrate Concentration

In addition to explaining the dependence of reaction rate on enzyme concentration under conditions in which excess substrate is present, the formation of an ES complex accounts for the hyperbolic relationship between reaction velocity and substrate concentration (Figure 14-4, A).

Single-Substrate Reactions

If the enzyme concentration is held constant and the substrate concentration varied, the rate of reaction is almost directly proportional to the substrate concentration at low values of the latter. Under these conditions the rate of the reaction is proportional and dependent on the substrate concentration, a situation termed **first order**. At low concentrations of substrate, only a fraction of the enzyme is associated with substrate, and the rate observed reflects the low concentration of the ES complex. At high substrate concentrations, the reaction rate is known as **zero order** and is independent of substrate concentration. With a zero-order reaction, the entire enzyme is bound to substrate, and a much higher rate of reaction is obtained. Moreover, because the entire enzyme is present in the form of the complex, no further increase in complex concentration and no further increment in reaction rate are possible. The maximum possible velocity for the reaction has been reached.

The significance of substrate rate curves was first emphasized by Michaelis and Menten, and such curves are referred to as Michaelis-Menten plots. A typical Michaelis-Menten curve (Figure 14-4, A, is described by the equation*

$$v = \frac{V_{max}[S]}{K_m + [S]} \qquad (3)$$

where V_{max} is the velocity that the observed value of the velocity (v) approaches at high values of substrate ([S]). It increases with increasing enzyme concentration. K_m, the Michaelis-Menten constant, is the substrate concentration at which $v = V_{max}/2$, and it is a constant for a given enzyme acting

*A derivation of this equation is found in Bais R, Panteghini M. Principles of clinical enzymology. In: Burtis CA, Ashwood ER, Bruns DE, eds, Tietz textbook of clinical chemistry and molecular diagnostics. 5th ed. St Louis: Saunders, 2012:355-77.

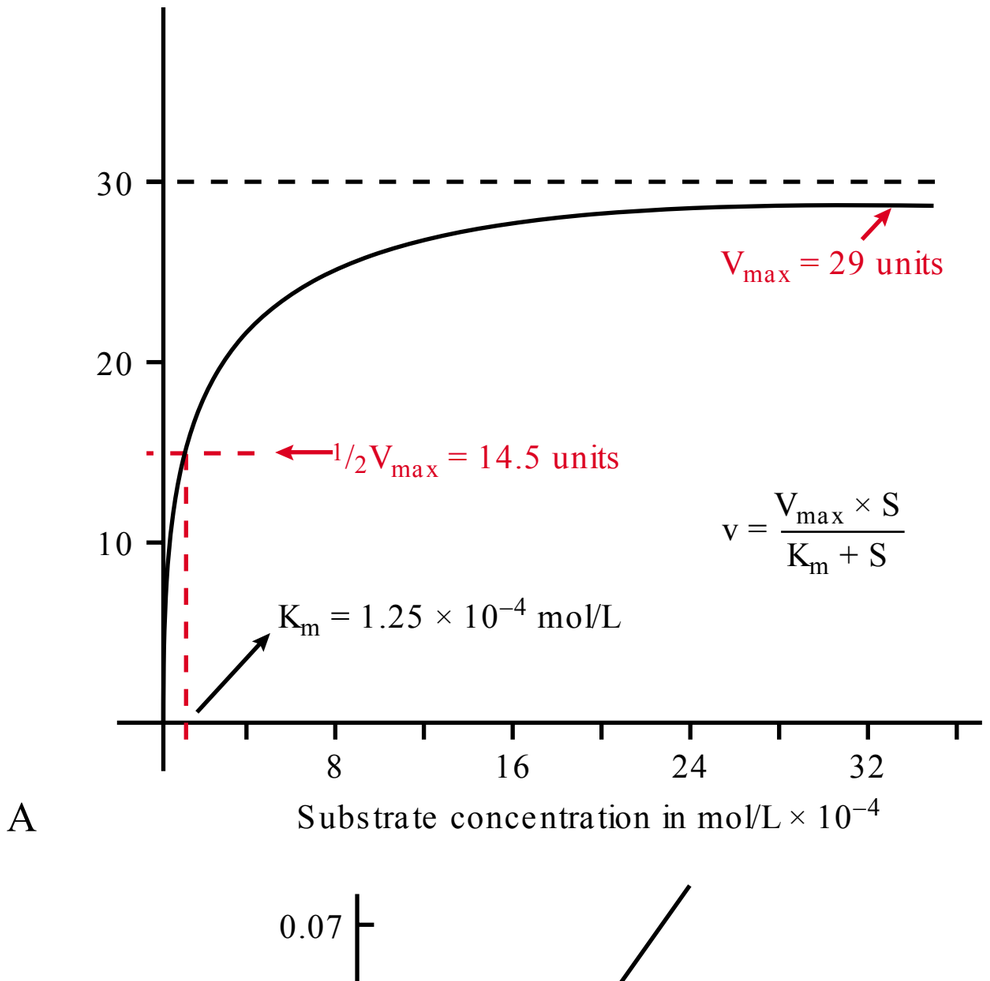

Figure 14-4 A, Michaelis-Menten curve relating the velocity (rate) of an enzyme-catalyzed reaction to substrate concentration. The value of K_m is given by the substrate concentration at which one-half of the maximum velocity is obtained. B, Lineweaver-Burk transformation of the curve in (A), with 1/v plotted on the ordinate (y-axis), and 1/[S] on the abscissa (x-axis). The indicated intercepts permit calculation of V_{max} and K_m.

under given conditions. If an equilibrium is set up between enzyme and substrate, K_m is the equilibrium constant of this reaction. However, the symbol K_S (substrate constant) is used if this meaning is intended, and K_m is reserved for the experimentally determined value of [S] at which at which the reaction proceeds at one half of its maximum velocity ($v = V_{max}/2$).

Although it is straightforward to set up an experiment to determine the variation of v with [S], the exact value of V_{max} is not easily determined from hyperbolic curves. Furthermore, many enzymes deviate from ideal behavior at high substrate concentrations and indeed may be inhibited by excess substrate, so the calculated value of V_{max} cannot be achieved in practice. In the past it was common practice to transform the **Michaelis-Menten equation** (2) into one of several reciprocal forms, and either 1/v was plotted against 1/[S], or [S]/v was plotted against [S].

$$\frac{1}{v} = \left(\frac{K_m}{V_{max}} \times \frac{1}{[S]} \right) + \frac{1}{V_{max}} \qquad (4)$$

T is equation, when plotted, gives a straight line, with intercepts at $1/V_{max}$ on the ordinate and $-1/K_m$ on the abscissa. T e graph on which the plots are made is known as the **Lineweaver-Burk plot** (Figure 14-4, B).

It is now routine practice to determine kinetic constants such as K_m and V_{max} using a software package. A large number of such packages are available; however, these vary from specialized routines for kinetic simulations or for data fitting to general mathematical, statistical, or graphical packages. T ese packages are free (public domain, shareware, or free license) or are commercially available. An example of the free software is the ENCORA 1.2 freeware package available from R.J.W. Slats and colleagues at the Delft University of Technology (http://www.tnw.tudelft.nl/en/about-faculty/departments/biotechnology/research/download-centre/encora/; accessed August 8, 2013), which was developed for an enzymatic kinetic parameter fitting using progressive curve analysis. DynaFit is an example of a commercially available routine (http://www.biokin.com/dynafit/; accessed August 8, 2013) that performs nonlinear least-squares regression of chemical kinetic, enzyme kinetic, or ligand receptor binding data. T e data can be initial reaction velocities for different concentrations of varied species (e.g., inhibitor concentration vs. velocity), or reaction progress curves (e.g., time vs. absorbance). SigmaPlot 11 is another example of commercially available software that will compute and plot enzyme kinetic data (http://www.sigmaplot.com/products/sigmaplot/enzyme-mod.php/; accessed August 8, 2013).

When setting up methods of enzyme assay, it is necessary to (1) explore the relationship between reaction velocity and substrate concentration over a wide range, (2) determine K_m, and (3) detect any inhibition at high substrate concentrations. Zero-order kinetics is maintained if the substrate is present in large excess (i.e., concentrations of at least 10 and preferably 100 times that of the value of K_m). When $[S] = 10 \times K_m$, v is approximately 91% of the theoretical V_{max}. T e K_m values for most enzymes are on the order of 10^{-5} to 10^{-3} mol/L; therefore substrate concentrations are usually chosen to be in the range of 0.001 to 0.10 mol/L. On occasion, the optimal concentrations of substrate cannot be used (e.g., when the substrate has limited solubility, when the concentration of a given substrate inhibits the activity of another enzyme needed in a coupled reaction system).

Two-Substrate Reactions

Most enzymes catalyze reactions with two or more interacting substrates symbolized by the following equation:

$$\underset{S_1}{\text{Substrate 1}} + \underset{S_2}{\text{Substrate 2}} \overset{E}{\rightleftarrows} \underset{P_1}{\text{Product 1}} + \underset{P_2}{\text{Product 2}} \qquad (5)$$

Among the bisubstrate reactions important in clinical enzymology are the reactions catalyzed by dehydrogenases—in which the second substrate is a specific coenzyme, such as reduced nicotinamide-adenine dinucleotide (NADH) or reduced NAD phosphate (NADPH)—or by aminotransferases. T e concentrations of both substrates affect the rates of two-substrate reactions. Values of K_m and V_{max} for each substrate are derived from experiments in which the concentration of the first substrate is held at saturating levels while the concentration of the second substrate is varied, and vice versa.

In practice, the choice of substrate concentrations is limited by such considerations as the solubility of the substrates, the viscosity and high initial absorbance of concentrated solutions, and the relative costs of the reagents. Furthermore, the selection of appropriate substrate concentrations is only one of the factors to be considered in formulating an optimal assay system for the measurement of activity of a specific enzyme. Critical choices must also be made with respect to other, frequently interdependent factors that affect reaction rate, such as the concentrations of activators and the nature and pH of the buffer system. T e traditional empirical approach to optimization has been replaced by newer techniques of simplex co-optimization and response surface methodology.[16] As an example, this technique has been used to determine optimal conditions for the IFCC-recommended method for amylase.[18]

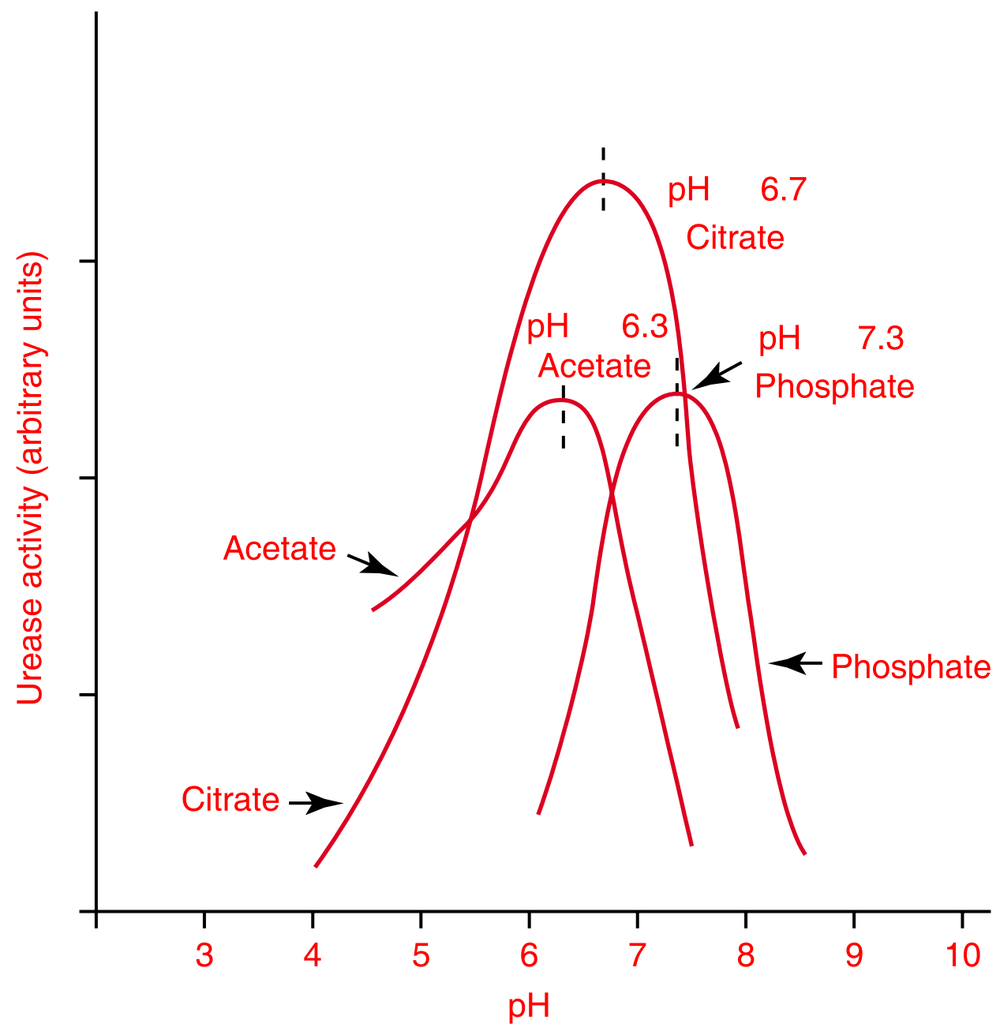

Figure 14-5 The pH activity curves for urease show the effects of buffer species on pH optimum. (Modifed from Howell SF, Sumner JB. The specifc effects of buffers upon urease activity, J Biol Chem 1934;104:619.)

Consecutive Enzymatic Reactions

As discussed previously, an enzymatic reaction is usually found to be more rapid in one direction than in the other, so that the reaction is virtually irreversible. If the product of the reaction in one direction is removed as it is formed, the equilibrium of the first enzymatic process is displaced, so that the reaction may continue to completion in that direction. Reaction sequences in which the product of one enzyme-catalyzed reaction becomes the substrate of another enzyme, often through many stages, are characteristic of metabolic processes. Analytically, several enzymatic reactions also may be linked together to provide a means of measuring the activity of the first enzyme or the concentration of the initial substrate in the chain. For example, the activity of creatine kinase is usually measured by a series of linked reactions, and glucose can be determined by consecutive reactions catalyzed by hexokinase and glucose-6-phosphate dehydrogenase.

When a linked enzyme assay, known as an indicator reaction, is used to determine the activity of a different enzyme, it is essential that the primary reaction be the rate-limiting step. For example, in the determination of aspartate aminotransferase activity, the indicator reaction is the reduction of the oxaloacetate formed in the aminotransferase reaction to malate by malate dehydrogenase and NADH. T e activity of the indicator enzyme must be sufficient to ensure the virtually instantaneous removal of the product of the first reaction, to prevent significant reversal of the first reaction. T e measured enzyme is typically acting under conditions of saturation with respect to its substrate; however, the concentration of the substrate of the indicator enzyme (i.e., the product of the first reaction) remains in the region of the Michaelis-Menten curve in which v is directly proportional to [S]. T erefore the rate of reaction catalyzed by the indicator enzyme is directly proportional to the rate of product formation in the first reaction.

During a lag period that occurs after the start of the first reaction, the concentration of its product reaches a steady state. Because the rate of the second reaction depends on the activity of the indicator enzyme and on the concentration of its substrate (the product of the primary reaction), the duration of the lag period is reduced by increasing the concentration of the indicator enzyme, thus lowering the steady state concentration of the product of the primary reaction.

Effect of pH

T e rate of enzyme-catalyzed reactions typically shows marked dependence on pH (Figure 14-5). Many of the enzymes in blood plasma show maximum activity in vitro in the pH range from 7 to 8. However, activity has been observed at pH values as low as 1.5 (pepsin) and as high as 10.5 (ALP). T e optimal pH for a given forward reaction may be different from the optimal pH for the corresponding reverse reaction. T e form of the pH dependence curve is the result of a number of separate effects, including ionization of the substrate and the extent of dissociation of certain key amino acid side chains in the protein molecule, both at the active center and elsewhere in the molecule. Both pH and ionic environment will also have an effect on the three-dimensional conformation of the protein and therefore on enzyme activity to such an extent that enzymes may be irreversibly denatured at extreme values of pH.

T e pronounced effects of pH on enzyme reactions emphasize the need to control this variable by means of adequate buffer solutions. Enzyme assays should be carried out at the

pH of optimal activity. In addition, the buffer system must be capable of counteracting the effect of adding the specimen (e.g., serum itself is a powerful buffer) to the assay system, as well as the effects of acids or bases formed during the reaction. Because buffers have their maximum buffering capacity close to their pK_a values, whenever possible a buffer system should be chosen with a pK_a value within 1 pH unit of the desired pH of the assay. Interaction between buffer ions and other components of the assay system (e.g., activating metal ions) may eliminate certain buffers from consideration.

Temperature

The rate of an enzymatic reaction is proportional to its reaction temperature. However, an increase in the rate of the catalyzed reaction is not the only effect of increasing temperature on an enzymatic reaction. In theory, the initial rate of reaction measured instantaneously will increase with rising temperature. In practice, however, a finite time is needed to allow the components of the reaction mixture, including the enzyme solution, to reach temperature equilibrium and to permit the formation of a measurable amount of the product. During this period, the enzyme is undergoing thermal inactivation and denaturation—a process that has a very large temperature coefficient for most enzymes and thus becomes virtually instantaneous at temperatures of 60 °C to 70 °C. The counteracting effects of the increased rate of the catalyzed reaction and more rapid enzyme inactivation as the temperature increases account for the existence of an apparent optimal temperature for enzyme activity (Figure 14-6).

As stated earlier, at some critical temperature, an enzyme will undergo thermal inactivation influenced by a number of factors. These include (1) presence of substrate and its concentration, (2) pH, and (3) nature and ionic strength of the buffer. In general, storage of serum samples at low temperatures is necessary to minimize loss of enzyme activity while awaiting analysis, although repeated freezing and thawing should be avoided. However, individual enzymes vary in their stability characteristics, and appropriate storage conditions vary correspondingly. Amylase, for example, is stable at room temperature (22 °C to 25 °C) for 24 hours, whereas acid phosphatase is exceedingly unstable, even when refrigerated, unless kept at a pH below 6.0. ALP exhibits an unusual property: the tendency for the activity of frozen, partially purified preparations of the enzyme to increase after thawing over a period of 24 hours or longer. This is effect is shared by reconstituted, lyophilized preparations of the enzyme and affects their use for quality control purposes. A few enzymes are inactivated at refrigerator temperatures; an example is the liver-type isoenzyme of lactate dehydrogenase, LD-5, which appears to be less stable at lower temperatures. As a result, sera for lactate dehydrogenase determinations should be kept at room temperature and should not be refrigerated.

Historically, the choice of temperature for the assay of enzymes of clinical importance was the subject of extensive debate. However, 37 °C is now the accepted measuring temperature for enzymes in the clinical laboratory. Reference methods for several clinically relevant enzymes have been developed at 37 °C.[14-26] In practice, accurate temperature control to within ±0.1 °C during the enzymatic reaction is essential.

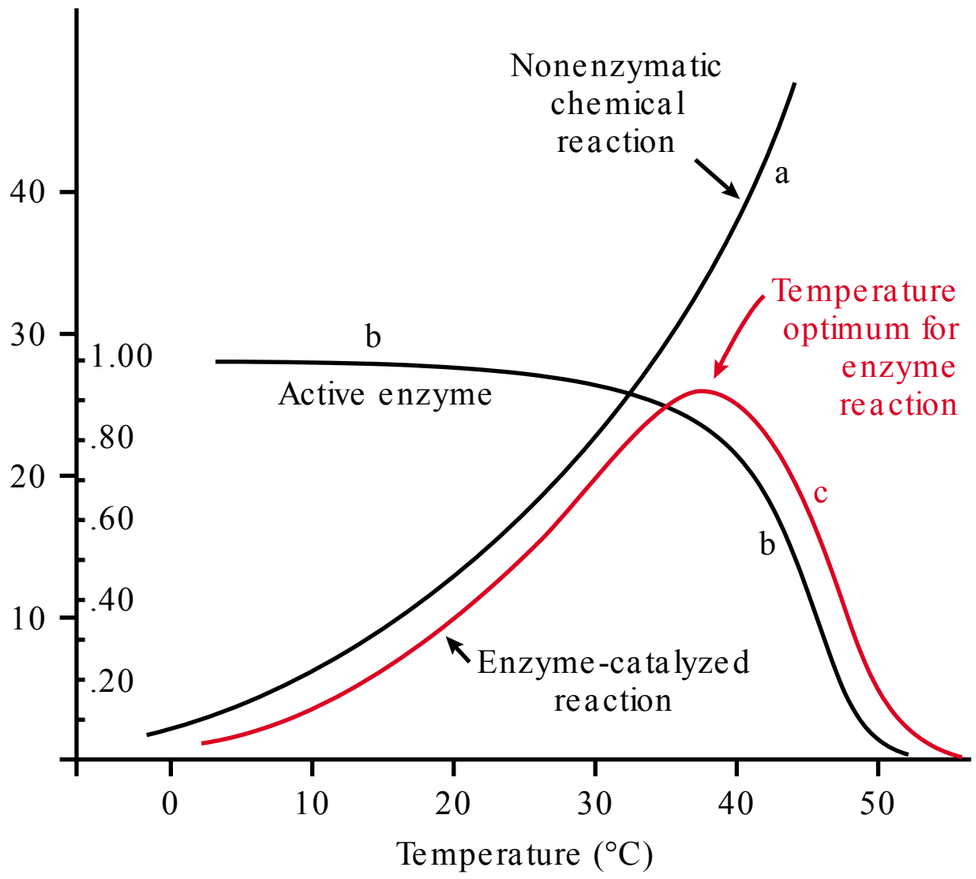

Figure 14-6 Schematic diagram showing effects of temperature on rates of non–enzyme-catalyzed and enzyme-catalyzed reactions.

Inhibitors and Activators

The rates of enzymatic reactions are often affected by substances other than the enzyme or the substrate. These modifiers may be inhibitors because their presence reduces the reaction rate, or they may be activators because they increase the rate of reaction. Activators and inhibitors are usually small molecules (compared with the enzyme itself) or even ions. They vary in specificity, ranging from modifiers that exert similar effects on a wide range of different enzymatic reactions at one extreme to substances that affect only a single reaction. Reagents, such as strong acids or multivalent anions and cations that denature or precipitate proteins, destroy enzyme activity and thus may be regarded as extreme examples of nonspecific enzyme inhibitors. These effects usually are not included in discussions of enzyme inhibition, although they have obvious practical implications in the treatment and storage of specimens in which enzyme activity is to be measured. The activity of some enzymes depends on the presence of particular chemical groups, such as reduced sulfhydryl (−SH) groups, in the active center. Reagents that alter these groups (e.g., oxidants of SH groups) therefore act as general inhibitors of such enzymes.

Some phenomena of enzyme activation or inhibition are caused by interactions between the modifier and a nonenzymatic component of the reaction system, such as the substrate (e.g., Mg^{2+} combining with ATP to form MgATP, the required substrate for the creatine kinase reaction). In most cases, however, the modifier combines with the enzyme itself in a manner analogous to the combination of enzyme and substrate.

Inhibition of Enzyme Activity

Inhibitors are classified as reversible or irreversible.

Reversible Inhibition. Reversible inhibition is characterized by the existence of equilibrium between enzyme, E, and inhibitor, I:

$$E + I \rightleftarrows EI \qquad (6)$$

The equilibrium constant of the reaction, K_i (the inhibitor constant), is a measure of the affinity of the inhibitor for the enzyme, just as K_m generally reflects the affinity of the enzyme for its substrate.

A competitive inhibitor is usually a structural analog of the substrate that combines with the free enzyme and competes with the normal substrate for binding at the active site. The actual rate of the reaction is strictly dependent on the relative concentrations of substrate and inhibitor.

Competitive inhibition is responsible for the inhibition of some enzymes by excess substrate caused by competition between substrate molecules for a single binding site. In two-substrate reactions, high concentrations of the second substrate may compete with binding of the first substrate. For example, aspartate aminotransferase is inhibited by excess concentrations of the substrate 2-oxoglutarate, and this inhibition is competitive with respect to l-aspartate. Therefore, to maintain a given velocity at high 2-oxoglutarate concentrations, the concentration of l-aspartate has to be increased to a value above that needed at lower concentrations of 2-oxoglutarate.

Competitive inhibition also contributes to the reduction in the rate of an enzymatic reaction over time. For example, a rate reduction occurs because increasing concentrations of reaction products tend to drive the reaction backward, if it is freely reversible. A product may itself be an inhibitor of the forward reaction, so even if the reaction is not readily reversible, it proceeds against a rising concentration of inhibitor. A familiar example of product inhibition is the release of the competitive inhibitor, inorganic phosphate, by the action of ALP on its substrates. In this case, both organic phosphates and inorganic phosphates bind to the active center of the enzyme with similar affinities (e.g., K_m and K_i are of the same order of magnitude).

Product inhibition is a cause of nonlinearity of reaction progress curves during fixed-time methods of enzyme assay. For example, oxaloacetate produced by the action of aspartate aminotransferase inhibits the enzyme, particularly the mitochondrial isoenzyme. The inhibitory product may be removed as it is formed by a coupled enzymatic reaction: Malate dehydrogenase converts the oxaloacetate to malate and at the same time oxidizes NADH to NAD^+.

Competitive inhibition by metal ions occurs when two metal ions compete for the same binding site on the enzyme. Sodium and lithium are potent inhibitors of pyruvate kinase, for which potassium is an obligatory activator.

A noncompetitive inhibitor is usually structurally different from the substrate. It is assumed to bind at a site on the enzyme molecule that is different from the substrate-binding site; thus, there is no competition between inhibitor and substrate, and a ternary enzyme/substrate/inhibitor (ESI) complex is formed. Attachment of the inhibitor to the enzyme does not alter the affinity of the enzyme for its substrate (i.e., K_m is unaltered), but the ESI complex does not break down to yield products. Because the substrate does not compete with the inhibitor for binding sites on the enzyme molecule, increasing the substrate concentration does not overcome the effect of a noncompetitive inhibitor. Thus, V_{max} is reduced in the presence of such an inhibitor, whereas K_m is not altered, as the Lineweaver-Burk plot shows (Figure 14-7).

Uncompetitive inhibition is produced by a combination of the inhibitor with the ES complex. It is more common in two-substrate reactions, in which a ternary ESI complex is formed after the first substrate has combined with the enzyme. In uncompetitive inhibition, parallel lines are obtained when plots of 1/v against 1/[S] with and without the inhibitor are compared (see Figure 14-7), that is, both K_m and V_{max} are decreased.

Irreversible Inhibition. Irreversible inhibitors inactivate the enzyme molecule by covalently and permanently modifying a functional group required for catalysis. The effect of an irreversible inhibitor is progressive with time and becomes complete when the amount of inhibitor present exceeds the total amount of enzyme. The rate of the reaction between enzyme and inhibitor is expressed as the fraction of enzyme activity that is inhibited in a fixed time by a given concentration of inhibitor. The velocity constant of the reaction of the inhibitor with the enzyme is a measure of the effectiveness of the inhibitor.

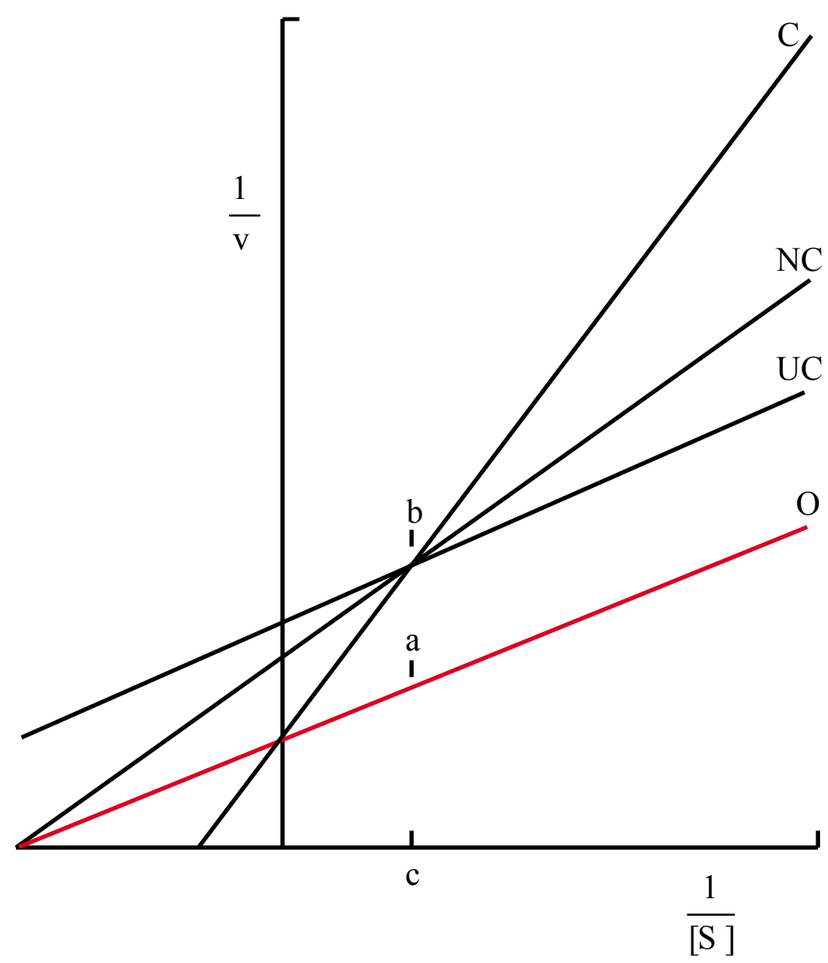

Figure 14-7 Effects of different types of inhibitors on the double-reciprocal plot of 1/v against 1/[S]. Each of the inhibitors has been assumed to reduce the activity of the enzyme by the same amount, represented by the change in 1/v from a to b at a substrate concentration of c. Line O is the plot for enzyme without inhibitor, C with a competitive inhibitor, NC with a noncompetitive inhibitor, and UC with an uncompetitive inhibitor. (From Moss DW. Measurement of enzymes. In: Hearse DJ, de Leiris J, eds. Enzymes in cardiology: diagnosis and research. New York: John Wiley & Sons Inc., 1979. Reprinted by permission of John Wiley & Sons, Inc.)

Irreversible inhibitors have been useful in mapping active sites by covalently modifying different types of functional groups in the enzyme molecule to establish whether such groups are necessary for catalytic activity.

A physiologically important category of irreversible enzyme inhibition is exemplified by various trypsin inhibitors. T ese are proteins that bind to trypsin irreversibly, nullifying its proteolytic activity. One such inhibitor is present in the α_1-globulin fraction of serum proteins; others are found in soybeans and lima beans. Similar proteolysis inhibitors present in plasma prevent the accumulation of excess thrombin and other coagulation enzymes, thus keeping the coagulation process under control.

Inhibition by Antibodies. T e combination of enzyme molecules with specific antibodies often has no effect on catalytic activity, which is retained by the enzyme/antibody complex.[2] However, in some cases, the reaction of the enzyme and the antibody reduces or even abolishes enzymatic activity. T e most probable explanation for this type of inhibition is that the antibody molecule restricts access of the substrate molecules to the active center by steric hindrance or, in extreme cases, completely masks the substrate-binding site. However, it appears that some examples of enzyme inhibition by combination with antibodies are caused by a conformational change induced in the enzyme molecule.

Inhibition of the activity of an enzyme molecule labeled with a hapten (e.g., morphine) as a result of combination with a specific antibody forms the basis for a homogeneous enzyme immunoassay See Chapter 15 for additional details.

Enzyme Activation

Activators increase the rates of enzyme-catalyzed reactions by promoting formation of the most active state of the enzyme itself or of other reactants, such as the substrate. T is generalization covers a wide variety of mechanisms of activation. For example, many enzymes contain metal ions as an integral part of their structure (e.g., zinc in ALP and carboxypeptidase A). Removal of divalent metal ions by treatment with an appropriate quantity of ethylenediaminetetraacetic acid (EDTA) solution is accompanied by conformational changes and inactivation of the enzyme. T e enzyme often is reactivated by dialysis against a solution of the appropriate metal ion or simply by addition of the ion to the reaction mixture.

When the activator ion is an essential part of the functional enzyme molecule, it is usually incorporated quite firmly into the enzyme molecule. T erefore it is not usually necessary to add the activator to reaction mixtures, and an excess of the ion may even have an inhibitory effect. However, in some cases, the activating ion is attached only weakly or transiently to the enzyme (or its substrate) during catalysis. Enzyme samples therefore may be deficient in the ion, so that addition of the ion increases the reaction rate or indeed may be essential for the reaction to take place. For example, all phosphate transfer enzymes (kinases), such as creatine kinase, require the essential presence of Mg^{2+} ions. Other common activating cations are Mn^{2+}, Fe^{2+}, Ca^{2+}, Zn^{2+}, and K^+. More rarely, anions may act as activators. For example, amylase functions at its maximal rate only if Cl^- or other monovalent anions, such as Br^- or NO_3^-, are present.[11] Some enzymes require the obligate presence of two activating ions. K^+ and Mg^{2+} are essential for the activity of pyruvate kinase, and both Mg^{2+} and Zn^{2+} are required for ALP activity.

Coenzymes and Prosthetic Groups

Coenzymes are generally more complex molecules than activators, although they are smaller molecules than the enzyme proteins themselves. Some compounds, such as the dinucleotides NAD and NADP, are classified as coenzymes even though they are specific substrates in two-substrate reactions. T eir effects on the rate of reaction follow the Michaelis-Menten pattern of dependence on substrate concentration. T e structures of these two coenzymes are identical, except for the presence of an additional phosphate group in NADP; nevertheless, individual dehydrogenases, for which these coenzymes are substrates, are predominantly or even absolutely specific for one or the other form.

Coenzymes, such as NAD and NADP, are bound only momentarily to the enzyme during the course of the reaction, as is the case for substrates in general. T erefore no reaction takes place unless the appropriate coenzyme is present in solution (e.g., when it is added to the reaction mixture in the assay of dehydrogenase activity). In contrast to these entirely soluble coenzymes, some coenzymes are more or less permanently bound to the enzyme molecules, where they form part of the active center and undergo cycles of chemical change during the reaction. When bound, the coenzyme is known as a prosthetic group.

An active holoenzyme results from the combination of the inactive apoenzyme with the prosthetic group. An example of a prosthetic group is pyridoxal-5′-phosphate (P-5′-P), a component of AST and ALT. T e P-5′-P prosthetic group undergoes a cycle of conversion of the pyridoxal moiety to pyridoxamine and back again during the transfer of an amino group from an amino acid to an oxo-acid. Prosthetic groups, such as activators with a structural role, do not usually have to be added to elicit the full catalytic activity of the enzyme unless previous treatment has caused the prosthetic group to be lost from some enzyme molecules. However, both normal and pathological serum samples contain appreciable quantities of apoaminotransferases, which are converted to active holoenzymes through a suitable period of incubation with P-5′-P.

Study of the formulas of coenzyme and prosthetic groups reveals that many contain structures derived from the vitamins (see Chapter 27). T us, the nicotinamide portion of NAD and NADP derives from the vitamin niacin, whereas the P-5′-P prosthetic group of the aminotransferases is a derivative of pyridoxine, vitamin B_6. Other derivatives of the B-group vitamins also participate in enzymatic reactions.

Analytical Enzymology

Analytically, the clinical laboratorian is concerned with measuring the activity or mass in serum or plasma of enzymes that are predominantly intracellular and that are physiologically

present in the serum in low concentrations only. By measuring changes in the quantities of these enzymes in disease, it is possible to infer the location and nature of pathological changes in tissues of the body.

Measurement of Reaction Rates

The rate of an enzyme-catalyzed reaction is directly proportional to the amount of active enzyme present in the system. Consequently, determination of the rate of reaction under defined and controlled conditions provides a measure of the amount of enzyme in a sample, such as serum.

Determination of reaction rate involves the kinetic measurement of the amount of change produced within a defined time interval.[6,30] Both fixed-time and continuous-monitoring methods are used to measure reaction rates. In the fixed-time method, the amount of change produced by the enzyme is measured after the reaction is stopped at the end of a fixed time interval. With the continuous-monitoring method, the progress of the reaction is monitored continuously. These two methods have different advantages and limitations. To appreciate them, it is necessary to consider the way in which the rate of an enzymatic reaction varies with time.

The progress of an enzyme reaction is monitored by measuring in time the decreasing concentration of the substrate or the increasing concentration of the products. Measurement of product formation is preferable, as determination of the increase in the concentration of a substance above an initially zero or low concentration has less analytical uncertainty than measurement of a decline from an initially high concentration.

At the moment when the enzyme and the substrate are mixed, the rate of the reaction is zero. The rate then typically rises rapidly to a maximum value, which remains constant for a period of time (Figure 14-8). During the period of constant reaction rate, the rate depends only on enzyme concentration and is completely independent of substrate concentration. The reaction is said to follow zero-order kinetics because its rate is proportional to the zero power of the substrate concentration. Ultimately, however, as more substrate is consumed, the reaction rate declines and enters a phase of first-order dependence on substrate concentration. Other factors that contribute to the decline in reaction rate include (1) accumulation of products that may be inhibitory, (2) the growing importance of the reverse reaction, and (3) enzyme denaturation. Although it is possible to compare the rates of reaction produced by different amounts of an enzyme under first-order conditions, it is obviously easier to standardize such comparisons when the enzyme concentration is the only variable that influences the reaction rate. Therefore, enzyme assays are usually made under conditions that are initially saturating with respect to substrate concentration. The rate of reaction during the zero-order phase is determined by measuring the product formed during a fixed period of incubation where the rate remains constant. This is illustrated in Figure 14-9. Measurement of reaction rates at any portion of curve A yields results that are identical to the true initial rate. However, curve B deviates from linearity over its entire course, and rates fall off with time. From curve C, correct results are obtained only if the rate is measured along segment II. Incorrect results are obtained if the rate is measured during phase I (the lag phase) or during phase III.

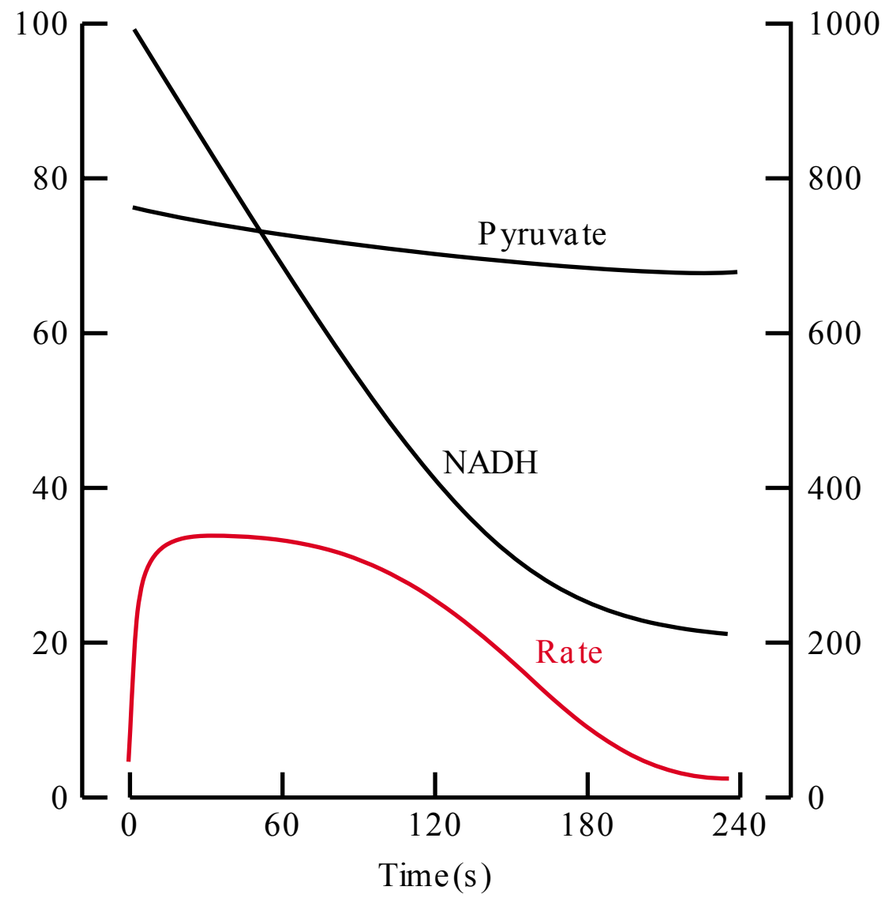

Figure 14-8 Changes in substrate concentrations and rates of reaction during an assay of lactate dehydrogenase activity at 37 °C in phosphate buffer, with pyruvate and NADH as substrates. This reaction is followed by observation of the fall in absorbance at 340 nm as NADH is oxidized to NAD^+. The rate of reaction rises rapidly to a maximum value, from which it declines only slightly until about half the NADH has been used up. During this phase of the reaction, the rate is essentially zero order with respect to substrate concentration. At the point at which the rate falls below about 90% of its maximum value, NADH concentration is approximately $10 \times K_m$. The K_m for NADH is on the order of 5×10^{-6} mol/L, whereas for pyruvate it is 9×10^{-5} mol/L. Thus an initial pyruvate concentration approximately 10 times that of NADH is used. (Concentrations per liter of reaction mixture are given.) (From Moss DW. Measurement of enzymes. In: Hearse DJ, de Leiris J, eds. Enzymes in cardiology: diagnosis and research. New York: John Wiley & Sons Inc., 1979. Reprinted by permission of John Wiley & Sons, Inc.)

Careful selection of reaction conditions, such as the concentrations of substrates and cofactors, improves the reaction progress curves, eliminating lag phases and prolonging the period of linearity so that fixed-time methods of analysis become feasible. Improvements in optical techniques, leading to more reliable and sensitive measurement of product formation, have also allowed the duration of incubation to be shortened compared with older assays. This has resulted in a corresponding increase in the interval over which enzyme activity is measured. Nevertheless, an upper limit of activity exists in all fixed-time methods, above which progress curves will no longer be linear. The upper limit of activity that is acceptable in the unmodified method is chosen so that samples with activities below it are presumed with a high degree of certainty to yield linear progress curves; alternatively, if the limit is set too low, many samples will be reanalyzed unnecessarily. Samples that are above the limit should ideally be reassayed by shortening the incubation period until a constant reaction rate is obtained. However, this is difficult or impossible with some

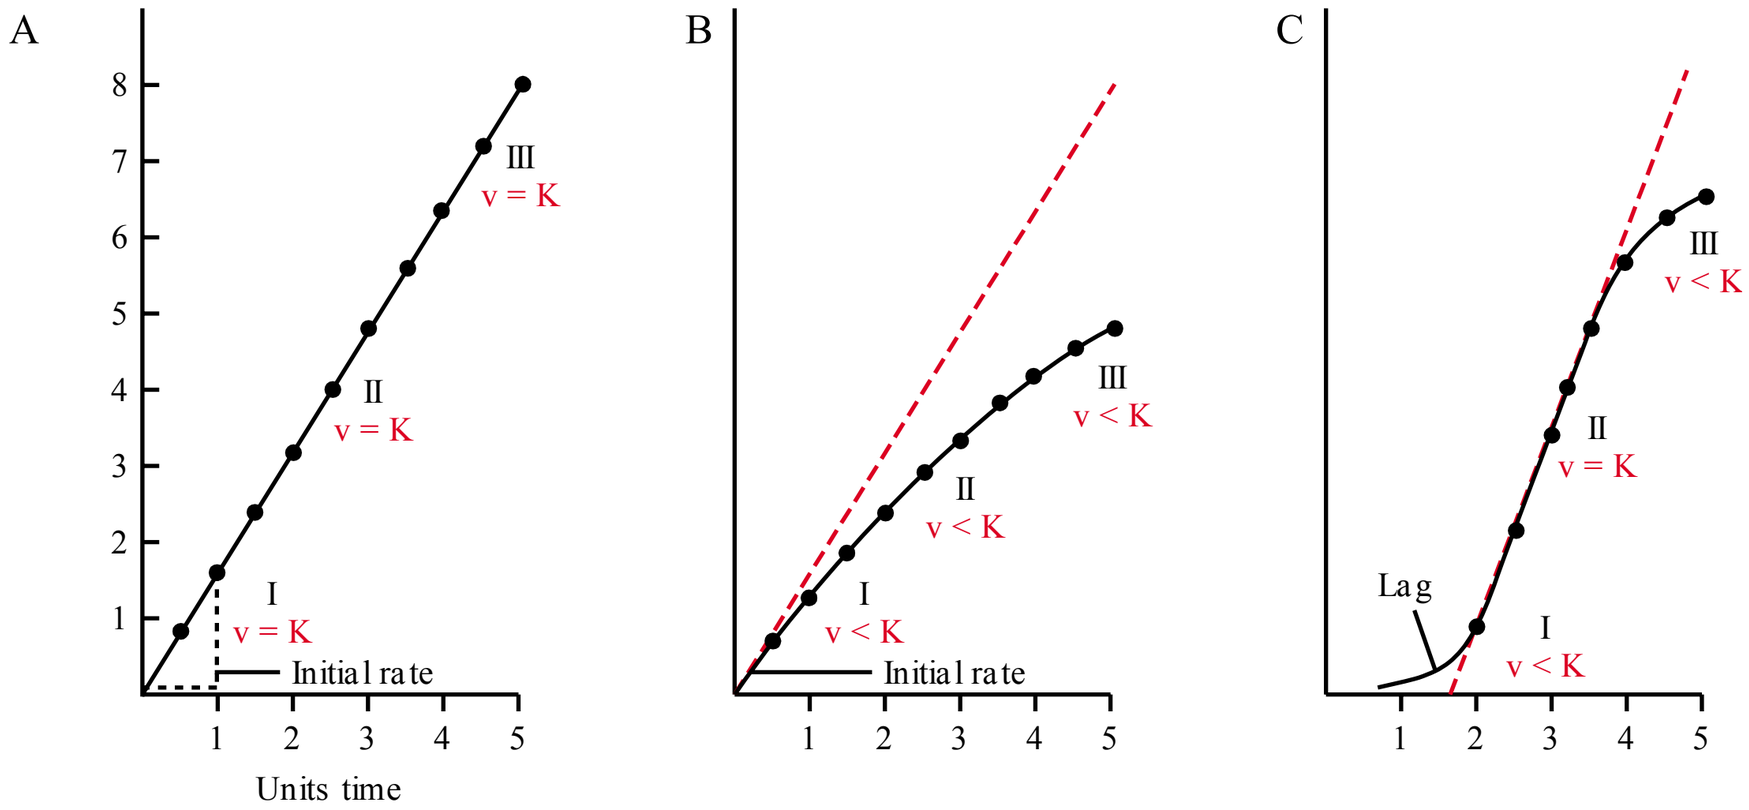

Figure 14-9 Forms of graphs showing changes in enzyme reaction rate as a function of time. In A, the rate is constant during the entire run, and rates calculated as I, II, and III will be identical to the initial rate. In B, the rate falls off continuously; rates calculated at I, II, and III will be different and less than the true initial rate. In C, a measurement at II will be representative of the maximum rate, but at I (lag period) and III (substrate depletion), it will be less than at II.

automated methods, in which the duration of incubation is fixed by the configuration of the apparatus. It then becomes necessary to dilute the specimen; however, dilution may not always result in a proportional change in activity.

The initial rate of reaction theoretically increases without limit as enzyme concentration increases, as long as no other factor, such as substrate concentration, becomes limiting. In practice, the reaction rate becomes so rapid at high enzyme activities that it is impossible to measure the initial rate of reaction, even with continuous-monitoring methods. Therefore, an upper limit of activity that is measurable without modification of the assay procedure exists even in continuous-monitoring methods, but this limit is usually much higher than that applied in corresponding fixed-time methods. Fewer samples therefore require special treatment. Furthermore, continuous monitoring allows identification of the appropriate zero-order portion of the progress curve for each sample and identification of samples that require special treatment. Continuous-monitoring methods provide a decisive advantage in enzyme assay and should be used whenever possible.

Measurement of Substrates

The amount of substrate transformed into products during an enzyme-catalyzed reaction can be measured with any appropriate analytical method, such as (1) spectrophotometry, (2) fluorometry, or (3) chemiluminescence (see Chapter 9).[10,17] For example, self-indicating reactions are particularly valuable, as they allow continuous monitoring. Important examples of self-indicating reactions include determination of dehydrogenase activity by monitoring the change in absorbance at 339 (340) nm of the coenzyme NADH or NADPH during oxidation or reduction, and measurement of ALP activity by generation of the yellow p-nitrophenolate ion from the substrate p-nitrophenyl phosphate in alkaline solution. These indicator reactions are so versatile that coupled reactions are frequently used to provide an observable optical change accompanying a primary reaction in which such a change is not present.

Optimization, Standardization, and Quality Control

To measure enzyme activity reliably, all factors that affect the reaction rate—other than the concentration of active enzyme—need to be optimized and rigidly controlled. Furthermore, because the reaction velocity is at or near its maximum under optimal conditions, a larger analytical signal is obtained that is measured more reliably. Much effort therefore has been devoted to determining optimal conditions for measuring the activities of enzymes of clinical importance.

Optimization

Optimization of reaction conditions for enzyme assays traditionally has been carried out by varying a single factor and studying its effect on the reaction rate, then repeating the experiment with a second factor and so on, until the effects of all variables have been tested. An optimal combination of variables is selected on the basis of these experiments, and the validity of the chosen conditions is verified. Not only is this approach labor intensive, it also is difficult to adapt in situations in which the effects of different variables are interdependent, as is frequently the case in enzyme analysis. This traditional empirical approach to optimization has been replaced by newer techniques of simplex co-optimization and response surface methodology.[16]

Standardization

Despite substantial effort and the development of reference procedures, considerable variability of results between

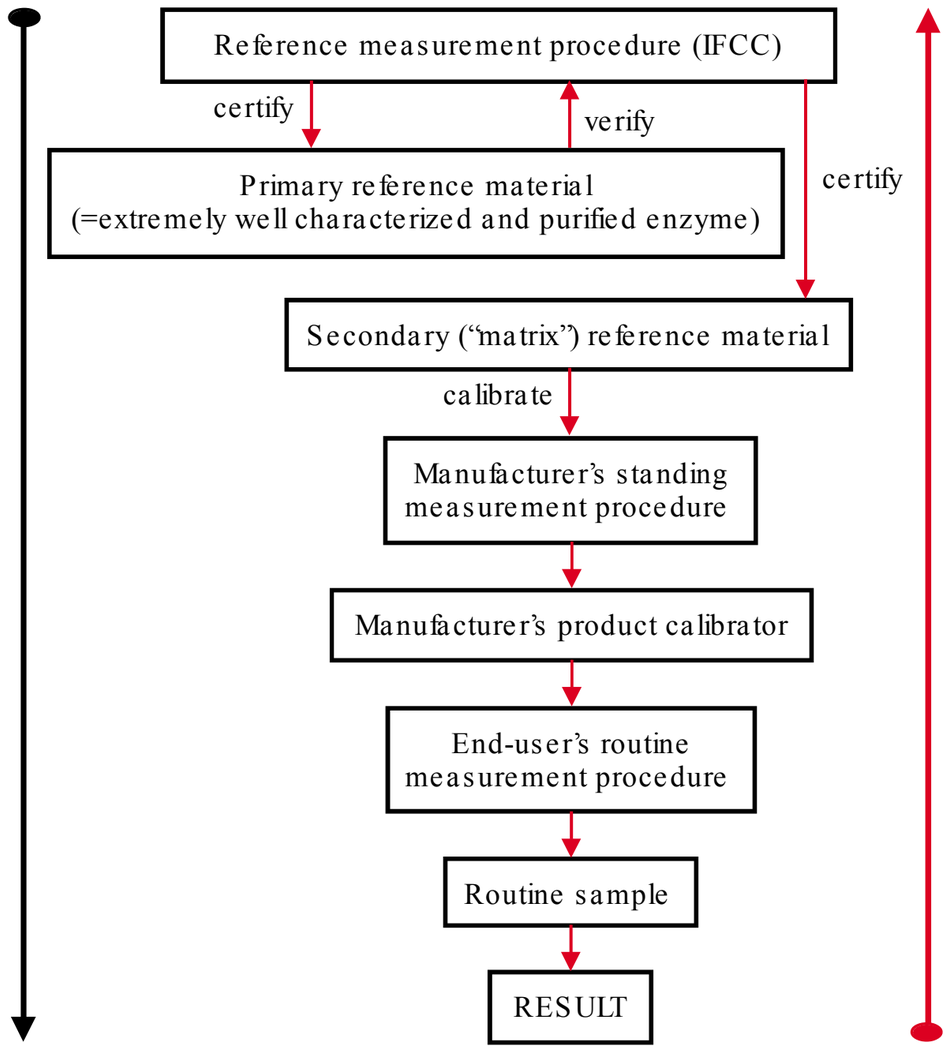

Figure 14-10 The proposed reference system for enzyme measurement showing the traceability of the laboratory result to the reference measurement procedure. (From Panteghini M, Ceriotti F, Schumann G, et al. Establishing a reference system in clinical enzymology. Clin Chem Lab Med 2001;39:795-800. Reprinted with permission of Walter de Gruyter.)

laboratories is still observed.[7,31] Consequently, current enzyme standardization efforts are focused on the development of a system that allows comparability of test results, independent of the measurement method. To achieve this, a "reference measurement system" based on the concepts of metrological traceability and on the hierarchy of analytical methods has been proposed.[8,15,32] A reference procedure and certified reference materials form the basis of the metrological traceability chain (Figure 14-10).[1,3] As part of this hierarchy, reference procedures at 37 °C for the most common enzymes have been developed, and reference laboratories are now available (http://www.bipm.org/jctlm/; accessed August 7, 2013) to perform enzyme measurements at an appropriately high metrological level.[18-26]

Reference procedures set standards of accuracy against which the relative performance of methods intended for routine use is judged. The reference procedure is used to assign a certified value to the reference material. Provided that its commutability is proven, this certified material is then used by manufacturers to assign values to commercial calibrators, resulting in traceability of the value obtained in the laboratory.

Several studies have demonstrated that it is possible to produce enzyme preparations with reproducible properties and purity and with assured stability. These may be derived from animal sources in which the enzymes closely resemble their human counterparts, although new possibilities have been created by gene transfer and recombinant techniques.

For a reference system to be capable of standardizing the results of different assays of a given enzyme activity, some conditions must be satisfied.[13] First, the reference procedure used to assign the value of the reference material and the routine method(s) to be calibrated must have identical specificities for the analyte enzyme, isoenzyme, or isoform under study. Second, the properties of the calibrator material must be the same as or closely similar to those of the analyte enzyme in its natural matrix, must be "commutable—substituted or interchanged," and must be capable of being exchanged for another or for something else that is equivalent to human serum samples for that particular method.

Quality Control

The application of quality control programs is as essential in enzyme analysis as it is in other forms of clinical analysis if the results obtained are to be useful in diagnosis and treatment.

Lyophilized and liquid preparations containing various enzymes are available from commercial sources; these have a useful function in quality control.

Measurement of Enzyme Mass Concentration

Many immunoassays have been developed for human enzymes and isoenzymes that measure protein mass instead of catalytic activity. To develop such assays, purified enzyme protein has to be prepared to (1) act as a calibrator, (2) be labeled, and (3) be used to raise the enzyme-specific antibody. These methods identify all molecules with the antigenic determinants necessary for recognition by the antibody, so that inactive enzyme molecules that are immunologically unaltered are measured along with active molecules. This has been found to be significant in the determination of some digestive enzymes, such as trypsin, when inactive precursors and inhibitors of catalytic activity are present in plasma. In most cases, however, no degradation or changes in the active enzyme occur in blood; therefore the clinical equivalence of the different measurement approaches is obtained.

Immunoassays typically are not used for determination of total activities for the more important diagnostic enzymes, as these assays generally cannot compete with automated measurements of catalytic activity in terms of (1) speed, (2) precision, and (3) cost. Furthermore, several enzyme activities in serum are caused by mixtures of immunologically distinct forms, so an assay using a single type of antibody usually determines only one of the enzyme forms. However, this disadvantage in the determination of total enzyme activity becomes a marked advantage in the measurement of specific isoenzymes and isoforms, and immunological methods have assumed great importance in isoenzyme analysis for diagnostic purposes.

Enzymes as Analytical Reagents

Enzymes are used as analytical reagents for the measurement of several metabolites and substrates and in immunoassays to detect and quantify immunological reactions.

Measurement of Metabolites

The use of enzymes as analytical reagents to measure metabolites frequently offers the advantage of great specificity for the substance being determined. This high specificity typically removes the need for preliminary separation or purification stages, so the analysis is carried out directly on complex mixtures such as serum. Uricase (urate oxidase), urease, and glucose oxidase are examples of highly specific enzymes used in clinically important assays for the measurement of (1) uric acid, (2) urea, and (3) glucose, specifically in biological fluids. However, high specificity is not always achieved in practice; knowledge of the substrate specificities of reagent enzymes is therefore essential to allow possible interferences with the assay to be anticipated and corrected. Coupled reactions are often used to construct an enzymatic analytical system that is used to determine a particular compound. An example of this is the determination of glucose by the hexokinase reaction. Hexokinase converts sugars other than glucose to their 6-phosphate esters. However, the indicator reaction used to monitor this change is catalyzed by glucose-6-phosphate dehydrogenase—an enzyme that is highly specific for its substrate—so the overall process is highly specific for glucose. In practice, both equilibrium and kinetic (rate) methods have been developed that use enzymes as reagents.[29]

Equilibrium Methods

Most assays used to determine the amount of a substance enzymatically are allowed to continue to completion, so that all substrate has been converted into a measurable product. These methods are called end point or, more correctly, equilibrium methods, because the reaction ceases when equilibrium is reached. Reactions in which the equilibrium point corresponds virtually to complete conversion of the substrate are obviously preferable for this type of analysis. However, an unfavorable equilibrium is often displaced in the desired direction by additional enzymatic or nonenzymatic reactions that convert or "trap" a product of the first reaction (e.g., in measuring lactate with lactate dehydrogenase, the pyruvate formed is trapped by the addition of hydrazine, with which it forms an irreversible hydrazone).

Kinetic Methods

First-order or pseudo–first-order reactions are the most important reactions for the kinetic determination of substrate concentration. For any first-order reaction, the substrate concentration [S] at a given time t after the start of the reaction is given by

$$[S]=[S_0]\times e^{-kt} \tag{7}$$

where $[S_0]$ is the initial substrate concentration, e is the base of the natural log, and k is the rate constant.

The change in substrate concentration $\Delta[S]$ over a fixed time interval, t_1 to t_2, is related to $[S_0]$ by the equation

$$[S_0]=\frac{-\Delta[S]}{e^{-kt_1}-e^{kt_2}} \tag{8}$$

which demonstrates that the change in substrate concentration over a fixed time interval is directly proportional to its initial concentration. This is a general property of first-order reactions.

For an enzymatic reaction, first-order kinetics is followed when [S] is small compared with K_m. Thus,

$$v=\frac{V_{max}}{K_m}\times[S] \tag{9}$$

or

$$v=k[S] \tag{10}$$

Methods in which some property related to substrate concentration such as (1) absorbance, (2) fluorescence, and (3) chemiluminescence is measured at two fixed times during the course of the reaction are known as two-point kinetic methods. Theoretically, they are most accurate for the enzymatic determination of substrates. However, these methods are technically more demanding than equilibrium methods, and all factors that affect reaction rate, such as (1) pH, (2) temperature, and (3) amount of enzyme, must be kept constant from one assay to the next, as must the timing of the two measurements. These conditions are readily achieved in automatic analyzers. A reference solution of the analyte (substrate) is used for calibration. To ensure first-order reaction conditions, the substrate concentration must be low compared with the K_m (i.e., on the order of less than $0.2 \times K_m$). Enzymes with high K_m values therefore are preferred for kinetic analysis to obtain a wider usable range of substrate concentrations.

Immunoassay

In enzyme immunoassay, first, enzyme-labeled antibodies or antigens are allowed to react with ligand; then an enzyme substrate is added. Enzymes such as (1) ALP, (2) horseradish peroxidase, (3) glucose-6-phosphate dehydrogenase, and (4) β-galactosidase have all been used as enzyme labels. A modification of this method is the enzyme-linked immunoabsorbent assay (ELISA), in which one of the reaction components is bound to a solid phase surface. With this technique, an aliquot of sample is allowed to interact with the solid phase antibody. After washing, a second antibody labeled with enzyme is added to form an Ab/Ag/Ab enzyme complex. Excess free enzyme–labeled antibody is then washed away, and the substrate is added; the conversion of substrate is proportional to the quantity of antigen. In immunoassays, it is not the specificity of labeled enzymes that is important, but their sensitivity.

Analytical Applications of Immobilized Enzymes

For some types of enzymatic analyses, enzyme consumption is reduced by the use of immobilized enzymes that are reused for several analyses. Immobilized enzymes have been chemically bonded to adsorbents, such as (1) microcrystalline cellulose, (2) diethylaminoethyl (DEAE) cellulose,

(3) carboxymethyl cellulose, and (4) agarose. Chemical groups such as (1) diazo, (2) triazine, and (3) azide are used to join the enzyme protein to the insoluble matrix, forming particles in contact with the substrate solution or a surface in contact with substrate solution, such as a membrane or a coating on the inner surface of a vessel holding the substrate solution. Among the enzymes available in such an immobilized form are (1) urease, (2) hexokinase, (3) α-amylase, (4) glucose oxidase, (5) trypsin, and (6) leucine aminopeptidase. Stability to heat and other forms of inactivation is considerably increased compared with enzymes in solution. Immobilized proteolytic enzymes are not subject to autodigestion. However, some properties of the enzyme, such as its K_m or its pH optimum, may be altered.

Electrochemical techniques, such as (1) potentiometry, (2) polarography, and (3) microcalorimetry, have been chosen to exploit the benefits of immobilized enzymes (see Chapter 10). Enzymes incorporated into membranes form a part of enzyme electrodes. The surface of an ion-sensitive electrode is coated with a layer of porous gel in which an enzyme has been polymerized. When the electrode is immersed in a solution of the appropriate substrate, the action of the enzyme produces ions to which the electrode is sensitive. For example, an oxygen electrode coated with a layer containing glucose oxidase has been used to determine glucose from the amount of oxygen consumed in the reaction. Urea has been estimated by the combination of a selective ammonium ion–sensitive electrode and a urease membrane.

Measurement of Isoenzymes and Isoforms

Various analytical techniques have been used to measure isoenzymes or isoforms. They include (1) electrophoresis (see Chapter 11), (2) chromatography (see Chapter 12), (3) chemical inactivation, and (4) differences in catalytic properties, but the most common routine methods are now based on (5) immunochemical assays.

Immunochemical methods of isoenzyme analysis are particularly applicable to isoenzymes derived from multiple gene loci, because they are usually most clearly antigenically distinct. However, the greater discriminating power of monoclonal antibodies has potentially brought all multiple forms of an enzyme within the scope of immunochemical analysis. Some of these methods make use of catalytic activity of the isoenzymes. For example, residual activity may be measured after reaction with antiserum. Radioimmunoassays, in which isoenzyme labeled with a radioactive tracer competes with unlabeled isoenzyme for antibody-binding sites, have also been applied to isoenzyme measurement. These methods do not depend on the catalytic activity of the isoenzyme being determined. However, with the development of automated immunoassay systems, the most common routine methods for measuring isoenzymes, such as CK-MB, are solid phase ELISAs.

The selection and application of various methods of isoenzyme analysis in clinical enzymology are discussed in Chapter 19 in relation to specific isoenzyme systems.

Review Questions

1. The Michaelis-Menten constant is:
   a. V_{max}.
   b. K_m.
   c. 1/v.
   d. [S].
2. The "active center" of an enzyme is:
   a. the protein part of an enzyme without the cofactor necessary for catalysis.
   b. that part of an enzyme that diminishes the rate of a chemical reaction.
   c. a site other than the substratebinding site.
   d. that part of an enzyme at which substrate binding occurs.
3. Which statement(s) below is (are) correct?
   a. Apoenzyme + Prosthetic group = Holoenzyme
   b. An enzyme without the prosthetic group attached is referred to as an apoenzyme.
   c. A prosthetic group is a coenzyme permanently bound to an enzyme molecule.
   d. All of the above statements are correct.
4. The graph on which the plot of 1/velocity versus 1/substrate concentration is illustrated is referred to as a:
   a. rate plot.
   b. Lineweaver-Burk plot.
   c. maximum velocity plot.
   d. Michaelis-Menten plot.
5. An enzyme assay during which a single measurement is taken at the termination of the enzymatic reaction is referred to as a:
   a. fixed-time assay.
   b. terminator assay.
   c. kinetic assay.
   d. continuous-monitoring assay.
6. A reactant in a catalysis reaction that binds to the enzyme's active site is the:
   a. enzyme.
   b. product.
   c. substrate.
   d. coenzyme.
7. Every enzymatic reaction follows specific kinetics as it proceeds from enzyme + substrate to product + enzyme. As substrate is consumed, the reaction rate decreases and becomes directly proportional to the amount of substrate that is present in low concentration. This is referred to as:
   a. V_{max}.
   b. K_m.
   c. first-order kinetics.
   d. zero-order kinetics.
8. An international unit (U) of enzyme activity is the amount of enzyme that will catalyze the reaction of:
   a. one micromole of substrate per minute.
   b. one mole of substrate per second.
   c. one micromole of enzyme per hour.
   d. one millimole of substrate per minute.

9. In an analytical enzymatic measurement of substrate, an enzyme reaction is accompanied by a change in absorbance of one component of the assay system. If this change is continuously monitored while it is occurring, the reaction is referred to as a(n):
   a. fixed-time reaction.
   b. end point assay.
   c. rate-limiting reaction.
   d. self-indicating reaction.
10. The most widely used method of isoenzyme analysis that allows the best discrimination between antigenically distinct isoenzymes derived from multiple-gene loci is:
   a. electrophoresis.
   b. an immunochemical method.
   c. chemical inactivation.
   d. chromatography.

CHAPTER

15 Immunochemical Techniques*

L.J. Kricka, D. Phil., F.A.C.B., C.Chem., F.R.S.C., F.R.C.Path.
and J.Y. Park, M.D., Ph.D., F.C.A.P

Objectives

1. Define the following:
   - Affinity
   - Antibody
   - Antigen
   - Avidity
   - Hapten
   - Immunoassay
   - Immunogen
   - Monoclonal antibody
   - Polyclonal antiserum
   - Sandwich immunoassay
2. Diagram, label and state the function of the components of an IgG antibody molecule.
3. List three binding forces that act to produce antigen/antibody binding.
4. Explain how the following factors affect antigen/antibody binding:
   - Addition of a linear polymer
   - Ion species
   - Mechanism of reaction
   - Precipitin reaction
5. For each of the following qualitative immunochemical techniques, state the principle and clinical use:
   - Immunoelectrophoresis
   - Immunofixation
   - Passive gel immunodiffusion
   - Western blotting
6. For each of the following quantitative immunochemical techniques, state the principle and clinical use:
   - Electroimmunoassay
   - Nephelometry
   - Radial immunodiffusion
   - Turbidimetry
7. List five nonisotopic labels used in a labeled immunochemical assay and provide one example of each type of label.
8. Compare the following types of assays, including procedure, assay components, and uses in the clinical laboratory: competitive with noncompetitive immunoassays and heterogeneous with homogeneous immunoassays.
9. For each of the following immunochemical techniques, state the principle, the components of each assay, the type of assay and the clinical uses:
   - Cloned enzyme donor immunoassay
   - Enzyme immunoassay
   - Enzyme-linked immunosorbent assay
   - Enzyme-multiplied immunoassay
   - Fluoroimmunoassay
   - Immunocytochemistry
   - Nanoparticle immunoassay
   - Simultaneous multianalyte immunoassay
10. State what is meant by the phrase "simplified immunoassay"; provide two examples of this type of assay used in a clinical setting.
11. Evaluate issues that can affect patient results when an immunoassay is used.

Key Words and Definitions

Affinity Energy of interaction of a single antibody-combining site and its corresponding epitope on the antigen.

Antibody Immunoglobulin (Ig) class of molecule (e.g., IgA, IgG, IgM) that binds specifically to an antigen or hapten.

Antigen Any material capable of reacting with an antibody without necessarily being capable of inducing antibody formation.

Avidity Overall strength of binding of antibody and antigen; includes the sum of the binding affinities of all individual combining sites on the antibody.

Competitive immunoassay An immunoassay in which all reactants are simultaneously or sequentially mixed together and unlabeled antigen competes with labeled antigen for binding sites on the antibody; no separation step is included in this assay.

Dot blotting A blotting technique in which the biomolecules to be detected are applied directly on a membrane as dots.

Hapten A chemically defined determinant that, when conjugated to an immunogenic carrier, stimulates the synthesis of antibody specific for the hapten.

*The author gratefully acknowledges the original contributions of Dr. Gregory Buffone, on which portions of this chapter are based.

Key Words and Definitions—cont'd

Heterogeneous immunoassay An immunochemical reaction in which it is assumed that the formation of the antigen/antibody complex occurs more quickly than the breakdown of the complex into antigen and antibody; in this assay, the antigen is labeled and separation of the free from the bound labeled antigen is required.

Homogeneous immunoassay An immunochemical reaction in which the activity of the label attached to the antigen is modulated directly by antibody binding; this assay does not require a separation.

Hook effect A phenomenon occurring with certain mmunoassays due to very high concentrations of a particular analyte; it results in a false negative result. The hook effect mostly affects one-step immunometric assays.

Immunoassay An assay based on the reaction of an antigen with an antibody specif c for the antigen.

Immunogen A substance capable of inducing an immune response.

Label Any substance with a measurable property attached to an antigen, antibody, or binding substance.

Noncompetitive immunoassay An immunoassay in which a capture antibody is bound to a surface with subsequent antigen binding followed by the addition of a second labeled antibody that reacts with the initial antigen/antibody complex.

Ouchterlony technique A technique in which both antigen and antibody are allowed to diffuse to each other in a gel in a precipitation reaction.

Northern blotting Membrane-based assay in which molecules of RNA are separated by electrophoresis, which is followed by transfer to a membrane and probing with a labeled antibody.

Radial immunodiffusion an immunodiffusion technique used to determine the quantity of an antigen by measuring the diameters of circles of precipitin complexes surrounding samples of the antigen.

Western blotting Membrane-based assay in which proteins are separated by electrophoresis, which is followed by transfer to a membrane and probing with a labeled antibody.

Immunochemical reactions form the basis for sensitive and specific clinical assays known as **immunoassays**.[1,2,7,10] In a typical immunoassay, an antibody is used as a reagent to detect the analyte of interest. T e exquisite specificity and high affinity of antibodies for specific antigens, coupled with the unique ability of antibodies to cross-link antigens, allows for the identification and quantification of specific substances by a variety of methods. Many of these assays are now automated. T e principles of the methods most commonly used in the laboratory are discussed in this chapter.

Basic Concepts and Def nitions

An **antigen** is any material capable of reacting with an antibody. With immunoassay, the antigen is the analyte of clinical interest that is being measured. **Antibodies** are immunoglobulins that bind specifically to a wide array of natural and synthetic antigens, such as (1) proteins, (2) carbohydrates, (3) nucleic acids, (4) lipids, and (5) other molecules. Analytically, immunoglobulin G (IgG) is the most prevalent immunochemical reagent in use. It is a glycoprotein that has a molecular weight (MW) of 158,000 Da and is composed of two duplex chains, with each set composed of a heavy (γ) and a light (λ or κ) chain joined by disulfide bonds (Figure 15-1). Interchain disulfide bonds hold the duplex chains together and create a symmetrical molecule. T e variable amino acid sequence at the amino terminal end of each chain determines the antigenic specificity of the particular antibody. Each unique amino acid sequence is a product of a single plasma cell line or clone, and each plasma cell line produces antibodies with single specificities. A complex antigen elicits a multiplicity of antibodies with different specificities derived from different cell lines. An antibody developed in this manner is termed polyclonal and exhibits diverse specificities in its reactivity with the immunogen. Each unique region of the molecular antigen that binds a complementary antibody is termed an epitope (antigenic determinant).

An **immunogen** is a protein or a substance coupled to a carrier, usually a protein. Introduction of an immunogen into a foreign host induces the formation of an antibody. A **hapten** is a chemically defined determinant that by itself will not stimulate an immune response. However, when conjugated to an immunogenic carrier, the conjugated molecule stimulates the synthesis of antibody specific for the hapten. Some general properties required for immunogenicity include the following:

1. Areas of structural stability within the molecule
2. Randomness of structure
3. Minimum MW of 4000 to 5000 Da
4. Ability to be metabolized (a necessary but insufficient criterion for some classes of antigens)
5. Accessibility of a particular immunogenic configuration to the antibody-forming mechanism
6. Structurally foreign quality

T e strength or energy of interaction between the antibody and the antigen is described in two terms. **Affinity** refers to the thermodynamic quantity defining the energy of interaction of a single antibody-combining site and its corresponding epitope on the antigen. **Avidity** refers to the overall strength of the binding of antibody and antigen and includes the sum of the binding affinities of all individual combining sites on the antibody. T us affinity is a property of the substance bound (antigen), and avidity is a property of the binder (antibody).

Polyclonal antiserum is produced in a normal animal host in response to immunogen administration. In contrast, a monoclonal antibody is the product of a single clone or plasma cell line rather than a heterogeneous mixture of antibodies

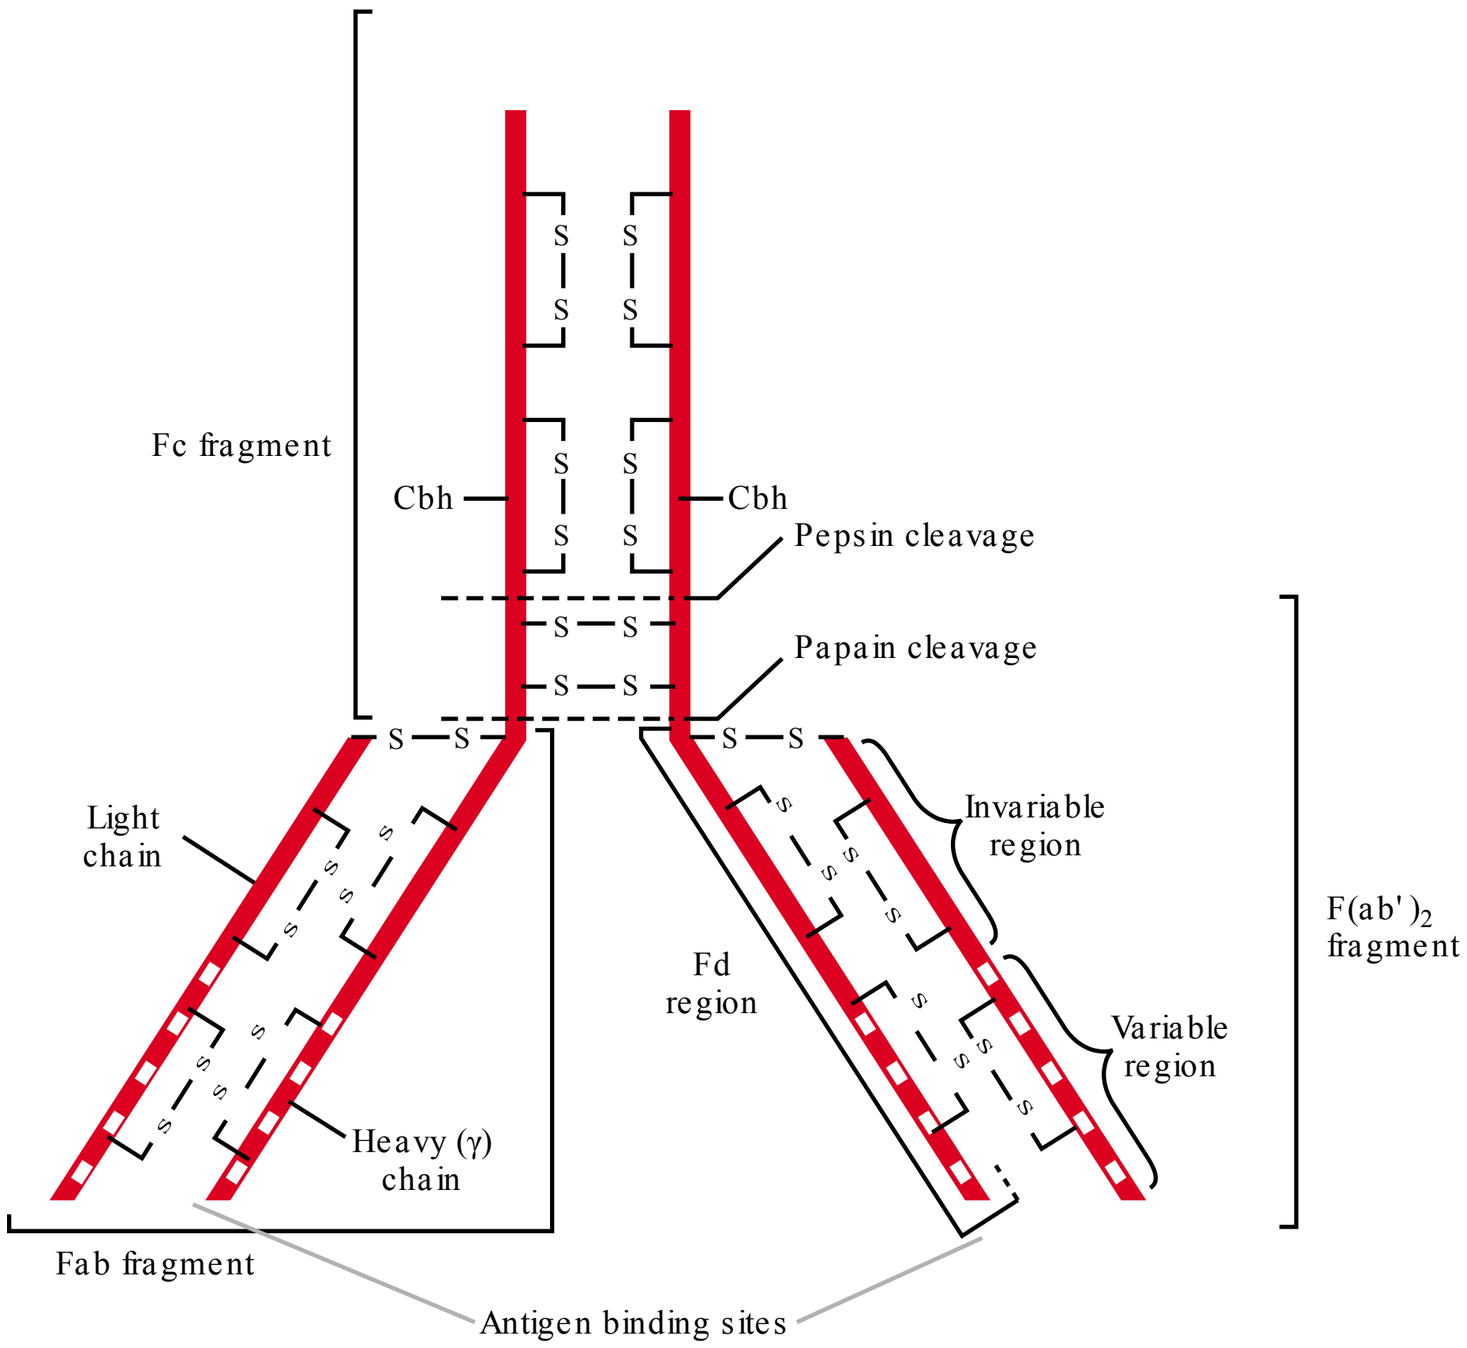

Figure 15-1 Schematic diagram of IgG (immunoglobulin G) antibody molecule showing carbohydrate (Cbh), disulfide bonds (SS), and major fragments produced by proteolytic enzyme treatment (F[ab′]$_2$, Fc, Fab, Fd).

produced by many cell clones in response to immunization. Monoclonal antibodies now are used widely as reagents in immunoassay techniques.[3] The usual method of production of monoclonal antibodies involves fusing of sensitized lymphocytes from the spleens or lymph nodes of immunized mice with a murine myeloma cell line from tissue culture (an immortal B-cell line). The murine myeloma cell lines most commonly used are deficient in the enzyme hypoxanthine guanine phosphoribosyl transferase (HGPRT) and therefore do not synthesize purine bases from thymidine and hypoxanthine in the presence of aminopterin. After the fusion, the cells are placed into a selection medium containing hypoxanthine, aminopterin, and thymidine (HAT medium) to grow selectively fused hybrid cell lines. The fused hybrid cells will survive in a HAT medium because the cells combine the immortality of the myeloma cell with the genetic material of the spleen cell necessary for synthesis of HGPRT. Colonies arising from the fused cells then are screened for antibody production, and those cell lines secreting antibody of the desired specificity are cloned in subcultures. Thus a single clonal line is then isolated that produces an antibody with a specificity for a single antigen epitope and with a single binding energy or affinity.

Monoclonal antibodies provide an analytical advantage in that two different antibody specificities are used in a single assay. For example, a solid phase antibody specific for a unique epitope and another labeled antibody specific for a different epitope are reacted with antigen in a single incubation step. This is combination eliminates (1) the two-step sequential addition of antigen and labeled antibody to the solid phase, (2) one incubation step, and (3) one washing step, which would be necessary when polyclonal antibodies binding to both sites are used. However, the unique ability of a monoclonal antibody to react with a single epitope on a multivalent antigen results in an inability of most monoclonal antibodies to cross-link and precipitate macromolecular antigens. Thus monoclonal antibodies are not applicable for all immunoassays in the clinical laboratory, especially those that use traditional precipitin methods.

Phage-display technology is a different in vitro approach for the production of antibodies that mimic the immune system.[11] Through this process, genes coding for the heavy and light chain variable domains of immunoglobulin isolated from lymphocytes are amplified by the polymerase chain reaction (PCR) and ligated into a filamentous bacteriophage vector to form combinatorial libraries of V_H and V_L genes. Individual bacteriophages display copies of a specific antibody on their surface, and the phage library then is screened for antibody of defined specificity through the use of immobilized antigen ("panning"). This is technique mimics immune selection, and antibodies with different binding specificities are isolated. Through this process, large libraries displaying more than 10^{12} antibodies have been formed.

Antigen-Antibody Binding

In this section, several of the factors that affect the binding of antigens and antibodies are discussed.

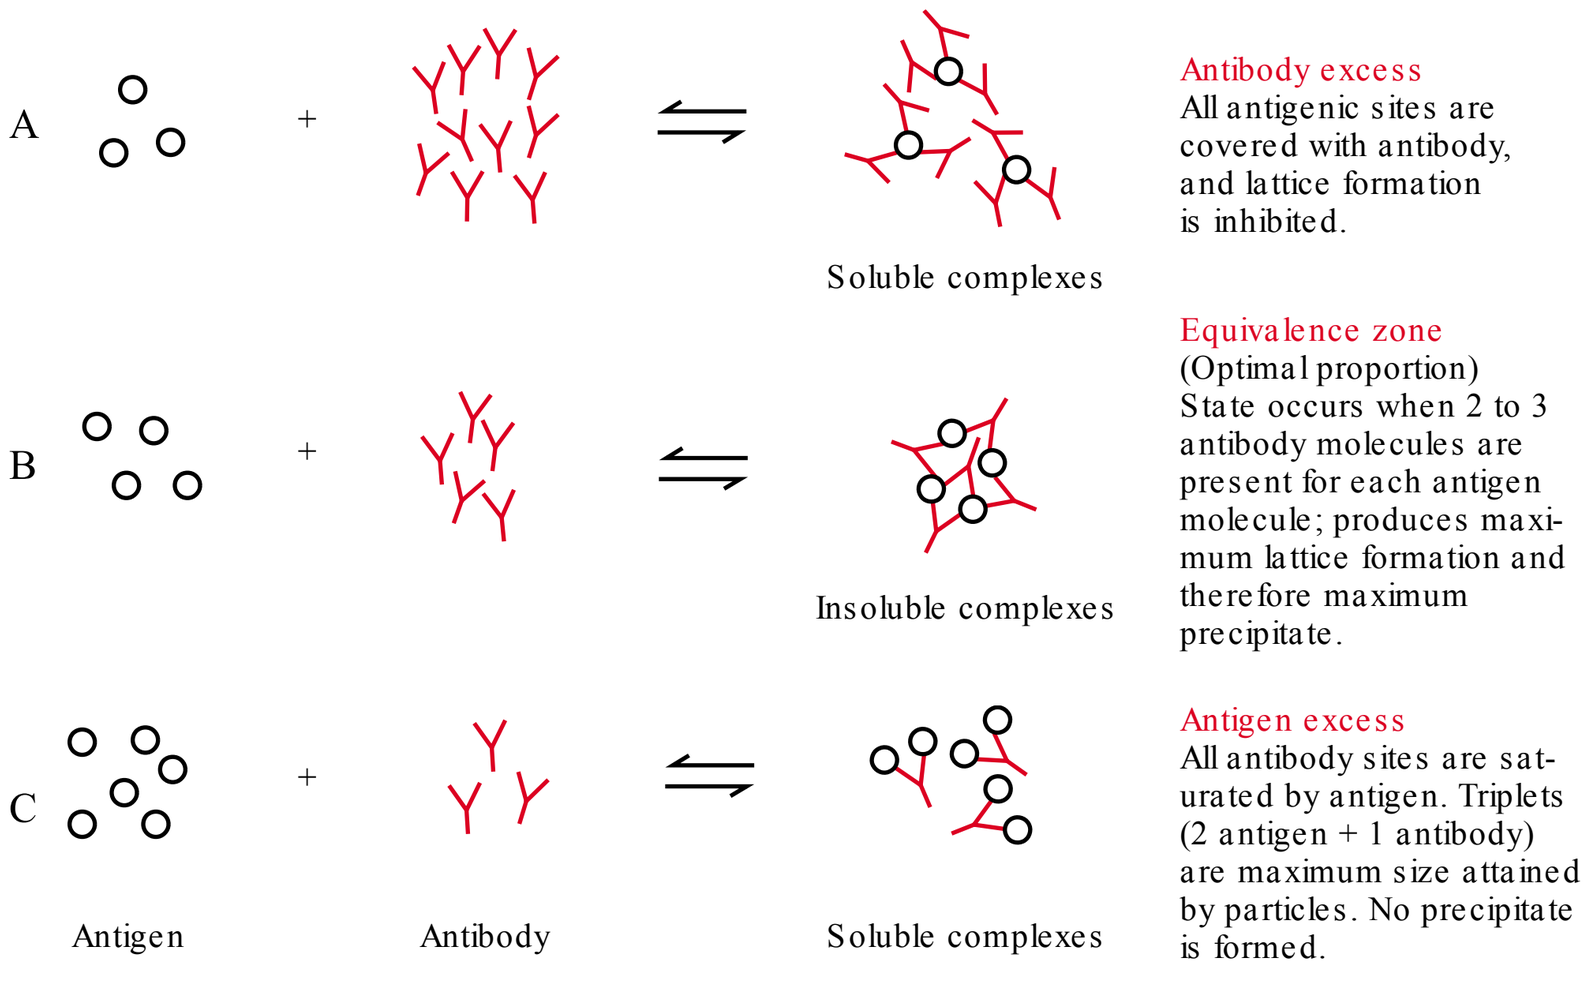

Figure 15-2 Schematic diagram for precipitin reaction. A, Antibody excess. B, Equivalence zone. C, Antigen excess.

Binding Forces

Several forces act cooperatively to produce antigen-antibody binding. The three major contributing forces are (1) electrostatic van der Waals–London dipole-dipole interactions, (2) hydrophobic interactions, and (3) ionic coulombic bonding (primarily between COO^- and NH_4^+ groups on the antigen and the antibody).

Reaction Mechanism

The binding of antigen to antibody is not static but is an equilibrium reaction that proceeds in three phases. The initial reaction (phase 1) of a multivalent antigen (Ag_n) and a bivalent antibody (Ab) occurs very rapidly in comparison with subsequent growth of the complexes (phase 2) and is depicted by the following equation:

$$Ag_n + Ab \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} Ag_n Ab \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} Ag_a Ab_b \qquad (1)$$

where $k_1 >>> k_2$, n is the number of epitopes per molecule, and a and b are the numbers of antigen and antibody molecules per complex. Phase 3 of the reaction involves the precipitation of the complex after a critical size is reached. The speed of these reactions depends on electrolyte concentration, pH, and temperature, as well as on antigen and antibody types and the binding affinity of the antibody.

Precipitin Reaction

If the number of antibody combining sites [Ab] is significantly greater than the number of antigen binding sites [Ag], then antigen binding sites are quickly saturated by antibody before cross-linking occurs, and the formation of small antigen/antibody complexes of the composition AgAb results (Figure 15-2, A). For the case in which antibody is in moderate excess ([Ab] > [Ag]), the probability of cross-linking of Ag by Ab is more likely, hence large complex formation is favored (Figure 15-2, B).

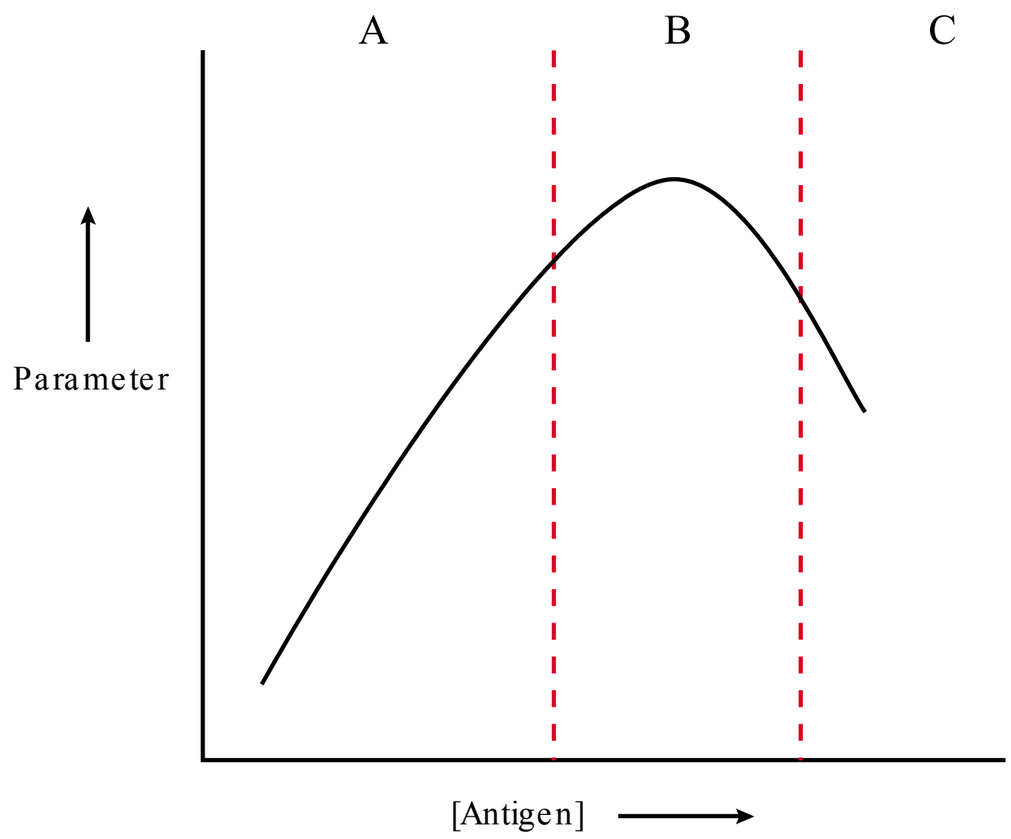

Figure 15-3 Schematic diagram of precipitin curve illustrating different antigen concentration zones. A, Antibody excess. B, Equivalence. C, Antigen excess. The parameter measured may be the quantity of protein precipitated, light scattering, or another measurable parameter. Antibody concentration is held constant in this example.

In the case in which [Ag] is in great excess, large complexes are less probable, and the theoretical minimum size of complexes is Ag_2Ab (Figure 15-2, C).

This model describes the results observed when antigens and antibodies are mixed in various concentration ratios. The curve shown in Figure 15-3 is a schematic diagram of the classic precipitin curve. Although the concentration of total antibody is constant, the concentration of free antibody, $[Ab]_f$, and of free antigen, $[Ag]_f$, varies for any given Ag/Ab ratio. A low Ag/Ab ratio exists in Figure 15-3, A (zone of antibody excess). Under these conditions, $[Ab]_f$ exists in solution, but $[Ag]_f$ does not. As total antigen increases, the size of the immune complexes increases up to equivalence (Figure 15-3, B), where

little or no $[Ab]_f$ or $[Ag]_f$ exists. This is the zone of equivalence, and it is the optimal combining ratio for cross-linking in the particular system under examination. As Ag/Ab increases (Figure 15-3, C), the immune complex size decreases and $[Ag]_f$ increases (zone of antigen excess).

Chemical Factors

Chemical factors that influence antibody-antigen binding include ionic species, ionic strength, and polymeric molecules.

Ion Species and Ionic Strength Effects

Cationic salts produce inhibition of the binding of antibody with a cationic hapten. The order of inhibition by various cations is $Cs^+ > Rb^+ > NH_4^+ > K^+ > Na^+ > Li^+$. This order corresponds to the decreasing ionic radius and the increasing radius of hydration. For anionic haptens and anionic salts, the order of inhibition of binding is $CNS^- > NO_3^- > I^- > Br^- > Cl^- > F^-$, again in the order of decreasing ionic radius and increasing radius of hydration.

Polymer Effect

The addition of a linear polymer to a mixture of antigen and antibody causes a significant increase in the rate of immune complex growth and enhances the precipitation of immune complex, especially with low-avidity antibody. Numerous polymer species, such as (1) dextran (a high-molecular-weight polymer of d-glucose), (2) polyvinyl alcohol, and (3) polyethylene glycol 6000 (PEG or Carbowax), have been used in immunochemical methods. The most desirable characteristics of the polymer are high (1) molecular weight, (2) degree of linearity (minimum branching), and (3) aqueous solubility. PEG 6000 has these characteristics and is particularly useful in immunochemical methods at concentrations of 3 to 5 g/dL.

Qualitative Methods

Immunochemical techniques used for qualitative purposes include (1) passive gel diffusion, (2) immunoelectrophoresis (IEP), and (3) western blotting.

Passive Gel Diffusion

Many qualitative and quantitative immunochemical methods are performed in semisolid media, such as agar or agarose. This is practice stabilizes the diffusion process with regard to mixing caused by vibration or convection and allows visualization of precipitin bands for qualitative and quantitative evaluation of the reaction. Antigen/antibody ratio, salt concentration, and polymer enhancement have the same influence on the antigen-antibody reaction in gels as they have on reactions in solution.

If the matrix does not interact with the molecular species under investigation, passive diffusion of reactants in a semisolid matrix is described by Fick's equation

$$\frac{dQ}{dt} = -DA\frac{dc}{dx} \qquad (2)$$

where

dQ = amount of diffusing substance that passes through area A during time t;
dt = change in time;
dC/dx = concentration gradient; and
D = diffusion coefficient.

The diffusion coefficient, D, is a direct function of temperature; it is inversely proportional to the hydrated molecular volume of the diffusing species. The ratio dQ/dt is a function of dC/dx, the concentration gradient. The amount of diffusing species transferred from the origin to a distant point (over the migration distance) is dependent on the length of time diffusion is allowed to occur.

The initial concentrations of antigen and antibody are critical. Each molecule in the system achieves a unique concentration gradient with time. When the leading fronts of antigen and antibody diffusion overlap, the reaction begins, but formation of a precipitin line does not occur until moderate antibody excess is achieved. A precipitin band may form and be dissolved many times by incoming antigen before equilibrium is established and the position of the precipitin band is stabilized.

Simple diffusion and double diffusion are the two basic approaches used for qualitative applications of passive diffusion. In simple diffusion, a concentration gradient is established for only a single reactant. This approach, which is called single immunodiffusion, usually depends on diffusion of an antigen into agar impregnated with antibody. A quantitative technique based on this principle is called **radial immunodiffusion** (RID).

In the second approach, which is called double diffusion, a concentration gradient is established for both antigen and antibody (Figure 15-4). This approach is known as the **Ouchterlony technique**. In practice, it permits direct comparison of two or more test materials and provides a simple and direct method by which to determine whether antigens in the test specimens are (1) identical, (2) cross-reactive, or (3) nonidentical.

Immunoelectrophoresis

Immunoelectrophoresis (IEP) is an analytical technique that combines separation of antigens by electrophoresis with immunodiffusion against an antiserum. It is used in a clinical laboratory to separate and identify the various protein species contained in a common solution, such as serum or spinal fluid. This technique has been used extensively for the study of antigen mixtures and for the evaluation of human gammopathies. Proteins in the serum are separated according to their electrophoretic mobility (Figure 15-5). After electrophoresis, an antiserum against the protein of interest is placed in a trough parallel and adjacent to the electrophoresed sample. Simultaneous diffusion of the antigen from the separated sample and of antibody from the trough results in the formation of precipitin arcs with shapes and positions characteristic of the individual separated proteins in the specimen.

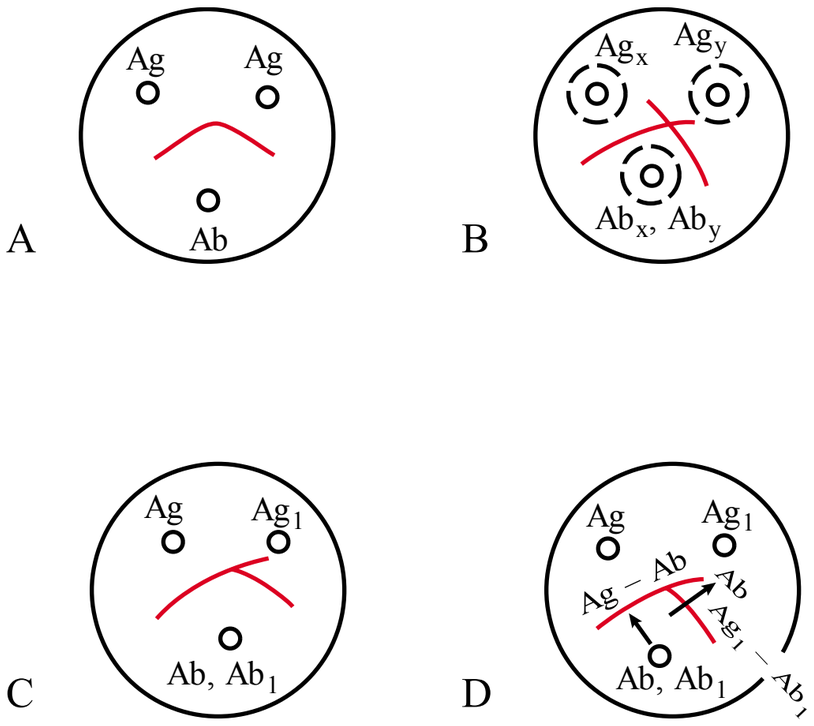

Figure 15-4 Double immunodiffusion in two dimensions by the Ouchterlony technique. Sample is placed in each Ag circular well. Antibodies or serum is placed in each Ab circular well. At the completion of the reaction, the antigen/antibody complex is visualized as a precipitated line. A, Reaction of identity; a single continuous line of precipitation is noted. The two samples have the same antigen(s) recognized by the antibody placed in the Ab circular well; the samples are antigenically identical. B, Reaction of nonidentity; two lines briefy overlap but appear to be independent. The two samples Ag_x and Ag_y are different antigens that react with their respective antibodies Ab_x and Ab_y; no cross-reaction is seen. C, Reaction of partial identity; two lines partially join and a "spur" is formed. The two samples have some epitopes that overlap, but complete identity does not occur. D, Scheme for spur formation. Ab, Antibody; Ag, antigen.

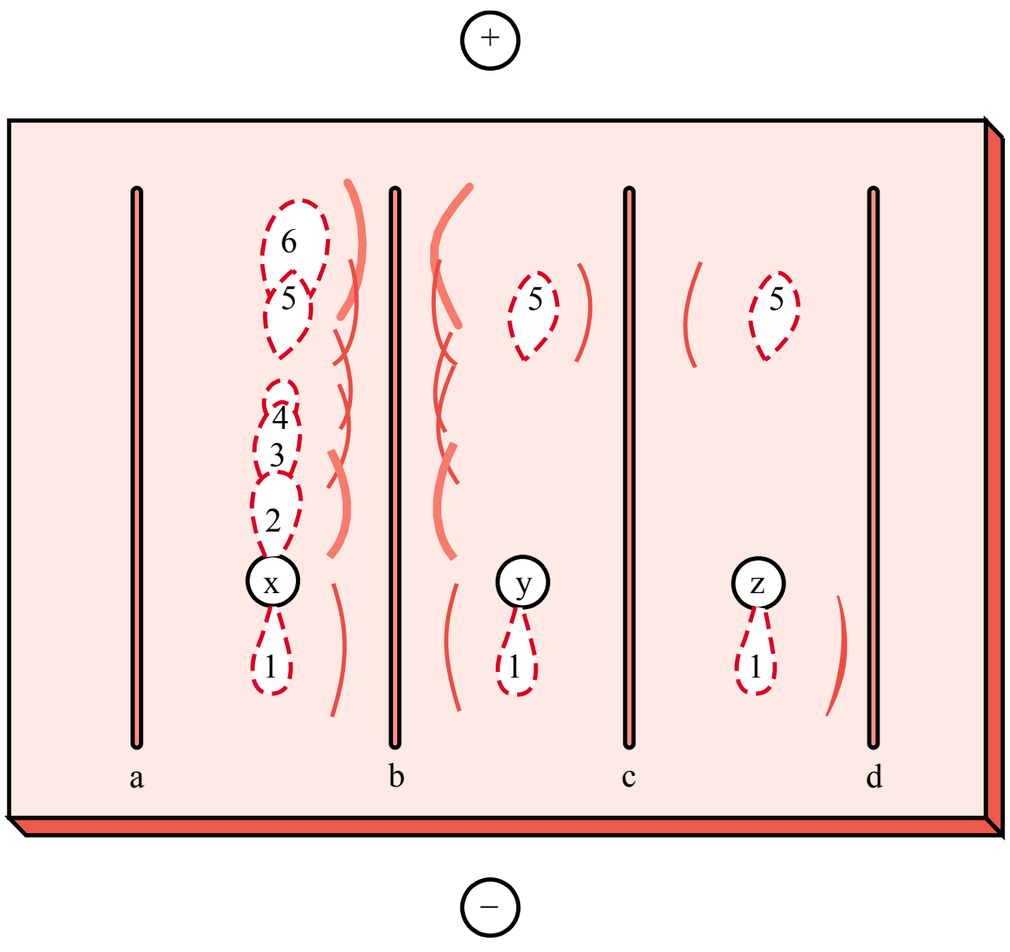

Figure 15-5 Configuration for immunoelectrophoresis. Sample wells are punched in the agar/agarose (x, y, z), sample is applied, and electrophoresis is carried out to separate the proteins in the sample. Antiserum is loaded into the troughs, and the gel is incubated in a moist chamber at 4 °C for 24 to 72 hours. Track x represents the shape of the protein zones after electrophoresis; tracks y and z show the reaction of proteins 5 and 1 with their specific antisera in troughs c and d. Antiserum against proteins 1 through 6 is present in trough b.

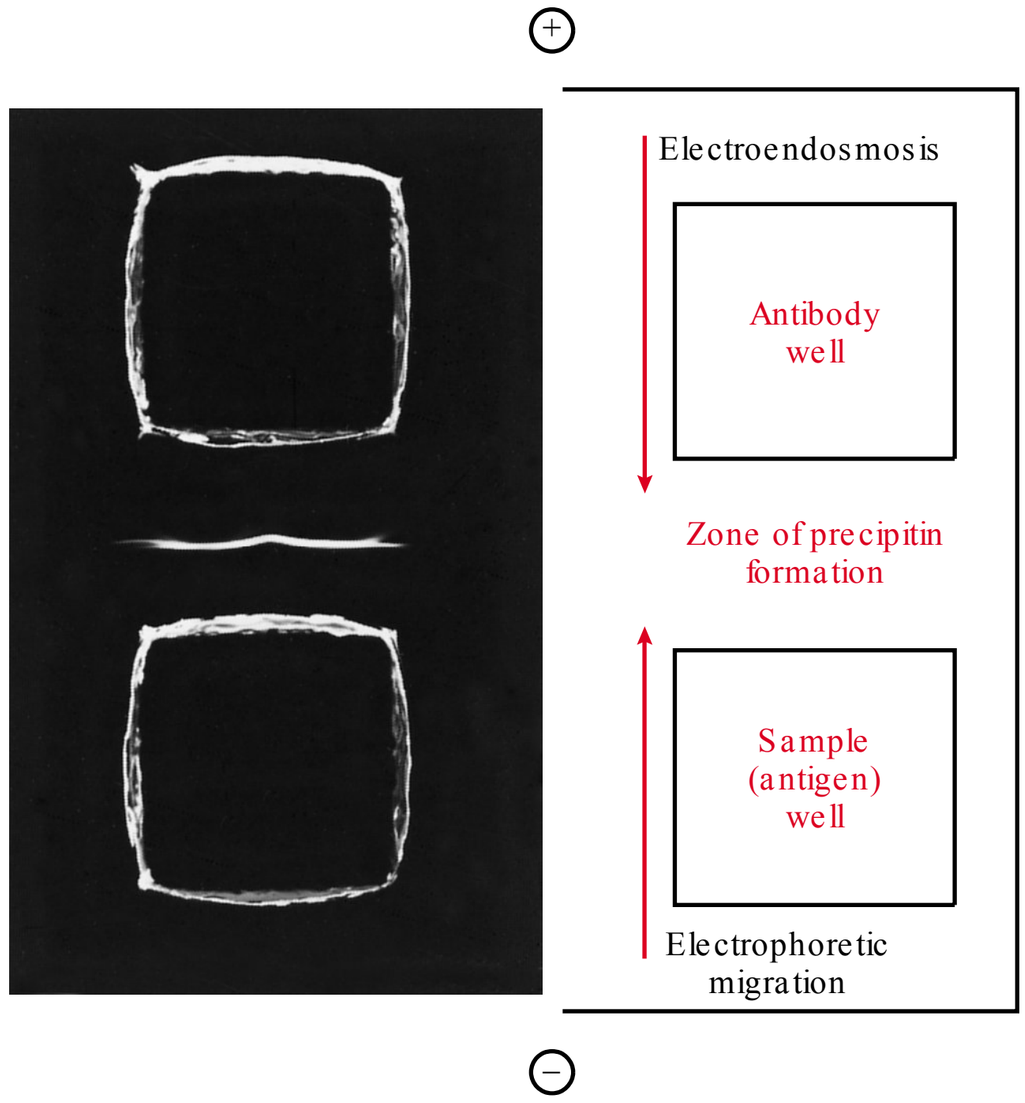

Figure 15-6 Counter immunoelectrophoresis showing a positive reaction between anti-Haemophilus infuenzae B (upper well) and a cerebrospinal fuid (CSF) sample containing H. infuenzae B (lower well).

In the clinical laboratory, this procedure has been applied to the evaluation of human myeloma proteins. However, the method gradually is being replaced by immunofixation electrophoresis, particularly in the study of protein antigens and their split products and in the evaluation of myeloma.

Crossed immunoelectrophoresis (CRIE, also known as two-dimensional immunoelectrophoresis) is a variation of IEP wherein electrophoresis is also used in the second dimension to drive the antigen into a gel containing antibodies specific for the antigens of interest.[5] In practice, CRIE is more sensitive and produces higher resolution than is possible with IEP. In counter immunoelectrophoresis (CIE), two parallel lines of wells are punched in the agar. One row is filled with antigen solution, and the opposing row is filled with antibody solution (Figure 15-6). Voltage is applied across the gel, causing antigen and antibody to move toward each other at a faster rate. A precipitin line is formed where they meet. T is qualitative information is used to identify the antigen and is provided within 1 to 2 hours. CIE has found application in the detection of bacterial antigens in (1) blood, (2) urine, and (3) cerebrospinal fuid.

Immunofixation (IF) has gained widespread acceptance as an immunochemical method used to identify proteins. With this technique, electrophoresis is first performed in agarose gel to separate the proteins in the mixture. Subsequently, antiserum spread directly on the gel causes the protein(s) of interest to precipitate. T e immune precipitate is trapped within the gel matrix, and all other nonprecipitated proteins are then removed by washing of the gel. T e gel then is stained for identification of the proteins. In practice, however, CRIE is more

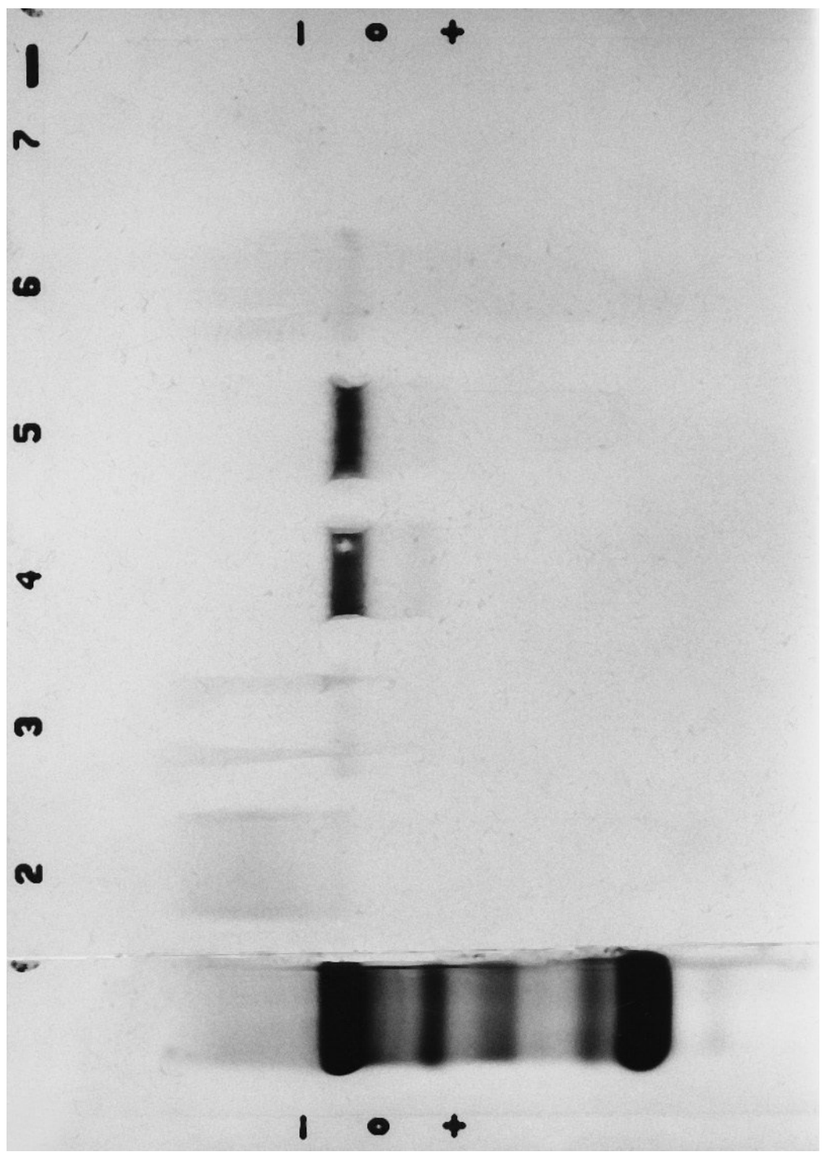

Figure 15-7 Immunofixation of a serum containing an immunoglobulin (Ig)M kappa paraprotein. Lane 1, Serum electrophoresis stained for protein; lane 2, Anti-IgG, Fc piece-specific; lane 3, Anti-IgA, α-chain–specific; lane 4, Anti-IgM, α-chain–specific; lane 5, Anti-κ light chain; lane 6, Anti-λ light chain. (Courtesy Katherine Bayer, Philadelphia.)

sensitive than IF in terms of limits of detection, and it demonstrates improved resolution. In addition, proteins of closely related or identical electrophoretic mobility are distinguished better by CRIE because in IF they appear as a single band. The utility of IF, which now is used widely for the evaluation of myeloma proteins, is illustrated in Figure 15-7.

Blotting

The previously discussed techniques use direct examination of immunoprecipitation of the protein(s) in the gel. However, certain media, such as polyacrylamide, do not lend themselves to direct immunoprecipitation, nor does sufficient antigen concentration always exist to produce an immunoprecipitate that is retained in the gel during subsequent processing. Under these circumstances, the technique of **Western blotting** is used. This technique involves an electrophoresis step, followed by transfer of the separated proteins onto an overlying strip of nitrocellulose or nylon membrane by a process called electro-blotting. Once the proteins are fixed to the membrane, they are detected with antibody probes labeled with molecules such as enzymes. With the use of such probes, the limits of detection are 10 to 100 times lower than the values obtained through direct immunoprecipitation and staining of proteins. This technique is analogous to Southern blotting (electrophoresed DNA blotted onto a membrane) and **Northern blotting** (electrophoresed RNA blotted onto a membrane).

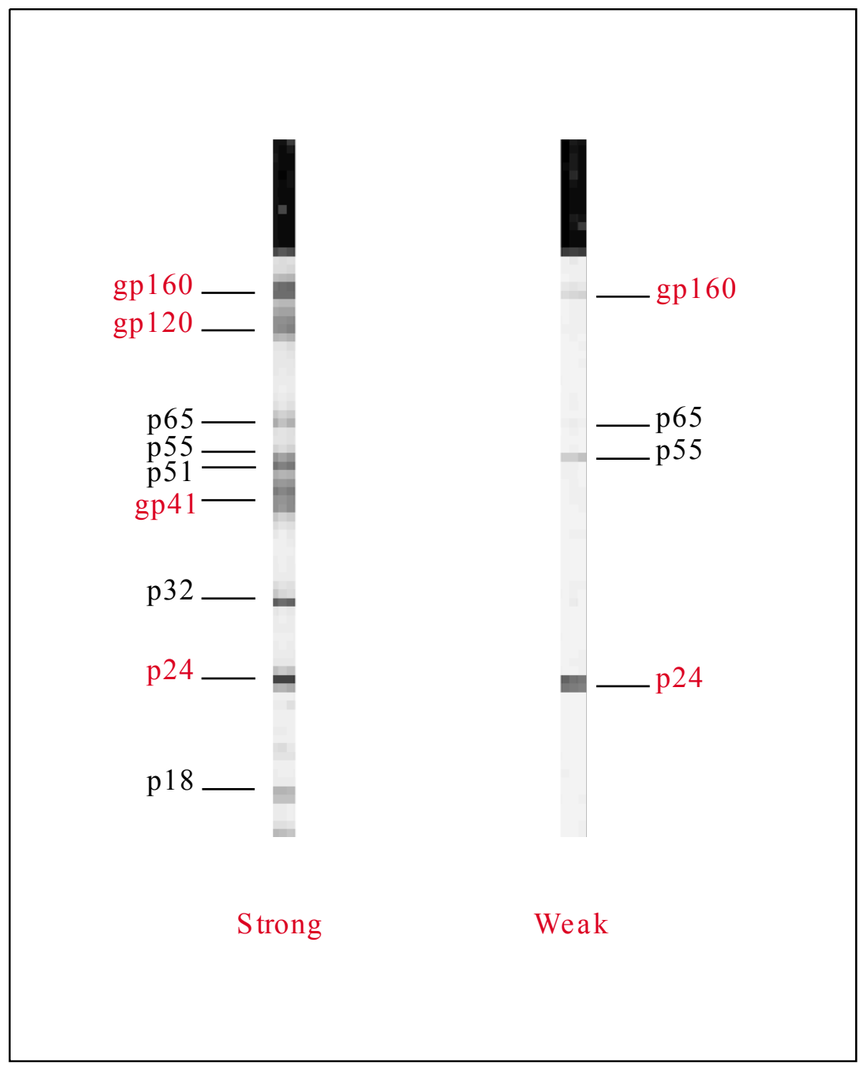

Figure 15-8 Blot analysis of serum samples strongly positive and weakly positive for human immunodeficiency virus (HIV)-1 antibody. Core proteins (GAG, group-specific antigens) p18, p24, and p55; polymerase (POL) p32, p51, and p65; and envelope proteins (ENV) gp41, gp120, and gp160. (Courtesy Bio-Rad Laboratories Diagnostics Group, Hercules, Calif.)

An example of a blotting analysis for human immunodeficiency virus type 1 (HIV-1) antibodies is shown in Figure 15-8. When applied to antigen assays, concentrations of antigen as low as 500 ng/mL or 2.5 ng per band in the gel have been detected. The detection limit of the technique is lowered even farther to approximately 100 pg by chemiluminescent detection of the enzyme-labeled antibody and by detection of light emission through the use of X-ray or photographic film.[4]

A simpler technique that bypasses the electrophoretic separation step is known as **dot blotting**. A sample of the (1) protein, (2) DNA, or (3) RNA to be analyzed is applied to a membrane surface as a small "dot" and is dried. The membrane then is exposed to a labeled antibody specific for the test antigen contained in the dotted mixture. After the membrane is washed, bound-labeled antibody is detected with a photometric or chemiluminescent detection system.

Quantitative Methods

Immunochemical techniques have been used to develop quantitative methods and include (1) radial diffusion and electroimmunoassays, (2) turbidimetric and nephelometric assays, and (3) labeled immunochemical assays.

Radial Immunodiffusion (RID) and Electroimmunoassay

Radial immunodiffusion (RID) and electroimmunoassay are commonly used for quantitative immunochemical measurements. RID is a passive diffusion method in which

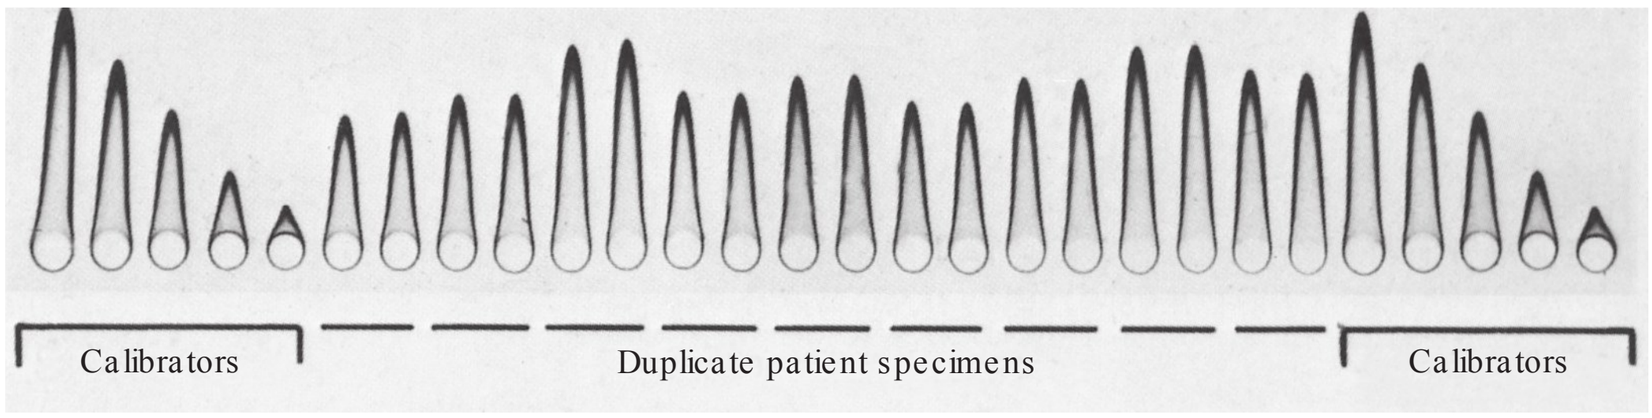

Figure 15-9 Rocket immunoelectrophoresis of human serum albumin. Patient samples were applied in duplicate. Calibrators were placed at opposite ends of the plate.

a concentration gradient is established for a single reactant, usually the antigen. The antibody is dispersed uniformly in the gel matrix. Antigen is allowed to diffuse from a well into the gel until antibody excess exists and immune precipitation occurs; a well-defined ring of precipitation around the well indicates the presence of antigen. The ring diameter continues to increase until equilibrium is reached. Calibrators are run simultaneous with the sample, and a calibration curve of ring area or diameter versus concentration is generated.

Electroimmunoassay (known as the "rocket" technique) is a type of immunoassay wherein a single concentration gradient is established for the antigen, and an applied voltage is used to drive the antigen from the application well into a homogeneous suspension of antibody in the gel (Figure 15-9). This process produces a unidirectional migration of antigen and results in a lowered limit of detection. The height of the resulting rocket-shaped precipitin line is proportional to the antigen concentration. Quantification is achieved through the processing of aliquots of calibrators and samples on the same plate Concentrations of the samples are subsequently estimated by comparing the height of the rockets obtained from the samples with a calibration curve generated from the heights of the rockets obtained from the calibrators. The calibration curve is linear only over a narrow concentration span; consequently, samples may have to be diluted or concentrated as necessary.

Turbidimetric and Nephelometric Assays

Turbidimetry and nephelometry are convenient techniques used to measure the rate of formation of immune complexes in vitro. Instrumental principles for these methods are described in Chapter 9. Studies have shown that the reaction between antigen and antibody begins within milliseconds and continues for hours. The performance of both types of assays has been improved significantly by increases in the reaction rate attained by the addition of water-soluble linear polymers.

Both turbidimetric and nephelometric immunochemical methods using rate and pseudoequilibrium protocols have been described for (1) proteins, (2) antigens, and (3) haptens. In rate assays, measurements usually are made early in the reaction because the largest change (dI_s/dt) in intensity of scattered light (I_s) with respect to time is attained during this time interval. For pseudoequilibrium assays, waiting 30 to 60 minutes is necessary so that the dI_s/dt is small relative to the time required to make the necessary measurements. (Note: Such assays are termed pseudoequilibrium rather than equilibrium because true equilibrium is not reached within the time allowed for these assays.)

Nephelometric methods in general are more sensitive than turbidimetric assays and have a lower limit of detection of approximately 1 to 10 mg/L for a serum protein. Lower limits of detection are attained in fluids such as cerebrospinal fluid and urine because of their lower lipid and protein concentrations, which result in a higher signal-to-noise ratio. In addition, for low-molecular-weight proteins such as myoglobin (MW 17,800 Da), limits of detection have been lowered through a latex-enhanced procedure based on antibody-coated latex beads.

Nephelometric and turbidimetric assays have also been applied to the measurement of drugs (haptens) with the use of inhibition techniques. To make the reagent, the drug of interest is attached to a carrier molecule, such as bovine serum albumin. The hapten-bound albumin then competes with free hapten (drug introduced in the sample) for antihapten-antibody. In the presence of free hapten, immune complex formation is decreased because more antibody sites are saturated; thus light scattering is decreased. The decrease in light scattering is related to the concentration of free hapten. Both kinetic and pseudoequilibrium methods have been described. In the absence of free hapten, bound hapten-albumin reacts with available antihapten-antibody sites to form cross-linked immune complexes with high light-scattering abilities.

Labeled Immunochemical Assays

The previously discussed methods rely on examination of the immune complex formation as an index of antigen-antibody reaction. As demonstrated in equation (1), the overall reaction occurs in sequential phases, and only the final phase consists of formation of the immune complex. However, initial binding of antibody and antigen has been used with antigens and antibodies that have **labels** to develop many sensitive and specific immunochemical assays. The reaction describing this initial binding and the kinetic constant for the overall reaction are shown in equations (3a) and (3b), respectively.

$$Ab + Ag \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} AbAg \qquad (3a)$$

$$K = \frac{[AbAg]}{[Ab]\,[Ag]} \qquad (3b)$$

TABLE 15-1 Labels Used for Nonisotopic Immunoassay

Chemiluminescent	Acridinium ester, sulfonyl acridinium ester, isoluminol
Cofactor	Adenosine triphosphate, flavin adenine dinucleotide
Enzyme	Alkaline phosphatase, marine bacterial luciferase, β-galactosidase, firefly luciferase, glucose oxidase, glucose-6-phosphate dehydrogenase, horseradish peroxidase, lysozyme, malate dehydrogenase, microperoxidase, urease, xanthine oxidase
Fluorophore	Europium chelate, fluorescein, phycoerythrin, terbium chelate
Free radical	Nitroxide
Inhibitor	Methotrexate
Metal	Gold sol, selenium sol, silver sol
Particle	Bacteriophage, erythrocyte, latex bead, liposome, quantum dot
Phosphor	Up-converting lanthanide-containing nanoparticle
Polynucleotide	DNA
Substrate	Galactosyl-umbelliferone

where

k_1 = rate constant for the forward reaction;
k_{-1} = rate constant for the reverse reaction; and
K = equilibrium constant for the overall reaction.

As predicted from the law of mass action, the concentrations of Ab, Ag, and Ab:Ag are dependent on the magnitude of k_1 and k_{-1}. For polyclonal antiserum, the average avidity of the antibody populations determines K, and the magnitude of k_1 in comparison with k_{-1} determines the ultimate limit of detection attainable with a given antibody population.

Types of Labels

In the decade following the pioneering developments of Yalow and Berson,[12] all immunoassays used radioactive labels in competitive assays. Since the introduction of enzyme immunoassays in the 1970s, sophisticated assays with nonisotopic labels (Table 15-1)[7] have been developed.

Methodological Principles

To capitalize on the exquisite specificity and enhanced sensitivity of immunochemical assays, various methodological principles have been applied in their development. These include competitive and noncompetitive reaction formats and different processing schemes for performing assays.

Competitive Versus Noncompetitive Reaction Formats

As shown in Figure 15-10, the two major types of reaction formats used in immunochemical assays are termed competitive (limited reagent assays) and noncompetitive (excess reagent, two-site, or sandwich assays).

Competitive Immunoassays. In a competitive immunochemical assay, all reactants are simultaneously or sequentially mixed together. In the simultaneous approach, labeled antigen (Ag*) and unlabeled antigen (Ag) compete to bind with the antibody. In such a system, the avidity of the antibody for labeled and unlabeled antigen must be the same. Under these conditions, the probability of the antibody binding the labeled antigen is inversely proportional to the concentration of unlabeled antigen, hence bound label is inversely proportional to the concentration of unlabeled antigen.

In a sequential competitive assay, unlabeled antigen is mixed with excess antibody and binding allowed to reach equilibrium (Figure 15-10, step 1). Labeled antigen is then added sequentially (Figure 15-10, step 2) and allowed to equilibrate. After separation, the bound label is measured and is used to calculate the unlabeled antigen concentration. With this two-step method, a larger fraction of unlabeled antigen is bound by the antibody than that fraction in the simultaneous assay, especially at low antigen concentrations. Consequently, a twofold to fourfold lowering of the detection limit is seen in a sequential immunoassay, compared with that in a simultaneous assay, provided $k_1 >> k_{-1}$. T is improvement in detection limit results from an increase in AgAb binding (and thus a decrease in Ag^* binding), which is favored by the sequential addition of Ag and Ag*. If $k_1 \geq k_{-1}$, dissociation of AgAb becomes more probable, resulting in increased competition between Ag* and Ag. A typical immunochemical binding curve is shown in Figure 15-11.

Noncompetitive Immunoassays. In a typical noncompetitive assay, the "capture" antibody is first passively adsorbed or covalently bound to the surface of a solid phase. Next, the antigen from the sample is allowed to react and is captured by the solid phase antibody. Other proteins then are washed away, and a labeled antibody (conjugate) is added that reacts with the bound antigen through a second and distinct epitope. After additional washing to remove the excess unbound labeled antibody, the bound label is measured, and its concentration or activity is directly proportional to the concentration of antigen.

In noncompetitive assays, either polyclonal or monoclonal, antibodies are used as capture and labeled antibodies. If monoclonal antibodies with specificity for distinct epitopes

Competitive (limited reagent)

Simultaneous

$$Ab + Ag + Ag\text{–}L \rightleftharpoons Ab{:}Ag + Ab{:}Ag\text{–}L$$
(free) (bound)

Sequential

$$\text{Step 1 } Ab + Ag \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} Ab{:}Ag + Ab$$

$$\text{Step 2 } Ab{:}Ag + Ab + Ag\text{–}L \rightleftharpoons Ab{:}Ag + Ab{:}Ag\text{–}L + Ag\text{–}L$$

Noncompetitive (excess reagent, two-site, sandwich)

are used, simultaneous incubation of the sample and the conjugate with the capture antibody is possible, thus simplifying the assay protocol.

Noncompetitive immunoassays are performed in simultaneous or sequential mode. In the simultaneous mode, a high concentration of analyte saturates both capture and labeled antibodies. Under these conditions, the analyte is present in such high concentrations that it reacts simultaneously with the capture and labeled antibodies, reducing the number of complexes formed and producing a falsely low result. This the calibration curve of the assay exhibits a "**hook effect**," in which the assay response drops off at high analyte concentrations in assays for analytes for which the normal pathological concentration range is very wide. For example, assays for chorionic gonadotropin (CG) and alpha fetoprotein (AFP) are particularly prone to this problem. Dilutions of a sample usually are reanalyzed to check for this type of analytical interference. In practice, the hook effect is eliminated if a sequential assay format is adopted and the concentrations of capture and labeled antibody are sufficiently high to cover analyte concentrations over the entire analytical range of the assay.

Heterogeneous Versus Homogeneous Immunochemical Assays

Immunochemical assays that require separation of the free from the bound label are termed **heterogeneous immunoassays**. **Homogeneous immunoassays** do not require separation.

Heterogeneous Immunoassays. Heterogeneous immumoassays implicitly assume that $k_1 >> k_{-1}$, and several physical separation techniques (Box 15-1) are used to separate the free, labeled (Ag^*) from the bound, labeled antigen (Ag^*:Ab).

Precipitation of the bound, labeled antigen (Ag^*:Ab) from the reaction mixture is achieved chemically or immunologically. Chemically, a protein-precipitating chemical, such as $(NH_4)_2SO_4$, is added. Immunologically, a second, "precipitating" antibody is added. In liquid phase adsorption, the free antigen is adsorbed onto particles of activated charcoal or dextran-coated charcoal that are added directly to the reaction mixture. The particles of charcoal and the adsorbed antigen then are removed by allowing the particles to settle or by performing centrifugation.

Solid phase adsorption is a widely used separation technique. With this method, binding and competition of labeled and unlabeled antigens for the binding sites of the antibody occur on the surface of a solid support. On the surface of this support, the capture antibody is attached by physical adsorption or by covalent bonding. Several different types of solid support are used, including (1) the inner surface of plastic tubes or wells of microtiter plates and (2) the outer surface of insoluble materials, such as cellulose or magnetic latex beads or particles.

Homogeneous Immunoassays. Homogeneous immunoassays do not require separation of bound and free labeled antibody or antigen.[8] In this type of assay, the activity of the label attached to the antigen is modulated directly by antibody binding. The magnitude of the modulation is proportional to the concentration of the antigen or antibody being measured. Consequently, it is necessary only to incubate the sample containing the analyte antigen with the labeled antigen and antibody and then directly measure the activity of the label "in place," making these assays technically easier and faster.

Immunoassay Calibration

Calibration of an immunoassay involves performing an assay of a series of calibrators with known values and fitting a straight line or curve to the resulting data to link the signal to concentration over the assayed range. This dose-response curve is then used to determine the concentration of analyte in the sample. Joining successive points in a calibration curve is usually achieved by means of an appropriate mathematical equation. Several curve-fitting methods are in use. Interpolation methods join successive points by straight lines (linear

BOX 15-1 Separation Methods Used in Immunoassays

Adsorption
Charcoal, Florisil, talc

Precipitation
Polymer precipitation: polyethylene glycol
Solvent or salt precipitation: ethanol, dioxane, $(NH_4)_2SO_4$
Protein A or double (second) antibody precipitation

Solid Phase Antibodies
Antibodies or other binding proteins (e.g., protein A, biotin-avidin, biotin-streptavidin) adsorbed or covalently attached to an insoluble matrix (e.g., plastic beads, inside surface of a plastic tube or microwell, magnetic beads)

Miscellaneous
Electrophoresis

†Personal communication.

interpolation) or curved lines (curvilinear interpolation). When the latter approach is used, a cubic polynomial ($y = a + bx + cx_2 + dx_3$) links the response (y) to the calibrator concentration (x), and the best fit is attained through a series of recalculations (iterations) that smooth the joints between the curves linking successive points on the curve. The resulting equation is called a spline *function*. Empirical curve-fitting methods use different mathematical models, including (1) hyperbolic, (2) polynomial, and (3) log-logit and its variants (e.g., four-parameter log-logistic), to calculate a curve to fit the calibration data.

It should be appreciated that a source of error with all curve-fitting methods is the uncertainty of the shape of the curve between successive calibrators and the imprecision in the measurement of each calibrator. Imprecision may not be constant over the concentration range represented by the calibrators, and in this case the response variable is termed heteroscedastic.

Analytical Detection Limits

The analytical limits of detection of competitive immunoassays are determined principally by the affinity of the antibody. Calculations have indicated that a lower limit of detection of 10 fmol/L (i.e., 600,000 molecules of analyte in a typical sample volume of 100 μL) is possible in a competitive assay when an antibody with an affinity of 10^{12} mol/L is used.

For noncompetitive immunoassays, the ability of the detector to measure the label determines the detection limit of an assay. Table 15-2 illustrates the detection limits for noncompetitive immunoassays when isotopic and nonisotopic labels are used. A radioactive label, such as ^{125}I, has low specific activity (7.5 million labels necessary for detection of 1 disintegration/s) compared with enzyme labels and chemiluminescent and fluorescent labels. Enzyme labels provide an amplification (each enzyme label producing many detectable product molecules), and the detection limit for an enzyme is lowered if the conventional photometric detection is replaced with chemiluminescent or bioluminescent detection. The combination of amplification and an ultrasensitive detection reaction makes noncompetitive chemiluminescent enzyme immunoassays among the most sensitive types of immunoassays. Fluorescent labels also have high specific activity; a single high–quantum-yield fluorophore is capable of producing 100 million photons/s. In practice, several factors degrade the detection limit of an immunoassay. These include (1) background signal from the detector, (2) assay reagents, and (3) nonspecific binding of the labeled reagent.

Secondary labels such as biotin are used to introduce amplification into an immunoassay. The binding constant of the biotin/avidin complex is extremely high (10^{15} mol/L). This high binding allows for the design of immunoassay systems that are even more sensitive than the simple antibody systems. Such a biotin/avidin system uses a biotin-labeled first antibody. Biotin is attached to the antibody in relatively high proportion without loss of immunoreactivity of the antibody. When an avidin-conjugated label is added, a complex of Ag:Abbiotin:avidin label is formed. Further amplification is achieved by a biotin:avidin:biotin linkage because the binding ratio of biotin:avidin is 4:1 (e.g., Ag:Ab-biotin:avidin:[3 biotin labels]). If the label is an enzyme, large numbers of enzyme molecules in the complete complex provide a large increase in enzymatic activity, coupled with the small amount of antigen being determined, and the antigen assay is correspondingly more sensitive. Other tactics that have been used to lower the analytical detection limits of immunoassays include the use of streptavidin-thyroglobulin conjugates and macromolecular complexes of multiple-label thyroglobulin and streptavidin-thyroglobulin. With these reagents, thyroglobulin acts as a carrier for multiple labels (e.g., Eu^{3+}), and amplification factors of several thousand are achieved.

BOX 15-2 Examples of Other Nonisotopic Immunoassays

Bioluminescent Immunoassays

Native or recombinant apoaequorin (from the bioluminescent jellyfish Aequorea) is used as the label. It is activated by reaction with coelenterazine, and light emission at 469 nm is triggered by reaction with calcium ions (calcium chloride).

Erenna Immunoassay

The Erenna Immunoassay System uses a modified microparticle-based sandwich immunoassay and single-molecule counting technology. It integrates capillary flow, laser-induced fluorescence, a highly sensitive detection optics module, and a 384-well plate format for sample analysis.

Fluorescence Excitation Transfer Immunoassay

Homogeneous competitive assay in which a fluorophore (donor)-labeled antigen competes with an antigen in the sample for binding sites on an antibody labeled with a fluorescent dye (acceptor). The fluorescence of the donor is quenched when it is bound to the acceptor-labeled antibody.

Immuno-PCR

Heterogeneous immunoassay in which a piece of single- or double-stranded DNA is used as a label for an antibody in a sandwich assay. Bound DNA label is amplified using the polymerase chain reaction (PCR). The amplified DNA product is separated by gel electrophoresis and is quantitated by densitometric scanning of an ethidium-stained gel.

Nanotechnology-Based Assays

A variety of immunoassays employ nanoparticles, spheres, or tubes as solid phases.

Luminescent Oxygen Channeling Immunoassay (LOCI)

Homogeneous sandwich immunoassay in which an antigen links an antibody-coated sensitizer dye-loaded particle (250 nm diameter) and an antibody-coated particle (250 nm diameter) loaded with a mixture of a precursor of a chemiluminescent compound and a fluorophore. Irradiation produces singlet oxygen at the surface of the sensitizer dye–loaded particle. This diffuses ("channels") to the other particle held in close proximity by the immunochemical reaction between antigen and antibodies on the particles. The singlet oxygen reacts with the chemiluminescent compound precursor in the particle to form a chemiluminescent dioxane, which then decomposes to emit light via a fluorophore-sensitized mechanism. No signal is obtained from precursor fluorophore-loaded particles that are not linked via immunological reaction with an antigen.

Phosphor Immunoassay

Heterogeneous immunoassay in which an up-converting phosphor nanoparticle is used as a label. The nanoparticle (200 to 400 nm diameter) is a crystalline lanthanide oxysulfide. It absorbs two or more photons of infrared light (980 nm) and produces light emission at a shorter wavelength (anti-Stokes shift). The phosphorescence is not influenced by reaction conditions (e.g., temperature, buffer), and no up-converted signal from biological components is present in the sample (low background). Multiplexing is possible because different types of particles produce different wavelengths of phosphorescence (e.g., yttrium/erbium oxysulfides are green [550 nm], yttrium/thulium oxysulfide particles are blue [475 nm]).

Quantum Dot Immunoassay

Heterogeneous immunoassay in which a nanometer-sized (<10 nm) semiconductor quantum dot is used as a label. A quantum dot is a highly fluorescent nanocrystal composed of CdSe, CdS, ZnSe, InP, or InAs or a layer of ZnS or CdS on, for example, a CdSe core. Multiplexing is possible with these labels because the emission properties can be modulated by changing the size and composition of the nanocrystal (e.g., CdS emits blue light, InP emits red light).

Solid Phase, Light-Scattering Immunoassay

Indium spheres are coated on glass to measure an antibody binding to an antigen. Binding of antibodies to antigens increases dielectrical layer thickness, which produces a greater degree of scatter than in areas where only an antigen is bound. Quantitation is achieved by densitometry.

Surface Effect Immunoassay

An antibody is immobilized on the surface of a waveguide (quartz, glass, or plastic slide, or a gold- or silver-coated prism), and binding of an antigen is measured directly by total internal reflection fluorescence, surface plasmon resonance, or attenuated total reflection.

Examples of Labeled Immunoassays

Specific examples of different types of labeled immunoassays are discussed in the following section. Others are described in Box 15-2.

Radioimmunoassay

Radioimmunoassays (RIAs) were developed in the 1960s and used radioactive isotopes of iodine, ^{125}I and ^{131}I, and tritium (^{3}H) as labels.[12] Combinations of labels (e.g., ^{57}Co, ^{125}I) have been used for simultaneous assays (e.g., vitamin B_{12} and folate). In practice, competition between radiolabeled and unlabeled antigen or antibody in an antigen-antibody reaction is used to analytically determine the concentration of the unlabeled antigen or antibody. It takes advantage of the specificity of the antigen-antibody interaction and the ability to measure very low quantities of radioactive elements. RIAs have been used to determine the concentration of antibodies or any antigen against which a specific antibody is produced. When used to measure the concentration of an antigen, RIA requires that the antigen be available in a pure form and be labeled with a radioactive isotope. An alternative assay design uses labeled antibody (e.g., immunoradiometric assay [IRMA]) and does not require purified antigen because the antigen need not be labeled. T is obviates potential problems that may be caused by iodination of labile antigens. Antibodies are more stable proteins and are easier to label without damage to the function of the protein.

Nonseparation RIAs have also been developed that are based on the modulation of a tritium or ^{125}I label by microparticles loaded with a scintillant.[6] T ese scintillation proximity assays have found routine application in high-throughput screening assays used for drug discovery.

Although they were once popular, the use of RIAs in clinical laboratories has declined primarily because of concerns over safe handling and disposal of radioactive reagents and waste.

Enzyme Immunoassay

Enzyme immunoassay (EIA) uses the catalytic properties of enzymes to detect and quantify immunological reactions. Enzymes such as (1) alkaline phosphatase (ALP), (2) horseradish peroxidase (HRP), (3) glucose-6-dehydrogenase (G6D), and (4) β-galactosidase are commonly used as labels in EIA.

Various detection systems have been used to monitor EIAs. Assays that produce compounds that are monitored photometrically are widely used and have been automated. EIAs that use fluorogenic or chemiluminogenic substrates are also popular because their measurement is inherently sensitive. Enzyme cascade reactions have been applied to the detection of enzyme labels in EIA; the principle of a cascade assay for ALP is illustrated in Figure 15-12. The advantage of such an assay is that it combines the amplification properties of two enzymes—the ALP label and the alcohol dehydrogenase in the assay reagent, thereby producing an extremely sensitive assay (see Table 15-2).

Examples of EIA include (1) enzyme-linked immunosorbent assay (ELISA), (2) enzyme-multiplied immunoassay technique (EMIT), and (3) cloned enzyme donor immunoassay (CEDIA).

Enzyme-Linked Immunosorbent Assay. ELISA is a heterogeneous EIA technique. With this type of assay, one of the reaction components is attached to the surface of a solid phase, such as that of a microtiter well. This attachment may consist of nonspecific adsorption or chemical or immunochemical bonding and facilitates separation of bound and free labeled reactants. Typically, with ELISA, an aliquot of sample or calibrator containing the antigen to be measured is added to and allowed to bind with a solid phase antibody. After the solid phase has been washed, an enzyme-labeled antibody different from the bound antibody is added and forms a "sandwich complex" of solid phase–Ab:Ag:Ab enzyme. Excess (unbound) antibody then is washed away, and enzyme substrate is added. The enzyme label then catalyzes the conversion of substrate to product(s), the amount of which is proportional to the quantity of antigen in the sample. Antibodies in a sample also are quantified through the use of an ELISA procedure in which antigen instead of antibody is bound to a solid phase, and the second reagent is an enzyme-labeled antibody specific for the analyte antibody. For example, in a microtiter plate format, ELISA assays have been used extensively for detection of antibodies to viruses and parasites in serum or whole blood. In addition, enzyme conjugates coupled with substrates that produce visible products have been used to develop ELISA-type assays with results that are interpreted visually. Such assays have been very useful in (1) screening, (2) point-of-care, and (3) home testing applications.

Enzyme-Multiplied Immunoassay Technique. EMIT is a homogeneous EIA (Figure 15-13).[8] Because it does not require a separation step, an EMIT assay is simple to perform and has been used to develop a wide variety of (1) drug, (2) hormone, and (3) metabolite assays. EMIT-type assays are automated easily and are included in the repertoire of the most automated clinical and immunoassay analyzers.

With the EMIT technique, the antibody against the analyte (1) drug, (2) hormone, or (3) metabolite is added together with substrate to the patient's sample. Binding of the antibody and the analyte then occurs. An aliquot of the enzyme conjugate of the analyte drug, hormone, or metabolite then is added as a second reagent; the enzyme-analyte conjugate then binds with the excess analyte antibody, forming an antigen/antibody complex.

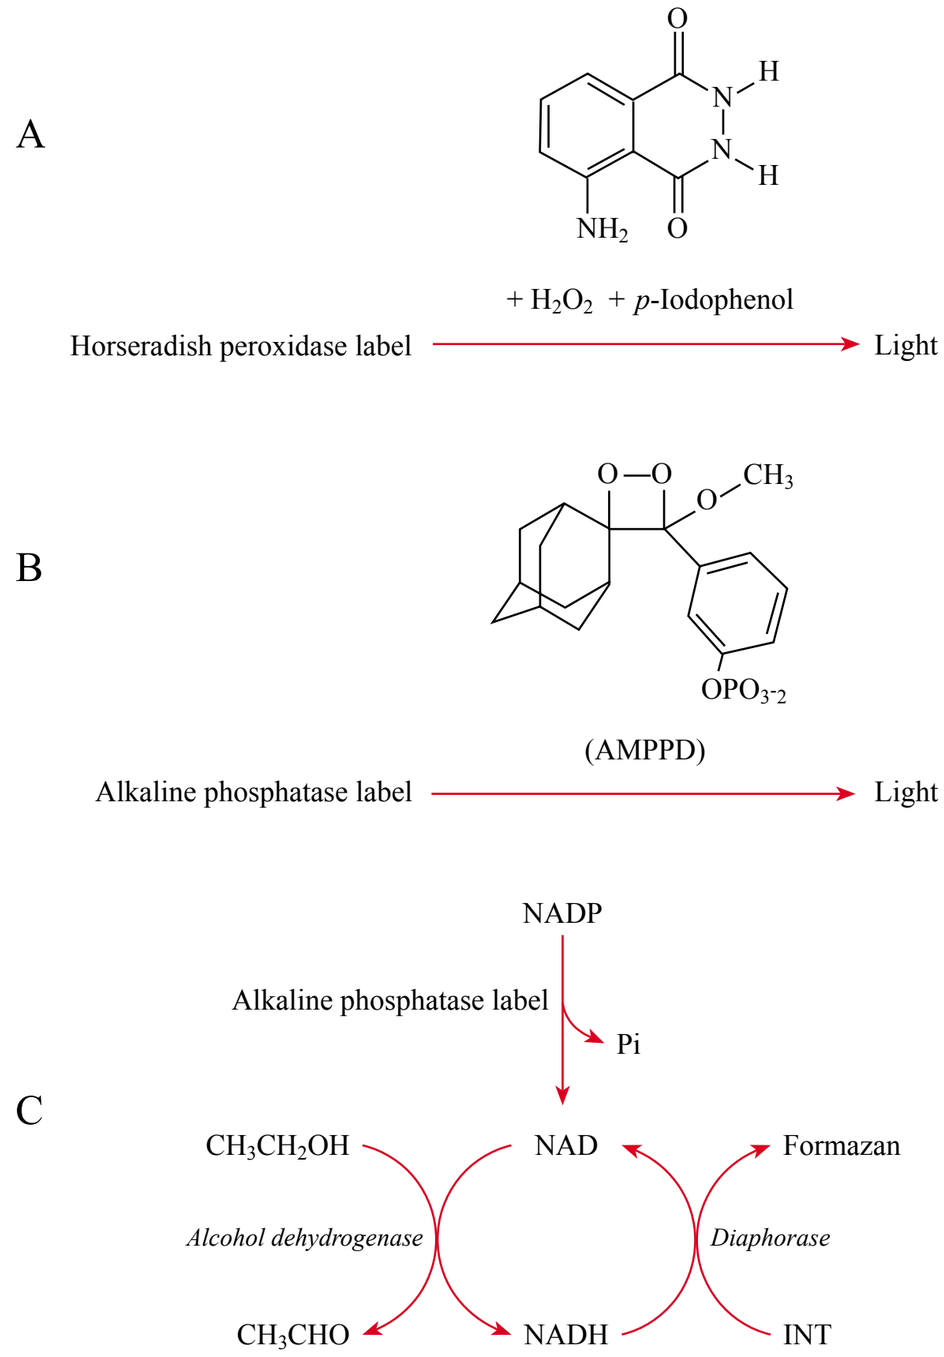

Figure 15-12 Ultrasensitive assays for horseradish peroxidase and alkaline phosphatase labels. A, Chemiluminescent assay for horseradish peroxidase label using luminol. B, Chemiluminescent assay for an alkaline phosphatase label using AMPPD (disodium 3-(4-methoxyspiro[1,2-dioxetane-3,2′-tricyclo[3.3.1.1]-decan]4-yl)phenyl phosphate). C, Photometric assay for an alkaline phosphatase label using a cascade detection reaction. INT, p-Iodonitrotetrazolium violet.

TABLE 15-3 Properties of Fluorescent Labels

Fluorophore	Excitation, nm	Emission, nm	Fluorescence Quantum Yield*	Lifetime, ns
Fluorescein isothiocyanate	492	520	0.0-0.85	4.5
Europium (β-naphthoyl trifluoroacetone)	340	590,613	—	500,000
Lucifer yellow VS	430	540	—	—
Phycobiliprotein	550-620	580-660	0.5-0.98	—
Rhodamine B isothiocyanate	550	585	0.0-0.7	3.0
Umbelliferone	380	450	—	—

*Fluorescence quantum yield: fraction of molecules that emit a photon.

The binding of the analyte antibody with the enzyme-analyte conjugate affects the enzyme and alters its activity. The relative change in enzyme activity is proportional to the analyte concentration in the patient's sample. Concentration of the analyte is calculated from a calibration curve prepared by analysis of calibrators that contain known quantities of analyte.

Cloned Enzyme Donor Immunoassay. CEDIA is a second type of homogeneous EIA (see Figure 15-13). It was the first EIA designed and developed through the use of genetic engineering techniques.[7] With this technique, inactive fragments (the enzyme donor and acceptor) of β-galactosidase are prepared by manipulation of the Z gene of the lac operon of Escherichia coli. These two fragments spontaneously reassemble to form active enzyme even if the enzyme donor is attached to an antigen. However, binding of an antibody to the enzyme donor-antigen conjugate inhibits reassembly, thereby blocking the formation of active enzyme. Thus competition between antigen and the enzyme donor-antigen conjugate for a fixed amount of antibody in the presence of the enzyme acceptor modulates the measured enzyme activity. High concentrations of antigen produce the least inhibition of enzyme activity; low concentrations, the greatest.

Fluoroimmunoassay

Fluoroimmunoassay (FIA) uses a fluorescent molecule as an indicator label to detect and quantify immunological reactions. Examples of fluorophores used as labels in FIA and their properties are listed in Table 15-3. An early problem with FIA was that background fluorescence from within the sample limited its utility. This problem has been overcome by the use of time-resolved immunoassay techniques that use chelates of rare earth (lanthanide) elements as labels (see Chapter 9). These techniques are based on the fact that fluorescent emissions from lanthanide chelates such as (1) europium, (2) terbium, (3) samarium have long lives (>1 μs) compared with the typical background fluorescence encountered in biological specimens. In a time-resolved FIA, a europium chelate label is excited by a pulse of excitation light (0.5 μs), and the long-lived fluorescence emission from the label is measured after a delay (400 to 800 μs); by this time, any short-lived background signal has decayed.

Fluorescent polarization immunoassay is a type of homogeneous FIA that is used widely (Figure 15-14). With this technique, the polarization of the fluorescence from a fluorescein-antigen conjugate is determined by its rate of rotation during the lifetime of the excited state in solution. A small, rapidly rotating fluorescein-antigen conjugate has a low degree of polarization; however, binding to a large antibody molecule slows the rate of rotation and increases the degree of polarization. Thus binding to antibody modulates polarization. The change in polarization is measured and related to antigen concentration.

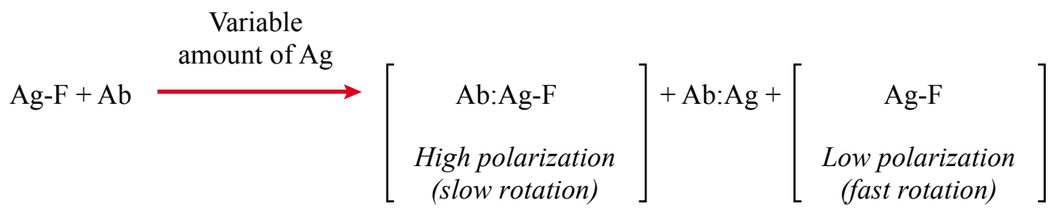

Figure 15-14 Homogeneous polarization fuoroimmunoassay. Ab, Antibody; Ag, antigen; F, fuorescein.

Another type of nonseparation FIA uses a multilayer device to eliminate the need for separation of bound and free fractions. The device consists of two agarose layers separated by an opaque layer of iron oxide. Sample is added to the upper (10 μm) layer and diffuses through the iron oxide (10 μm) layer to the thin (1 μm) signal layer, which contains antibody:antigen/rhodamine complexes. Antigen-rhodamine conjugate is displaced from the signal layer by antigen within the sample and diffuses into the upper layer. Residual bound antigen-rhodamine conjugate in the signal layer is measured by front surface fuorometry. Displaced free conjugate does not contribute to the signal because it is shielded from the fluorescence excitation light by the iron oxide layer. As listed in Box 15-2, many other types of homogeneous FIAs have been developed.

Chemiluminescent Immunoassay

Chemiluminescence is the light emission produced during a chemical reaction (see Chapter 9). In a chemiluminescent immunoassay, a chemiluminescent molecule is used as an indicator label to detect and quantify immunological reactions. Acridinium esters are examples of chemiluminescent labels. Oxidation of an acridinium ester by alkaline hydrogen peroxide in the presence of a detergent (e.g., Triton X-100) produces a rapid flash of light at 429 nm. Acridinium esters are high–specific activity labels (detection limit for the label being 800 zeptomoles) that have been used to label both antibodies and haptens (Figure 15-15, A).

(A, From Law S-J, Miller T, Piran U, et al: Novel poly-substituted aryl acridinium esters and their use in immunoassay. J Biolum Chemilum 1989;4:88-98.)

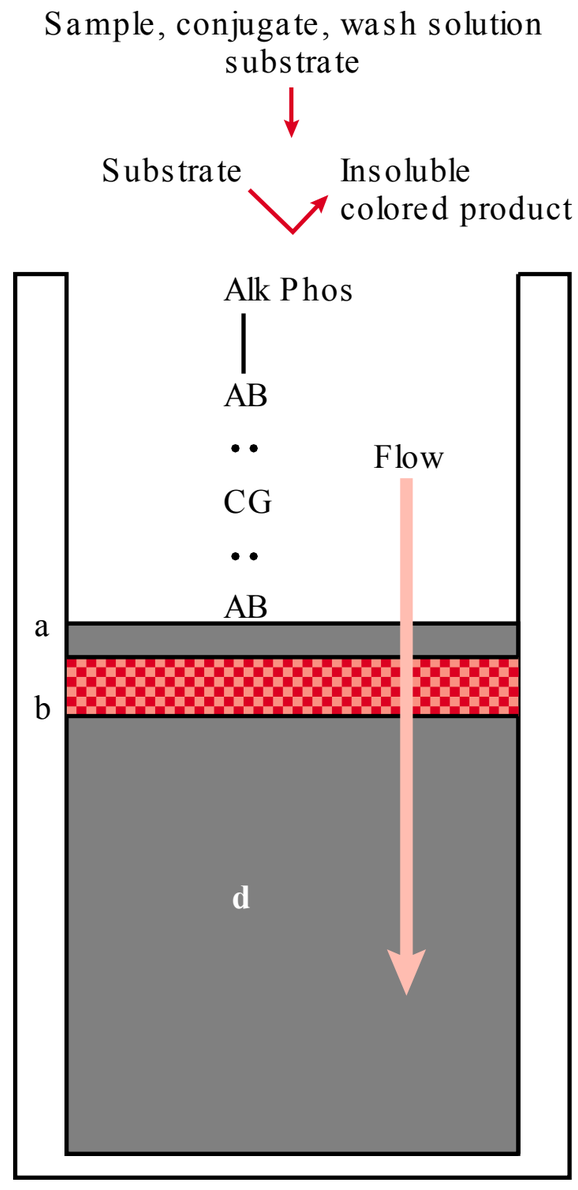

Figure 15-16 ICON immunoassay device illustrating immobilized antibody membrane (a), separating membrane (b), container (c), and adsorbent pad (d). AB, Monoclonal antibody to CG; Alk Phos, alkaline phosphatase; CG, human chorionic gonadotropin.

Electrochemiluminescence Immunoassay

In an electrochemiluminescence immunoassay, an electrochemiluminescence molecule, such as ruthenium, is used as an indicator label in competitive and sandwich immunoassays. In such assays, ruthenium (II) tris(bipyridyl) (Figure 15-15, B) undergoes an electrochemiluminescent reaction (620 nm) with tripropylamine at an electrode surface. With this label, various assays have been developed in a flow cell, with magnetic beads as the solid phase. Beads are captured at the electrode surface, and unbound label is washed from the cell by a wash buffer. Label bound to the bead undergoes an electrochemiluminescent reaction, and the light emission is measured by an adjacent photomultiplier tube.

Simplified Immunoassays

The integration of technical advances made in molecular immunology with those made in the material and processing sciences has resulted in the development of several "simplified" immunoassays for use in physicians' offices or in the home (see Chapter 17). Early efforts were directed toward pregnancy and fertility testing and were based on agglutination and inhibition of agglutination using labeled red blood cells or latex particles in a slide format. Subsequently, sandwich immunoassays have been adapted for similar applications. For example, as listed in the package insert, the ICON II pregnancy test (Beckman Coulter, Fullerton, Calif) is an operationally simple and sensitive assay for human chorionic gonadotropin (CG) that has a lower limit of detectiony of 10 mIU/mL for serum and 20 mIU/mL for urine. As shown in Figure 15-16, the ICON II test is a sandwich EIA device that uses a murine monoclonal antibody, which is immobilized onto the surface of a microporous nylon membrane located on top of an adsorbent pad. The pad functions as a capillary pump to draw liquid through the membrane. To perform an analysis, an aliquot of urine is added to the surface of the membrane; CG is removed as liquid is drawn through it, resulting in the removal of CG in the sample by its binding to the capture antibody on the membrane. Next, a matched murine monoclonal anti-CG antibody ALP conjugate is added and is allowed to drain into the adsorbent pad. Wash solution is then added, followed by an indoxyl phosphate substrate. Bound conjugate converts this to an insoluble indigo dye, which appears as a discrete blue spot. The second generation of the ICON test includes two additional control zones. An immobilized anti-ALP zone acts as a procedural control; it binds the ALP conjugate and appears as a blue spot. A further zone contains an immobilized irrelevant murine monoclonal antibody; this detects the presence of heterophile antibodies in samples, particularly human antimouse antibodies. These mimic antigen and bridge the capture and conjugated mouse antibodies, thus yielding what appears to be a positive result.

Other point-of-care testing (POCT) devices require only the addition of sample, simplifying the assay protocol and minimizing possible malfunction resulting from operator error. The TestPack Plus (Iverness Medical International, Cranfield, United Kingdom) is a one-step pregnancy test that illustrates the general principles of the new devices. It uses colloidal selenium particles (160 nm in diameter) labeled with monoclonal anti-α-CG antibody, which is red and is easily visible. Sample (urine) is applied to the sample well and soaks into a glass fiber pad containing the conjugate. Any CG in the urine sample combines with the selenium-labeled antibody, and the mixture migrates along a nitrocellulose track to a region where a line of polyclonal anti-CG antibody and an orthogonal line of anti-α-CG:CG complex have been immobilized. The complex captures unreacted selenium-labeled anti-α-CG to form a minus sign visible in the viewing window. If CG was present in the urine sample, then the selenium-labeled anti-α-CG:CG complexes bind to the immobilized polyclonal anti-CG, and a plus sign is formed, denoting a positive result. The remainder of the reaction mixture migrates to the end of the track and reacts with a Quinaldine red pH indicator in an "end-of-assay" window to signal that the flow in the device has functioned correctly. Variants of this type of device use antibody-coated beads loaded with blue dye and include a microspectrophotometer that reads the blue line and displays on a built-in LCD screen a result of "Pregnant" or "Not pregnant" based on the intensity of the blue line (e.g., Clearblue Digital Pregnancy Test; SPD Swiss Precision Diagnostics GmbH, Geneva, Switzerland).

Nanoparticle Immunoassay

In one type of highly sensitive nanoparticle immunoassay, the conjugate is a gold nanoparticle that is coated with both capture antibody and hundreds of carrier-oligonucleotides hybridized to its complementary oligonucleotide (biobarcodes). Isolated complexes (magnetic particle-capture antibody:antigen:capture antibody-gold nanoparticle-carrier oligonucleotides) are heated to release the biobarcode oligonucleotides from the carrier oligonucleotides attached to the gold nanoparticles. The biobarcodes are then captured by an oligonucleotide immobilized on a slide surface, and the captured biobarcode is hybridized to a gold nanoparticle (13 nm in diameter) labeled detection probe. A final amplification procedure deposits silver (silver decoration) onto the gold nanoparticle labels attached to the detection probes and the silver-decorated gold nanoparticles detected by light scattering.

Simultaneous Multianalyte Immunoassays

Types of simultaneous multianalyte immunoassays in which two or more analytes are detected in a single assay are becoming increasingly popular both for routine immunoassays and in proteomic research. Two different strategies have been developed on the basis of discrete reaction zones (planar arrays or sets of microbeads) or combinations of different labels.[9]

For example, the Afinion AS100 Analyze is a POCT device (Alere, Waltham, Mass) that measures simultaneously several clinically-related analytes. For example, in the Alere Toxicology drug screen, discrete test zones are placed on a small piece of nylon membrane. Each test zone is composed of antibodies to a specific drug immobilized onto the membrane surface. This zone captures free gold sol-drug conjugate from the sample antidrug:antibody gold conjugate reaction mixture and appears as a purple band. A variant of this strategy uses small pieces of glass or plastic, onto which is spotted an array of capture antibody or antigen for different tests (e.g., antigen arrays for antinuclear antibody [ANA] testing). Yet another strategy uses combinations of distinguishable microbeads (e.g., Luminex beads have a unique fluorescent signature) in which each type of bead is coated with a different capture antibody or antigen. A panel of reagent beads is mixed with the sample and fluorescent detection reagents. Fluorescent measurements identify the different beads (via their fluorescence signature) and quantitate the signal caused by the captured analyte. The benefit of this approach consists of work simplification because all of the tests are performed simultaneously on the same array or in the same tube in the case of microbead-based assays.

Combinations of distinguishable labels, such as europium (613 nm, emission lifetime of 730 μs) and samarium (643 nm, emission lifetime of 50 μs) chelates, serve as the basis for quantitative simultaneous immunoassays. These two chelates have different fluorescence emission maxima and different fluorescence decay times and thus are distinguished easily from measurements at 613 nm, delay time 0.4 ms (europium), and 643 nm, delay time 0.05 μs (samarium). Two examples of clinically useful combined assays using these differences in fluorescence wavelengths and delay times are combined free and bound prostate-specific antigen and combined myoglobin and carbonic anhydrase III.

Protein Microarrays

Arrays of hundreds or thousands of micrometer-sized dots of antigens or antibodies immobilized on the surface of a glass or plastic chip are emerging as an important tool in genomic studies and in assessment of protein-protein interactions.[9] This format facilitates simultaneous multianalyte immunoassays using, for example, enzyme- or fluorophore-labeled conjugates. The arrays are made by printing or spotting 1-nL drops of protein solutions onto a flat surface, such as a glass microscope slide. In a typical sandwich assay, the array on the surface of the slide is incubated with sample and then with conjugate. Bound conjugate is detected using chemiluminescence or fluorescein using a scanning device. The pattern of the signal provides information on the presence and quantities of individual analytes in the sample or the reactivity of a single analyte with the range of proteins arrayed on the surface of the slide.

Interferences

A particular problem that has been recognized for sandwich immunoassays is an interference caused by circulating human antibodies that react with animal immunoglobulins, particularly human antimouse antibodies (HAMAs). This type of

antibody causes positive or negative interferences in two-site antibody-based sandwich assays that use mouse monoclonal capture antibody reagents. HAMAs cause false positive interference by bridging between a mouse immunoglobulin capture antibody and a mouse immunoglobulin conjugate, thus mimicking the specific analyte. A false negative result is thought to be caused by HAMA reacting with one of the assay reagents (immobilized antibody or the conjugate) and preventing formation of the sandwich with specific analyte.

HAMAs often are present in the blood of patients who have received mouse monoclonal antibody imaging or therapeutic agents. They also occur because of exposure to mouse antigens (e.g., as a result of handling mice). Nonimmune mouse serum usually is included in mouse monoclonal antibody-based immunoassays to complex HAMAs. However, despite this precaution, reactivity leading to false positive or false negative results still is encountered. The presence of HAMAs and other antianimal antibodies is uncovered by dilution experiments because samples containing antianimal antibodies do not give proportional results. Reanalysis of a sample after incubation with an animal protein or serum (e.g., mouse IgG, mouse serum for HAMA) can also reveal and confirm an interference.

Other Immunochemical Techniques

Other analytical methods of clinical interest that employ antibodies include cytochemical and agglutination assays.

Immunocytochemistry

Labeled antibody reagents are used as specific probes for protein and peptide antigens to examine single cells for synthetic capability and for specific markers for identification of various cell lines. Immunochemistry has been expanded rapidly by immunoenzymatic methods, such as HRP-labeled (immunoperoxidase) assays. Enzyme labels provide several advantages over fluorescent labels. First, they permit the use of fixed tissues (unembedded or embedded in paraffin), which provides excellent preservation of cell morphology and eliminates the problem of autofluorescence from tissue. Second, immunoperoxidase stains are permanent, and only a standard light microscope is needed to identify labeled features. Immunoperoxidase methods also are applicable in electron microscopy.

Immunochemical Agglutination Assays

Agglutination is the "clumping" together in suspension of antigen-bearing cells, microorganisms, or particles in the presence of specific antibodies, also known as agglutinins. Assays based on agglutination have been used for many years for the qualitative and quantitative measurement of antigens and antibodies. The visible clumping of particulates, such as cells and latex particles, is used to indicate the primary reaction of antigen and antibody. Agglutination methods require (1) stable and uniform particulates, (2) pure antigen, and (3) specific antibody. IgM antibodies are more likely to produce complete agglutination than are IgG antibodies because of the size and valence of the IgM molecule. Therefore when only IgG antibodies are involved, the use of chemical enhancement or an antiglobulin-agglutination method may be necessary. As with all immunochemical reactions in which aggregation is the measured end point, the ratio of antigen to antibody is critical. Extremes in antigen or antibody concentration inhibit aggregation.

Hemagglutination describes an agglutination reaction in which the antigen is located on an erythrocyte. Erythrocytes are good passive carriers of antigen; they also are coated easily with foreign proteins and are easily obtained and stored. Direct testing of erythrocytes for blood group, Rh, and other antigenic types is used widely in blood banks. Specific antisera, such as anti-A, anti-C, and anti-Kell, are used to detect such antigens on the erythrocyte surface. In indirect or passive hemagglutination, the erythrocytes are used as particulate carriers of foreign antigen (and in some tests, of antibody); this technique has wide applications. Other materials available in the form of fine particles, such as latex, have been used as antigen carriers, but they are more difficult to coat, standardize, and store. In a related variation of this technique, known as hemagglutination inhibition, the ability of antigens, haptens, or other substances to inhibit specifically hemagglutination of sensitized (coated) cells by antibody is determined.

In general, agglutination methods are quite sensitive but not as quantitative as the other immunochemical methods discussed previously. Nonisotopic immunoassays, especially EIAs, are as convenient as agglutination reactions and therefore are replacing agglutination methods in many laboratories.

Review Questions

1. The component of an immunoassay that determines the analytical sensitivity and specificity of the reaction is the:
   a. labeled antigen.
   b. antigen.
   c. immunochemical label.
   d. antibody.
2. The energy of interaction of a single antibody-combining site and its corresponding epitope on the antigen is referred to as:
   a. sensitivity.
   b. specificity.
   c. immunogenicity.
   d. affinity.
3. The type of immunochemical assay that requires separation of the free label from the bound labeled substance is the:
   a. homogeneous assay.
   b. heterogeneous assay.
   c. competitive assay.
   d. simplified immunoassay.
4. An example of a simultaneous multianalyte immunoassay would be a(n):
   a. counter immunoelectrophoresis for myeloma proteins.
   b. nephelometric assessment of spinal fluid proteins.
   c. antigen array for antinuclear antibody testing.
   d. sandwich immunoassay using multiple antibodies.

5. An example of a qualitative immunochemical technique would be:
   a. immunoelectrophoresis.
   b. enzyme-multiplied immunoassay technique.
   c. radial immunodiffusion.
   d. nephelometry.
6. The addition of a linear polymer such as dextran to a mixture of antigen and antibody causes_____ in the rate of immune complex formation and precipitation.
   a. a decrease
   b. an increase
   c. no change
7. Transferring electrophoretically separated proteins into a strip of nylon membrane by electro-blotting is the second step in:
   a. radial immunodiffusion.
   b. enzyme-linked immunosorbent assay.
   c. western blotting.
   d. immunofixation.
8. In a two-site antibody-based sandwich immunoassay, the presence of human antimouse antibodies produces a false negative result by:
   a. binding a mouse immunoglobulin capture antibody and the mouse immunoglobulin conjugate to form a bridge.
   b. mimicking the specific analyte being assessed.
   c. binding to the mouse monoclonal capture antibody reagents.
   d. reacting with one of the assay reagents to prevent formation of the sandwich.
9. An immunoassay procedure that involves the coating of a solid phase with antibody or antigen is:
   a. enzyme-multiplied immunoassay technique (EMIT).
   b. enzyme immunoassay.
   c. enzyme-linked immunosorbent assay (ELISA).
   d. affinity immunoassay.
10. The immunoglobulin most often used in immunochemical assays is:
    a. IgG.
    b. IgA.
    c. IgM.
    d. IgE.

CHAPTER

16 Automation

James C. Boyd, M.D., and Charles D. Hawker, Ph.D., M.B.A., F.A.C.B.

Objectives

1. Define the following terms:
   - Automation
   - Carry-over
   - Closed-system analyzer
   - Continuous-flow analysis
   - Discrete analysis
   - Instrument cluster
   - Integrated automation
   - Multiple/single-channel analysis
   - Open-system analyzer
   - Random-access analysis
   - Unit operations
2. List four benefits of automation use in the clinical laboratory.
3. Describe the steps involved in the completion of an automated analysis; state the problems encountered in each step and how these are resolved.
4. Compare the following analyzer configurations with regard to specimen and reagent handling and processing:
   - Random-access
   - Sequential
   - Discrete
   - Continuous-flow
   - Multiple-channel
   - Single-channel
5. State five advantages of the use of bar-coded labels to identify a specimen.
6. State the benefit of using whole blood in an automated assay system.
7. Compare an "open" versus a "closed" automated analyzer with regard to reagent usage.
8. Describe six measurement approaches that are used with automated chemistry analyzers.
9. List and describe the three main data processing functions performed by a computer in an automated analyzer.
10. Describe two types of automated specimen processing operations.
11. List and describe the considerations that must be evaluated when an automated laboratory system is selected.
12. List the problems encountered when automated laboratory processes are used and integrated, including during specimen identification, specimen delivery, reagent identification, and the chemical reactant phases.

Key Words and Definitions

Automation The process whereby an analytical instrument performs many tests with only minimal involvement of an analyst; also defined as the controlled operation of an apparatus, process, or system by mechanical or electronic devices without human intervention.

Batch analysis Type of analysis in which many specimens are grouped in the same analytical session.

Carry-over The transport of a quantity of analyte or reagent from one specimen reaction into and contaminating a subsequent one.

Continuous-flow analysis Type of analysis in which each specimen in a batch passes through the same continuous stream at the same rate and is subjected to the same analytical reactions.

Discrete analysis Type of analysis in which the sample is aspirated into the sample probe and then is delivered, often with reagent, through the same orifice into a reaction cup or another container.

Multiple-channel analysis Type of analysis in which each specimen is subjected to multiple analytical processes so that a set of test results is obtained on a single specimen; similar to random-access analysis.

Parallel analysis Type of analysis in which all specimens are subjected to a series of analytical processes at the same time and in a parallel fashion.

Random-access analysis The most common configuration of an automated analyser, in which analyses are performed on a collection of specimens sequentially and each specimen is analyzed for a different selection of tests.

Sequential analysis Type of analysis in which each specimen in a batch enters the analytical process one after another, and each result or set of results emerges in the same order as the specimens are entered.

Single-channel analysis Type of analysis in which each specimen is subjected to a single process so that only results for a single analyte are produced; similar to batch analysis.

Throughput The number of specimens processed by an analyzer during a given period of time, or the rate at which an analytical system processes specimens.

Workstation A clinical laboratory workstation dedicated to a defined task and contains appropriate laboratory instrumentation to carry out that task.

The term **automation** has been applied in clinical chemistry to describe the process whereby an analytical instrument performs many tests with only minimal involvement of an analyst. The availability of automated instruments enables laboratories to process much larger workloads without comparable increases in staff. The evolution of automation in the clinical laboratory has paralleled that in the manufacturing industry, progressing from fixed automation, whereby an instrument performs a repetitive task by itself, to programmable automation, which allows the instrument to perform a variety of different tasks. Intelligent automation also has been introduced into some individual instruments or systems to allow them to self-monitor and respond appropriately to changing conditions.

One benefit of automation is a reduction in the variability of results and errors of analysis through elimination of tasks that are repetitive and monotonous for most individuals. The improved reproducibility gained by automation has led to a significant improvement in the quality of laboratory tests.

Many small laboratories now have consolidated into larger, more efficient entities in response to market trends involving cost reduction. The drive to automate these mega-laboratories has led to new avenues in laboratory automation. No longer is automation being used simply to assist the laboratory technologist in test performance; it now includes (1) processing and transport of specimens, (2) loading of specimens into automated analyzers, and (3) assessing the results of the tests performed. We believe that automating these additional functions is crucial to the future prosperity of the clinical laboratory.[1,3]

This chapter discusses the principles that apply to automation of the individual steps of the analytical process—both in individual analyzers and in the integration of automation throughout the clinical laboratory.

Basic Concepts

Automated analyzers generally incorporate mechanized versions of basic manual laboratory techniques and procedures. However, modern instrumentation is packaged in a wide variety of configurations. The most common configuration is the random-access analyzer. In **random-access analysis**, analyses are performed on a collection of specimens sequentially, with each specimen analyzed for a different selection of tests. The tests performed with random-access analyzers are selected through the use of different vials of (1) liquid reagents, (2) reagent packs, or (3) reagent tablets, depending on the analyzer. This approach permits measurement of variable numbers and types of analytes in each specimen. Profiles or groups of tests are defined for a specimen at the time the tests to be performed are entered into the analyzer (1) via a keyboard or touchscreen, (2) by instruction from a laboratory information system in conjunction with bar coding on the specimen tube, or (3) by operator selection of appropriate reagent packs.

Historically, other analyzer configurations used include continuous-flow, and centrifugal analyzers. Continuous-flow analyzers were the first automated analyzers used in clinical laboratories. Initially, these analyzers were used in a **single-channel analysis** configuration to carry out a **sequential analysis** of each specimen. Subsequently, **multiple-channel analysis** versions were developed in which analysis of each specimen was performed on every channel in parallel. Results from nonrequested tests in the test profile were discarded as necessary after the analysis was complete. Inflexibility in the menu of tests that could be performed on these analyzers eventually led to their replacement in the marketplace by more versatile configurations.

Centrifugal analyzers use discrete pipetting to load aliquots of specimens and reagents sequentially into discrete chambers in a rotor, with the specimens subsequently analyzed in parallel (**parallel analysis**). Such analyzers are operated in a multiple-specimen/single-chemistry mode or in a single-specimen/multiple-chemistry mode.

BOX 16-1 Unit Operations in an Analytical Process

- Specimen identification
- Specimen preparation
- Specimen delivery
- Specimen loading and aspiration
- Specimen processing
- Sample introduction and internal transport
- Reagent handling and storage
- Reagent delivery

Automation of Analytical Processes

The following individual steps required to complete an analysis often are referred to collectively as unit operations (Box 16-1). These operations are described individually in this section, and examples are provided that demonstrate how they have been automated in terms of operational and analytical performance. With most automated systems, these steps usually are performed sequentially, but with some instruments, they may occur in parallel.

Specimen Identification

Typically the identifying link (identifier) between patient and specimen is confirmed at the patient's bedside, and maintenance of this connection throughout (1) transport of the specimen to the laboratory, (2) subsequent specimen analysis, and (3) preparation of a report is essential. Several technologies are available for automatic identification and data collection purposes (Box 16-2). In practice, automatic identification consists of only those technologies that electronically detect a unique characteristic or a unique data string associated with a physical object. For example, identifiers such as (1) serial number, (2) part number, (3) manufacturer, and (4) assigned patient number have been used to identify an object or a patient through electronic data processing. In the clinical laboratory, labeling with a bar code has become the technology of choice for purposes of automatic identification.

BOX 16-2 Technologies Used for Automatic Identification and Data Collection

- Bar coding
- Optical character recognition
- Magnetic stripe and magnetic ink character recognition
- Voice identification
- Radio frequency identification
- Touch screens
- Light pens
- Hand print tablets
- Optical mark readers
- Smart cards

Labeling

With many laboratory information systems, electronic entry of a test order in the laboratory or at a nursing station for a uniquely identified patient generates a specimen label bearing a unique laboratory accession number. A record is established that remains incomplete until a result (or a set of results) is entered into the computer against the accession number. The unique label is affixed to the specimen collection tube when the blood is drawn. Proper alignment of the label on the collection tube is critical for subsequent specimen processing when bar-coded labels are used. Arrival of the specimen to the laboratory is recorded by a computerized log-in procedure. With other systems, the specimen is labeled at the patient's bedside, patient identification and collection information is added, and the labeled specimen is sent to the laboratory along with a requisition form. Once in the laboratory, it is assigned a computer accession number as part of the log-in procedure.

After accessioning, specimens begin to undergo technical handling processes. For those processes that require physical removal of serum from the original tube, secondary labels bearing essential information from the original label must be affixed to any secondary tubes created. Some automated analyzers sample directly from the original collection tube while simultaneously reading the accession number from the bar-coded label on the tube. Secondary bar-coded labels, if necessary, may be generated at the time of accessioning or, with some analyzers, by a built-in printer that is activated when the analyzer is programmed.

Many methods are used to achieve secondary labeling when bar-coded labels are not available. A number may be handwritten on the specimen cup, or a coded label may be affixed to the original tube or to a specimen cup. Label numbers may require correlation with a manually prepared or computer-generated work or load list. The load list usually records accession numbers in sequence along with the physical positions of cups or tubes in the loading zone of the analyzer. This loading zone may consist of (1) a revolving tray or turntable, (2) a mechanical belt, or (3) a rack or a set of racks by which specimens are delivered in a predetermined order to the sample aspiration station of the analyzer.

For those analyzers that do not automatically link specimen identity and sample aspiration, the sequence of results produced must be linked manually with the sequence of entry of specimens. Some analyzers print out or transmit to a host computer each result or set of results from a specimen either through the position of the specimen in the loading zone or by the accession number programmed to that position.

Bar Coding

A major advance in the automation of specimen identification in the clinical laboratory is the incorporation of bar coding technology into analytical systems. In practice, a bar-coded label (often generated by the laboratory information system and bearing the sample accession number) is placed onto the specimen container and is subsequently "read" by one or more bar code readers placed at key positions in the analytical sequence. The resultant identifying and ancillary information is then transferred to and processed by the system software. Initiating bar code identification at a patient's bedside ensures greater integrity of the specimen's identity in an analyzer. Systems that transfer information concerning a patient's identity to blood tubes at the patient's bedside are now commercially avaialible.

Unequivocal positive identification of each specimen is achieved by analyzers that contain bar code readers. Advantages of the use of coded labels include the following:

1. Elimination of work lists for the system.
2. Avoidance of mistakes in placement of the tubes into the analyzer or during sampling.
3. Analysis of specimens in random sequence.
4. Avoidance of possible tube mix-up when serum must be transferred to a secondary container.

The Clinical Laboratory and Standards Institute (CLSI) Standard AUTO02-A2 specifies that the bar code symbology that should be used in clinical laboratories for laboratory automation systems and for sample handling in automated instrumentation is Code 128.[6] The standard notes that the bar code symbologies Code 39, Codabar, NW7, and Interleaved 2 of 5 all should have been replaced by Code 128 by December 31, 2003.

Identification Errors

Many opportunities arise for the mismatch of specimens and results. Risks begin at the bedside and are compounded with each processing step that a specimen undergoes between collection from the patient and analysis by the instrument. The risks are particularly great when hand transcription is invoked for accessioning and labeling and relabeling, and for the creation of load lists. An incorrect accession number, one in which the digits are transposed, or a load list with transposed accession numbers may cause test results to be attributed to the wrong patient. An additional hazard exists when specimens must be inserted into certain positions in the loading zone as defined by a load list. Human misreading of specimen labels or loading lists may cause misplacement of specimens, calibrators, or controls. Automatic reading of bar-coded labels reduces the error rate from 1 in 300 characters (for human entry) to about 1 in 1 million characters.

Specimen Delivery

Several methods are used to deliver specimens to the laboratory, including (1) courier service, (2) pneumatic tube systems, (3) electric track vehicles, and (4) mobile robots.

Courier Service

Historically, couriers have been used to transport specimens from collection sites to the laboratory and between laboratories. Courier service, although generally reliable, has its drawbacks. Delivery is a batch process, and couriers usually service a given pickup point only at specified times. Arrangements for immediate pickup are possible but add costs to the analytical process and delay reporting of results. In addition, the risk of specimen breakage or loss is greater when specimens are handled manually.

Pneumatic Tube Systems

Pneumatic tube systems provide rapid specimen transportation and are reliable when installed as point-to-point services. However, when switching mechanisms are introduced to allow carriers (the bullet-shaped containers used to hold specimens) to be sent to various locations, mechanical problems in the switching process have been known to cause misrouting of carriers. In addition, close attention to the design of the pneumatic tube system is necessary to prevent hemolysis of the specimen. Avoidance of sudden accelerations and decelerations and the use of proper packing material inside the carriers will minimize hemolysis.

Electric Track Vehicles

Electric track vehicles have a larger carrying capacity than pneumatic tube systems and are not associated with problems such as damage to specimens caused by acceleration and/or deceleration forces. Some systems maintain the carrier in an upright position by using a gimbal (a device that permits a body to incline freely in any direction or suspends it so that it will remain level when its support is tipped), which enables the carrier to move both vertically and horizontally on an installed electric track. The larger carrying capacity of containers allows them to hold dry ice or refrigerated gel packs along with the specimens if desired.

Mobile Robots

Mobile robots from several vendors have been used successfully to transport laboratory specimens both within the laboratory and outside the central laboratory.[16] These robots are easily adapted to carry specimen containers of various sizes and shapes and are reprogrammable with changes in laboratory geometry. In addition, in a busy laboratory setting, delivery of specimens to lab benches by a mobile robot is usually more frequent than human pickup and has been shown to be cost-effective. Inexpensive models follow a line on the floor, whereas others use more sophisticated guidance systems. Limitations include the need to batch specimens (**batch analysis**) for greater efficiency and, in most cases, the requirement that laboratory personnel place specimens onto or remove specimens from the mobile robot at each stopping place.

Specimen Preparation

The (1) clotting of blood in specimen collection tubes, (2) their subsequent centrifugation, and (3) transfer of serum to secondary tubes require a finite time to complete. This process, if performed manually, delays the preparation of a specimen for analysis. To eliminate such delays in specimen preparation, various automated approaches have been developed.

Use of Whole Blood for Analysis

When whole blood is used in an assay system, specimen preparation time essentially is eliminated. Automated or semi-automated ion-selective electrodes, which measure ion activity in whole blood rather than ion concentration, have been incorporated into automated systems to provide certain test results within minutes of drawing a specimen. This approach now is used commonly for assays of electrolytes and some other common analytes. Another approach involves manual or automated application of whole blood to dry reagent films and visual or instrumental observation of a quantitative change (see Chapter 17).

Automation of Specimen Preparation

Several manufacturers have developed fully automated specimen preparation systems. (These systems will be described in later sections of this chapter.)

Specimen Loading and Aspiration

In most situations the specimen for automatic analysis is serum or plasma. Many analyzers sample directly from primary collection tubes of various sizes. With such analyzers, the collection tubes most frequently used contain separator material that forms a barrier between supernatant and cells (see Chapter 6).

Many analyzers also sample from cups or tubes filled with aliquots from the original specimen tubes. Often the design of the sampling cup is unique for a particular analyzer. Sample cups are designed to minimize dead volume—the excess amount of sample that must be present in a cup to permit aspiration of the full volume required for testing. Their shape should, even without a cap, minimize evaporation, and they should be made of inert material that does not interact with the analytes being measured.

Specimens may undergo other forms of degradation in addition to evaporation. Specimens that contain thermolabile constituents may undergo degradation of such analytes if held at ambient temperatures. Other constituents, such as bilirubin, are photolabile. Thermolability is minimized when both specimens and calibrators are held in a refrigerated loading zone. Photodegradation is reduced by the use of semi-opaque cups and by placement of smoke-colored or orange plastic covers over the specimen cups.

The loading zone of an analyzer is the area in which specimens are held inside the instrument before they are analyzed. The holding area may be a circular tray, a rack or series of racks built into a cassette, or a serpentine chain of containers into which individual tubes are inserted. When specimens are not identified automatically, they must be presented to the sampling device in the correct sequence, as specified by a loading list. The sampling mechanism determines the exact volume of sample removed from the specimen.

With many analyzers, specimens for a subsequent run may be prepared on a separate tray while one run is already in progress. This process permits machine operation and human actions to proceed in parallel for optimal efficiency. With other analyzers, specimens may be added continuously by the operator as they become available. A desirable feature of any automated analyzer is the ability to insert new specimens ahead of specimens already in place in the loading zone. This feature allows for the rapid analysis of specimens with high medical priority. With bar-coded specimens in random-access analyzers, it is possible for the operator to easily reposition specimens within the loading zone. When specimen identification is tied to a loading list, however, insertion or repositioning of specimens must be accompanied by revision of the loading list.

Transmission of infectious diseases by automated equipment is a matter of concern in clinical laboratories. The method of transmission by equipment primarily involves splatter of serum or blood from rapidly moving specimen probes during the acquisition of samples. The use of level sensors, which restrict the penetration of sample probes into specimens and provide smoother motion control, greatly reduces splatter.

Because the potential for contamination exists when the stoppers of primary containers are opened or "popped" to decant serum into specimen cups, several firms have developed closed-container sampling systems for use in their automated hematology and chemistry analyzers. With these systems, the specimen probe passes through a hollow needle that initially penetrates the primary container's rubber stopper. This configuration prevents damage to or plugging of the specimen probe, while allowing the level sensor (used to reduce carry-over and detect short sample) to remain active. After the specimen probe is withdrawn, the outer hollow needle is withdrawn so that the stopper reseals and no specimen escapes.

Specimen Processing

Automation of some analytical procedures requires the capability to remove proteins and other interferents from specimens and to separate free and bound fractions of heterogeneous immunoassays.

Removal of Protein and Other Interferents

The removal of proteins and other interferents from specimens is sometimes necessary to ensure the specificity of an analytical method. Procedures used to remove proteins and other interferents from specimens include (1) dialysis, (2) column chromatography, and (3) filtration.[2]

Separations in Immunoassay Systems

Automation of some immunoassay procedures requires the separation of free and bound fractions of heterogeneous immunoassays. To achieve this separation step, several automated immunoassay analyzers use bound antibodies or proteins in a solid-phase format. Through this approach, binding of antigens and antibodies occurs on a solid surface to which the antibodies or other reactive proteins have been adsorbed or chemically bonded. Different types of solid phases are used, including (1) beads, (2) coated tubes, (3) microtiter plates, (4) magnetic and nonmagnetic microparticles, and (5) fiber matrices. Additional details on automated systems that use various solid phases are found in books by Wild[17] and Price and Newman.[15]

Sample Introduction and Internal Transport

The method used to introduce the sample into the analyzer and to provide its subsequent transport within the analyzer is the major difference between continuous-flow and discrete systems. With continuous-flow systems, the sample is aspirated through the sample probe into a stream of flowing liquid, from which it is transported to analytical stations in the instrument. In **discrete analysis,** an aliquot of the sample is aspirated into the sample probe and then is delivered, often with reagent, through the same orifice into an individual reaction cup or another container. Carry-over is a potential problem with both types of systems.

Continuous-Flow Analyzers

Of historical note, theTechnicon Instruments Corporation (Tarrytown, New York) pioneered the use of peristaltic pumps and plastic tubing to advance the sample and reagents in **continuous-flow analysis**. Although these types of analyzers are no longer used owing to inflexibility in the test menu as outlined previously, the peristaltic pump still is used in some analyzers with ion-selective electrodes. Peristaltic pumps trap a "slug" of fluid between two rollers that occlude the tubing. As the rollers travel over the tubing, the trapped fluid is pushed forward and, as the leading roller lifts from the tubing, is added to the fluid.

Discrete Processing Systems

Positive–liquid displacement pipettes are used for sampling in most discrete automated systems in which (1) specimens, (2) calibrators, and (3) controls are delivered by a single pipette to the next stage in the analytical process.

A positive-displacement pipette may be designed for one of two operational modes: (1) to dispense only an aliquot of aspirated sample into the reaction receptacle, or (2) to flush out the aliquot together with diluent. Both systems use a plastic or glass syringe with a plunger, the tip of which usually is made of Teflon.

Pipettes may be categorized as (1) fixed-, (2) variable-, or (3) selectable-volume (see Chapter 9). Selectable-volume pipettes allow the selection of a limited number of predetermined volumes. In general, pipettes with selectable volumes are used in systems that allow many different applications, whereas fixed-volume pipettes usually are used for samples and reagents in instruments dedicated to the performance of only a small variety of tests.

Carry-over

Carry-over is defined as the transport of a quantity of analyte or reagent from one specimen reaction into a subsequent one. Because it erroneously affects the analytical results

obtained from the subsequent reaction, carry-over needs to be minimized. Most manufacturers of discrete systems reduce carry-over by setting an adequate flush-to-specimen ratio and incorporating wash stations for the sample probe. As much as a 4:1 ratio of flush to specimen may be needed to limit carry-over to less than 1%, although advances in materials and in dispenser velocity control have permitted lower ratios. Appropriate choices of (1) sample probe material, (2) geometry, and (3) surface conditions also will reduce carry-over.

With some systems, carry-over has been reduced by flushing the internal and external surfaces of the sample probe with copious amounts of diluent. T e outside of the sample probe in other instruments is wiped clean to prevent transfer of a portion of the previous specimen into the next specimen cup. In discrete systems with disposable reaction vessels and measuring cuvets, carry-over is caused by the pipetting system. In instruments with reusable cuvets or flow cells, carry-over may arise at each point through which samples pass sequentially. Disposable sample-probe tips eliminate both the contamination of one sample by another inside the probe and the carry-over of one specimen into the specimen in the next cup. Because a new pipette tip is used for each pipetting, carry-over is eliminated completely.

In practice, reduction of carry-over is a stricter requirement for automated analyzers that perform immunoassays, as some analytes have a wide range of concentrations. For example, the concentrations of chorionic gonadotropin vary over a wide range. Some systems use extra steps, such as additional washes, or an additional washing device to reduce carry-over to acceptable limits. Because extra steps reduce the overall **throughput**, additional rinsing functions are initiated (by computer operator selection) only for assays like chorionic gonadotropin that have large clinical measurement ranges.

Reagent Handling and Storage

Many automated systems use liquid reagents stored in plastic or glass containers. For those analyzers in which a working inventory of reagents is maintained in the system, the volumes of reagents stored depend on the number of tests to be performed between cycles of restocking reagents. Whenever possible, manufacturers use single reagents for test procedures, although two or more reagents may be required for some tests. Some analyzers use reagents in dry tablet form. Others use reagent-impregnated slides or strips. Still others rely entirely on electrodes to react with specimens.

For many analyzers in which specimens are not processed continuously, reagents are stored in laboratory refrigerators and are introduced into the instruments as required. In larger systems, sections of the reagent storage compartments are maintained at 4 °C to 10 °C. Refrigerated storage for reagents also is provided in most immunoassay systems. Many of the reagents delivered in liquid form by the manufacturers of these systems are stable for 2 to 12 months.

Reagent Identification

Labels on reagent containers include information such as (1) reagent identification, (2) volume of the contents or number of tests for which the contents of the container are to be used, (3) expiration date, and (4) lot number. Many reagent containers carry bar codes that contain some or all of this information, and the manufacturer is able to retrieve any pertinent information when necessary.

Other advantages of using reagent bar codes include (1) facilitation of inventory management, (2) ability to insert reagent containers in random sequence, and (3) ability to automatically dispense a particular volume of liquid reagent. Furthermore, when a bar code reader is coupled with a level-sensing system on the reagent probe, the operator is alerted as to whether a sufficient quantity of reagent exists to complete a workload.

In immunoassay systems, a bar code on a reagent container contains key information about (multiple) calibrators, such as the definition of a calibration curve algorithm and values of curve constants defined at the time of reagent manufacture. Accompanying calibrator materials provided in their own bar-coded tubes at the time of manufacture ensure that calibration functions are integrated properly into the analysis.

Open Versus Closed Systems

Automated analyzers are classified as "open" or "closed." With an open analyzer, the operator is able to change the parameters related to an analysis and prepare "in-house" reagents or use reagents from a variety of suppliers. Such analyzers usually have considerable flexibility and are adapted readily to new methods and analytes.

A closed-system analyzer requires the reagent to be in a unique container or format provided by the manufacturer. In general, liquid reagents for open systems are less expensive than the proprietary components required for closed analyzers. Yet closed systems contain a hidden cost advantage because reconstitution or preparation of reagents for use does not require a technologist's time. T e variability arising from reconstitution of dry reagents has been overcome by the use of predispensed liquid reagents or the provision of premeasured liquids. Liquid reagents for some open systems now are approaching the longer stability that has characterized many closed systems. Most immunoassay systems are closed, as are most systems that have been developed for point-of-care applications (see Chapter 17).

Reagent Delivery

Liquid reagents are acquired and are delivered to mixing and reaction chambers by pumps (through tubes) or by positive-displacement syringe devices. In a few high-throughput automated analyzers, reagents and diluent are drawn from bulk containers through tubes, and the sample from the specimen cup is drawn through the aspirating probe.

Syringe devices for reagent and sample delivery are common to many automated systems. T ey are usually positive-displacement devices, and the volume of reagents they deliver is programmable. For those analyzers in which more than one reagent is acquired and dispensed by the same syringe, washing or flushing of the probe is essential to prevent reagent carry-over.

Chemical Reaction Phase

Sample and reagents react in the chemical reaction phase. Factors that are important in this phase include (1) the vessel in which the reaction occurs, (2) the cuvet in which the reaction is monitored, (3) the timing of the reaction(s), (4) mixing and transport of reactants, and (5) thermal conditioning of fluids. As discussed previously, separation of bound and unbound fractions is a fif h issue for some immunoassay systems.

Type of Reaction Vessel and Cuvet

In a continuous-flow system, each specimen passes through the same continuous stream and is subjected to the same analytical reactions as every other specimen and at the same rate. In such systems, the reaction occurs within the tube that serves as both a flow container and a cuvet.

In discrete systems, each specimen in a batch has its own physical and chemical space, separate from every other specimen. Discrete analyzers use individual (disposable or reusable) reaction vessels transported through the system af er sample and reagent have been dispensed, or they use a stationary reaction chamber. In some discrete systems, reaction vessels are discarded af er each use. T e use of disposable cuvets has simplified automation and has eliminated carry-over in the cuvets and the maintenance of flow cells. Disposable cuvets became possible through the development of improved plastics (notably acrylic and polyvinyl chloride) and manufacturing technology.

In other instruments, reaction vessels are reused. T e time before reusable cuvet/reaction vessels must be replaced depends on their composition (e.g., 1 month for plastic, 2 years for standard glass vessels). Pyrex glass vessels usually are not replaced unless physically damaged.

T e typical cleaning sequence of a reusable cuvet/reaction vessel involves aspiration of the reaction mixture from the cuvet at an in situ wash station. A detergent, alkaline, or acid wash solution then is dispensed repeatedly into and aspirated from the cuvet. T e cuvet is rinsed several times with deionized water and is dried by vacuum or pressurized air.

Dry reagent systems, which use slides of multilayer films or impregnated fiber strips, eliminate the need for dispensing and mixing of liquid reagents. Nevertheless, these instruments still require a mechanism to maintain a stable temperature and provide accurate positioning of the reaction unit for optical measurements.

Timing of Reactions

T e time allowed for a reaction to occur depends on a variety of factors. In some analyzers, reaction time depends on (1) the rate of transport of reaction mixture through the system to the measurement station, (2) on timed events of reagent addition (or activation) relative to measurement, or (3) on both. In discrete random-access analyzers, samples and reagents are added to a cuvet in a timed sequence, and detector signals are measured at intervals to follow the course of each reaction. Usually, the total read time for a reaction in these systems is constrained to a maximum value defined by the manufacturer, but it may be programmed to be shorter.

Mixing of Reactants

Various techniques are used to mix reactants. In a discrete system, these include:

1. Forceful dispensing.
2. Magnetic stirring.
3. Vigorous lateral displacement.
4. A rotating paddle.
5. T e use of ultrasonic energy.

Continuous-flow analyzers rely on the tumbling action of the stream in a mixing coil. Dry reagent systems obviate the need for mixing because the serum completely interacts with the dry chemicals as it flows through the matrix of the reaction unit. However, regardless of the technique used, mixing is a difficult process to automate.

Thermal Regulation

T ermal regulation requires the establishment of a controlled-temperature environment in close contact with the reaction container and efficient heat transfer from the environment to the reaction mixture. Devices used to control temperature include (1) air baths, (2) water baths, and (3) contact with warm plates.

Measurement Approaches

Automated chemistry analyzers use a variety of optical measurement devices including (1) photometers (2) spectrophotometers, (3) reflectance photometers, (4) fluorometers, and (5) luminometers. Immunoassay systems use reaction schemes that produce (1) fluorescence, (2) chemiluminescence, and (3) electrochemiluminescence to enhance sensitivity. Ion-selective electrodes and other electrochemical techniques also are used widely.

Photometry/Spectrophotometry

Measurement of absorbance requires the following three basic components (see Chapter 9):

1. An optical source.
2. A means of spectral isolation.
3. A detector.

Optical Source

Optical sources used in automated systems include (1) tungsten lamps, (2) quartz-halogen lamps, (3) deuterium lamps, (4) mercury lamps, (5) xenon lamps, and (6) lasers. In the quartz-halogen lamp, low-pressure halogen vapor such as iodine, bromine is enclosed in a fused silica envelope in which a tungsten filament serves as an incandescent light source. T e spectrum produced includes wavelengths from approximately 300 to 700 nm.

Spectral Isolation

In automated systems, spectral isolation commonly is achieved with interference filters. Typical interference filters have peak transmissions of 30% to 80% and bandwidths of 5 to 15 nm (see Chapter 9). In several multitest analyzers, filters are mounted in a filter wheel, and the appropriate filter is moved into place under command of the system's computer.

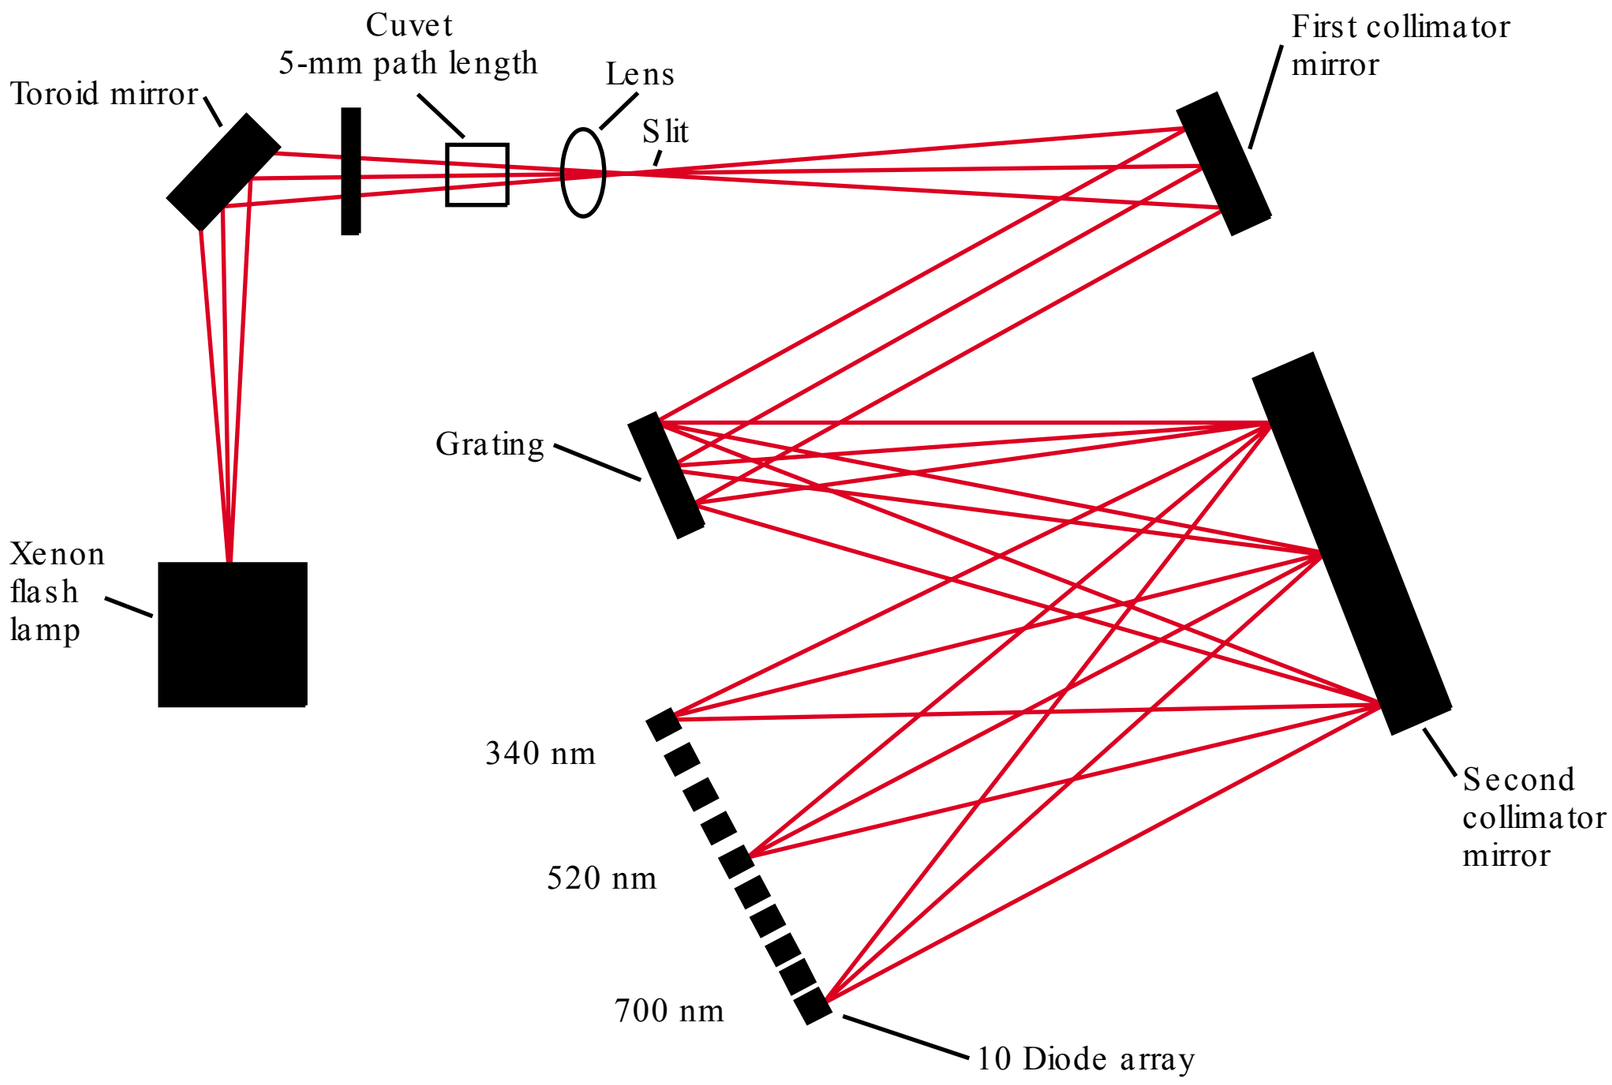

Figure 16-1 Use of a diode array in the SYNCHRON CX7 monochromator reduces requirements for moving parts. For simplicity, ray traces for only three wavelengths are shown. (Courtesy Beckman Coulter, Inc.; www.beckmancoulter.com.)

Monochromators with movable gratings and slits provide a continuous choice of wavelengths. They offer great flexibility and are suited especially for the development of new assays. However, because relatively few wavelengths are required for analyses in routine analyzers, many manufacturers use a stationary, holographically ruled grating, coupled with a stationary photodiode array, to isolate the spectrum. These two elements are coupled with fiber-optic light guides to transfer the passage of light energy through cuvets at locations convenient for mechanization. Use of these passive elements enhances the reliability of a system because no moving parts are required for spectral isolation (Figure 16-1).

Photometric Detectors

Photodiodes are used as detectors in many automated systems, either as individual components or in multiples as an array. Photomultiplier tubes are required in many immunoassay systems to provide a high signal-to-noise ratio and fast detector response times for fluorescent and chemiluminescent measurements.

Proper alignment of cuvets with the light path(s) is important in both automated and manual analyzers. In addition, stray energy and internal reflections must be kept to acceptable levels. When the light path is not perpendicular to the cuvet, inaccuracy and imprecision may occur, particularly in kinetic analyses.

Reflectance Photometry

In reflectance photometry, diffuse reflected light is measured. The reflected light results from illumination with diffused light of a reaction mixture in a carrier or from the diffusion of light by a reaction mixture in an illuminated carrier. The intensity of the reflected light from the reagent carrier is compared with that reflected from a reference surface. As the intensity of reflected light is nonlinear with concentration of the analyte, mathematical algorithms commonly are used to linearize the relation of reflectance to concentration.[2]

Fluorometry

Fluorescence is the emission of electromagnetic radiation by a species that has absorbed exciting radiation from an outside source. Intensity of emitted (fluorescent) light is directly proportional to the concentration of the excited species (see Chapter 9).

Fluorometry is used widely for automated immunoassay. It is approximately 1000 times more sensitive than comparable absorbance spectrophotometry, but background interference due to fluorescence of native serum is a major problem. This interference is minimized by (1) careful design of the filters used for spectral isolation, (2) selection of a fluorophor with an emission spectrum distinct from those of interfering compounds, or (3) the use of time- or phase-resolved fluorometry (see Chapter 9).

Different optical configurations are represented in different manufacturers' equipment. Right-angle fluorescence measurement is one of the common approaches, with emitted light passing through the emission interference filter to a photomultiplier tube. In fluorescence polarization, the light source takes the form of polarized light. The change in the degree of polarized light emitted by a fluorescent molecule is then measured (see Chapters 9 and 15).

Turbidimetry and Nephelometry

Turbidimetry and nephelometry are optical techniques that are applicable particularly to methods used to measure precipitate formation in antigen-antibody reactions (see Chapter 15). These techniques are used to measure plasma proteins and to perform therapeutic drug monitoring.

Chemiluminescence and Bioluminescence

Chemiluminescence and bioluminescence differ from fluorometry in that the excitation event is caused by a chemical or electrochemical reaction, not by photoluminescence (see Chapter 9). Applications of chemiluminescence and bioluminescence have increased significantly with the development of automated instrumentation and several new reagent systems. Because of their attamole-to-zeptomole lower limits of detection, chemiluminescence and bioluminescence reactions have been used widely as direct and indicator labels in the development of immunoassays.

Electrochemical

A variety of electrochemical methods have been incorporated into automated systems. The most widely used electrochemical approach involves ion-selective electrodes. These electrodes have replaced flame photometry in the determination of sodium and potassium. Electrochemical detectors also have been used for the measurement of other electrolytes and for indirect application in the analysis of several other serum constituents (see Chapter 10). The relationship between ion activity and the concentration of ions in the specimens must be established with calibrating solutions, and such electrodes need to be recalibrated frequently to compensate for alterations in electrode response.

Peristaltic pumps are used to move the sample into chambers containing fixed sample and reference electrodes. The electrodes must remain in contact with the specimen from 7 to 45 seconds to reach steady-state conditions. The most common arrangement is to provide electrodes to assay (1) sodium, (2) potassium, and (3) chloride. Because specimens and calibrators usually flow past a group of electrodes, results for all analytes are reported for most systems. Ion-selective electrode capability also has been incorporated into medium-sized and large automated analyzers as integrated three- and four-parameter modules; this incorporation has increased throughput of these systems as several results are produced in parallel.

Signal Processing, Data Handling, and Process Control

The interfacing and integration of computers into automated analyzers and analytical systems have had a major impact on the acquisition and processing of analytical data. Analog signals from detectors are converted to digital forms by analog-to-digital converters at a rate of 10^3 to 10^5 conversions per second. The computer and resident software then process the digital data into useful and meaningful output. Data processing has allowed automation of such procedures as nonisotopic immunoassays and reflectance spectrometry because computer algorithms readily transform complex, nonlinear standard responses into linear calibration curves. Several functions performed by integrated computers in automated analyzers are listed in Box 16-3. Additional functions include the following:

1. Computer control of the electromechanical operation of the analyzer, ensuring that all functions are performed uniformly, in a repeatable manner, and in the correct sequence. Such control of the automated equipment, calculation of results, and monitoring of operation contribute to the increased reproducibility of results.
2. Computer acquisition, processing, and storage of operational data from the analyzers. Built-in computers monitor instrument functions for correct execution and react to improper function by recording the site and nature of the malfunction.
3. Computer interfacing with the instrument operator. Diagnostic computer messages to the user describing the site and type of problem enable quick identification of problems and prompt correction. Graphical displays provide detailed and interactive troubleshooting guidance to instrument operators and visual display of the status of each specimen and associated quality control data. Output data are flagged by comparison with pre-set criteria and are displayed for the operator's evaluation and assessment. Such information may specify that (1) linearity of a reaction has been exceeded, (2) a reaction is nonlinear, (3) substrate exhaustion has occurred, (4) absorbance of a reagent is too high or too low, or (5) baseline drift is excessive. Operators may reprogram certain functions of the analyzer (e.g., the timing interval for a kinetic reaction and set point of the reaction temperature); enter certain values, such as calibrator

BOX 16-3 Signal and Data Processing Functions Performed by Computers of Automated Analyzers

Data Acquisition and Calculation
- Acquisition of response signal and signal averaging
- Subtraction of blank response
- Correction of response of unknown for interferences (e.g., Allen-type corrections)
- Linear regression for determining slope
- ($\Delta A/\Delta t$) of rate reactions; ($\Delta A/\Delta C$) of absorbance/concentration relation; ($\Delta R/\Delta C$) of any response parameter to concentration
- Statistics (mean, SD, CV) on patient or control values
- Mathematical transformation of nonlinear relations to linear counterpart
- Mathematical transformation of results to alternative reporting units

Monitoring
- Test for fit of data to linearity criteria for calibration curves or rate reactions
- Test of patient result against reference interval criteria
- Test of control result against criteria of a quality control standard of performance
- Test of moving average of patient results against quality criteria for detecting assay drift

Display
- Display of specimens currently being analyzed, tests ordered on each specimen, and expected times of completion
- Accumulation of sets of patient results
- Collation of results for patient-oriented printout
- Warning messages provided to alert operator to instrument malfunction, need for maintenance, or unusual clinical situation
- Quality control charts provided for operator review
- Troubleshooting flow charts provided to assist operator

CV, Coefficient of variation; SD, standard deviation.

concentrations; display stored information in raw or processed form; or define the format of printed output through simple interaction with the computer software.

4. Computer facilitation of communication with mainframe computers. Typical interfaces in the past have used serial Recommended Standard 232 (RS-232) connections to permit interactive communication between computer systems in the modern laboratory analyzer and the Laboratory Information System (LIS). More recently, instrument manufacturers have been developing ethernet interfaces for networked connections with TCP/IP (**T**ransmission **C**ontrol **P**rotocol/**I**nternet **P**rotocol).
5. Computer integration of the monitoring functions of one or more analyzers with a single workstation. Typically, the workstation (1) serves as the point of interaction with the instrument operator, (2) accepts test orders, (3) monitors the testing process, (4) assists with analysis of process quality, and (5) provides facilities for review and verification of test results. The workstation is usually directly interfaced with the LIS host, accepting downloaded test orders and uploading test results. Most workstations have facilities to (1) display Levy-Jennings quality control charts, (2) monitor the progress of each test order, and (3) troubleshoot the analyzers. They may also provide facilities to assist with the review of completed test results. Some workstations have rule-based software, which allows the operator to program rules for autoverification of test results.

Integrated Automation for the Clinical Laboratory

Considerable progress has been made in integrating the individual steps of the analytical process into analytical systems. Consequently, advanced analytical systems are now available from multiple vendors for automated (1) chemistry, (2) hematology, (3) immunoassay, (4) coagulation, (5) microbiology, and (6) nucleic acid testing, which provide efficient and cost-effective operation with a minimum of operator input. In addition, clinical laboratories are automating their preanalytical and postanalytical operations.

Some manufacturers have developed stand-alone "front-end" automation systems, which (1) sort, (2) centrifuge, (3) decap, (4) aliquot, and (5) label tubes. Although they require manual transport of the tubes to the analytical areas, these systems have automated steps in specimen processing. More advanced automation systems provide options such as (1) conveyors to transport specimens, (2) direct sampling interfaces to the laboratory's higher-volume analyzers, and (3) refrigerated storage and retrieval systems.[16]

Large-scale automation of the laboratory includes an automated specimen processing area where specimens are (1) identified, (2) labeled, (3) scheduled for analysis, (4) centrifuged, and (5) sorted. After specimens are processed, automated specimen conveyor devices transport the sorted specimens to appropriate workstations in the laboratory, where they are analyzed without human intervention. Rule-based expert system software (1) assists with the review of laboratory results by automatically releasing results that have no associated problems and (2) identifies any problematic results to be brought to the attention of trained medical technologists. All specimens are catalogued after analysis and are stored in a central storage facility, available for automated retrieval if necessary. As previously discussed, particularly important aspects of large-scale automation projects are the approaches used to process and transport specimens and the overall integration of automated components into a smoothly functioning whole.

Workstations

The task of integrating laboratory automation begins with the laboratory **workstation**. In general, a clinical laboratory workstation is usually dedicated to a defined task and contains appropriate laboratory instrumentation to carry out that task. Frequently, the workstation in the modern laboratory is defined in terms of the automated analyzer that is being used. Current laboratory instruments and systems are highly developed for stand-alone operation and fit into the workstation concept. Movement of specimens into and out of the workstation is accomplished by manual transport, and the instrument operator activities are largely independent of those at other workstations. On a typical instrument, the instrument operator follows a manufacturer-recommended sequence of (1) calibration, (2) quality control, and (3) daily maintenance activities, and (4) uses the instrument's front-panel functions to introduce specimens for analysis. If the analyzer has a bidirectional interface with an LIS and bar code–reading capabilities, information regarding which assays should be run on each specimen is downloaded from the LIS, and the instrument operator simply loads bar code–labeled specimens into the specimen input area. The built-in diagnostics supplied in most modern analyzers provide sufficient "intelligence" in the analyzer that the operator is able to "walk away" from the instrument for short periods, confident of its reliable operation. Nevertheless, the operator needs to attend periodically to (1) performing instrument operation, (2) replenishing reagents, (3) evaluating instrument diagnostic messages, and (4) introducing new specimens into the specimen input tray.

Instrument Clusters

To reduce labor costs, instrument manufacturers are developing approaches that will allow a single technologist to simultaneously control and monitor the functions of several instruments. Initially, such workstations were configured with clusters of identical instruments, such as (1) chemistry, (2) immunochemistry, or (3) hematology analyzers. More advanced instrument clusters may incorporate both chemistry and immunoassay analyzers from the same vendor, and a possible extension of this concept is the development of clusters of unlike instruments that cross traditional laboratory disciplines. An example might be a cluster of chemistry and hematology analyzers.

A cluster of analyzers has its own central control module (a PC) with software designed to assist the technologist in monitoring the functions of each analyzer and to aid in the review of laboratory results generated by the cluster. Access

to the many front-panel functions of each analyzer is provided by the interface between the analyzer and the central control module. Thus, the technologist loads specimens onto each instrument in the cluster and then monitors subsequent instrument operation and reviews the results at the central workstation. By incorporating the activities of what would be several workstations in most current laboratories into a single integrated workstation, this approach shows promise in saving laboratory manpower.

Work Cells

Another extension of the instrument cluster concept is the addition of robotic specimen handling and preparation. A robotic system is used to carry out various specimen preparation steps, such as checks of specimen adequacy, and will (1) centrifuge, (2) aliquot, (3) label, (4) transport, and (5) store specimens. The robotic system is then responsible for introducing specimens into the appropriate analyzer, allowing the technologist to assume primarily a monitoring role. An interface between the central control module and the robot controller (or combining these functions in a single computer) allows the activities of the robotic cluster to be fully coordinated.

Automated Specimen Transport

Different approaches have been developed to transport and manipulate specimens within the laboratory.[10,11]

Conveyor Belts

Conveyor belts have been used in the laboratory to transport specimens from one clinical laboratory workstation to another. Ordinary industrial conveyor belts have been used successfully when only transportation is required. However, when conveyors have been integrated with other robotic systems to automate preanalytical and/or postanalytical functions, this technology has had difficulty in handling the large variety of specimen containers found in the clinical laboratory. To increase the variety of types of specimen containers that are carried on a conveyor belt system, specimens are placed into specially designed carriers that fit on the conveyor belt line. Sometimes known as "pucks" or "racks" (depending on whether they carry individual specimens or groups of specimens), the carriers have receptacles for variously sized tubes, generally ranging from 13 × 75 mm to 16 × 100 mm—sizes that are consistent with the CLSI Standard AUTO01-A.[5]

Transfer of specimens from the conveyor belt to the laboratory workstation has been implemented in various ways. For example, many manufacturers have equipped their laboratory instruments with devices to obtain specimens from conveyor belt systems. In practice, the automation system requires a device that stops the tube in the exact location required by the analyzer and verifies and transfers the tube's bar code identification to the analyzer. In another example, a specialized robotic system is required to remove the tube from its carrier and place it in the analyzer's rack or carousel.

Robot Arms

Robotic arms are capable of performing highly complex clinical assays.[15] Cartesian, cylindrical, and articulating robotic devices are available commercially (Figure 16-2). Robots, by virtue of their operational flexibility, enable the rapid reconfiguration of systems for new and varying protocols. This ability (1) enhances versatility and safety, (2) improves precision and productivity, and (3) reduces errors due to human mismatch of specimen identity.

Cartesian systems currently are the most common form of robotics used in laboratories. These systems are built into programmable pipette stations and provide flexible pipetting routines to suit varied protocols.

Automated Specimen Processing

Although the manual operations carried out in a specimen processing area look simple, considerable complexity underlies them. Consequently, specimen processing has been one of the most difficult areas of the clinical laboratory to automate. It has been approached in various ways using both integrated and modular approaches, which are discussed later. Each specimen passing through a specimen processing area has to undergo a series of operations, beginning with (1) receiving the specimen, (2) inspecting it for appropriateness (labeling, container type, temperature, and quantity of specimen), (3) logging onto the LIS, (4) labeling the specimen with an accession number, and (5) separating urgent and stat specimens

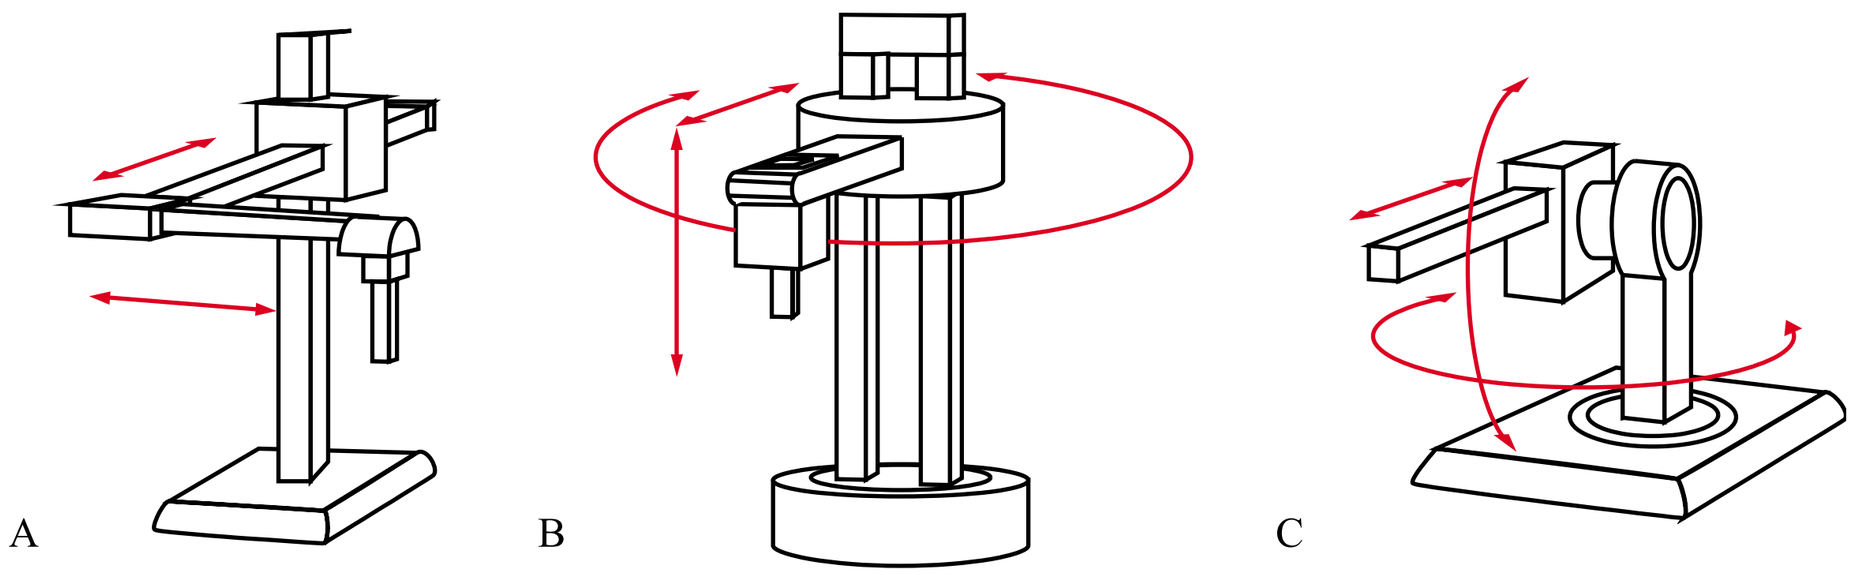

Figure 16-2 Three basic configurations of robotic devices that have applications in the clinical laboratory. A, Cartesian. B, Cylindrical. C, Articulating (polar) or jointed. (Modifed *from* Journal *of* the International Federation *of* Clinical Chemistry 1992;4:175.)

from routine specimens. Also, specimens have to be sorted for centrifugation, aliquoted, or otherwise prepared for the appropriate laboratory station.

Stand-alone Specimen Processing Systems

An example of a stand-alone specimen processing system is shown in Figure 16-3. Similar systems place processed specimens into racks that are transported manually to the testing areas, with some exceptions. Some of these are about the size of a large automated analyzer, and others may be a little larger. They may be a good choice for laboratories (1) with daily workloads of 500 to 2500 specimens, (2) with space limitations, or (3) that desire an upgrade path and ease of use with different analyzers from different vendors. Some laboratories may choose to use multiples of a stand-alone specimen processing system to automate archiving and preanalytical specimen processing.

These systems will (1) receive incoming specimens, (2) sort, (3) decap, (4) aliquot, and (5) label aliquot specimen containers with bar codes. All are interfaced to the laboratory's LIS. Some systems even include automated centrifugation. Several of the systems sort into instrument-specific racks for analyzers from a number of different vendors. In addition to sorting for particular analyzers or laboratory sections, some users apply these systems to aliquot and sort reference or "send-out" testing, saving considerable time in locating the original specimens after testing in their own laboratory.

Integrated and Modular Automation Systems

Several manufacturers offer integrated or modular automation systems for specimen processing that provide additional functionality. In addition to the functions described in the preceding section, these systems typically add (1) conveyor transport, (2) interfacing to automated analyzers, (3) more sophisticated process control, and, in some cases, (4) a specimen storage and retrieval system. All systems are of modular design, allowing the customer to choose which modules/features should be included. Some systems use an open design, which permits interfaces to analyzers from a variety of vendors, whereas other systems are of a closed design and are interfaced only to the vendor's own or a limited number of analyzers. It should be noted that closed systems typically do not have process control software that is independent of the instruments or system, but rather, the automation process control is integrated to work with the vendor's analyzers. An example of one integrated automation system is shown in Figure 16-4.

To achieve maximum effectiveness of an automation system, process control software should be able to read the specimen's identification (ID) bar code and obtain information from the laboratory's LIS about specimen type and ordered tests. It should then determine the processes the specimen requires and the exact route or course of action needed for each specimen. The software should be able to (1) calculate the number of aliquots and the proper volume for each, depending on the tests requested, (2) route the specimens to analyzers, (3) recap the specimens, and (4) retain the specimens for automatic recall. In addition, the software should be able to monitor analyzers for in-control production status and automatically make decisions if a test is not available. Specimen integrity checking should be automatic; rules-based decisions should monitor specimen quality and enable these decisions. Finally, most process control software should include (1) "autoverification," which consists of validating analyzer results by making rules-based decisions that flag exceptions for technologist review, and (2) "autoretrieval" of specimens for repeat, reflex, and dilution testing.

Although most of these systems are restricted to handling specific types of specimen containers, they are capable of processing much of the daily workload of a large clinical laboratory. Although a few laboratories with daily workloads as low as 600 to 800 specimen tubes have justified these systems

Figure 16-3 The Yaskawa AutoSorter III work cell uses two cartesian robots to perform automated centrifugation, decapping, and sorting into analyzer-specific racks selected by the customer with a maximum throughput of 800 tubes per hour. (Courtesy Yaskawa America, Inc., Motoman Robotics Division, West Carrollton, OH; www.motoman.com.)

Figure 16-4 Beckman Coulter Power Express System. The system design includes preanalytical, connected, and analytical for all disciplines and postanalytical processing. (Courtesy Beckman Coulter, Inc.; www.beckmancoulter.com.)

because of a shortage of technical help, these systems typically are designed for laboratories with workloads of 1000 to 10,000 specimens per day. In addition to process control software and the ability to be interfaced to the laboratory's LIS, each of these systems incorporates some or all of the following components:

1. Specimen input area. A holding area where bar code–labeled specimens are introduced into the system.
2. Bar code reading stations. In most systems, the bar codes on specimens are read at the time the specimen is placed in a carrier or puck, which usually has its own ID in the automated system. The automated system then routes the carrier or puck to the correct destination, saving repeated reading of the specimen bar code.
3. Transport system. Segments of a conveyor belt line that move specimens to the appropriate location.
4. High-level device to sort or route specimens. A device that separates specimens by type (such as by tube height) or by order code and passes them to the transport system or to a system using racks. A high-level sorter is often used to separate specimens that require centrifugation or other processing steps from specimens that do not, or to route specimens into completely different pathways within the total automation system.[10,11]
5. Automated centrifuge. An area of the specimen processor in which specimens requiring centrifugation are removed from the conveyor belt, introduced into a centrifuge that is automatically balanced, centrifuged (refrigerated or at room temperature), and then removed from the centrifuge and placed back on the transport system.
6. Level detection and evaluation of specimen adequacy (specimen integrity). An area in which sensors are used to evaluate the volume of specimen in each specimen container and to look for the presence of hemolysis, lipemia, or icterus.
7. Decapper station. An area or device in the automated system in which specimen caps or stoppers are automatically removed and discarded into a waste container.
8. Recapper station. An area or device in the automated system in which specimen tubes are automatically recapped with new stoppers or covered with an air-tight closure.
9. Aliquoter. Aspirates appropriately sized aliquots from each original specimen container and places them into bar-coded secondary specimen containers for sorting and transport to multiple analytical workstations.
10. Interface to automated analyzer. A direct physical connection to an automated analyzer that permits the analyzer's sampling probe to aspirate directly from an open specimen container while the container is still on the conveyor, or that may robotically lift the container from the conveyor and place it into the analyzer. Some automation systems interface only to their own brand of analyzers or to a limited number of systems, whereas other automation systems use a so-called open design that complies with CLSI standards and permits interfaces to a variety of automated analyzers.
11. Sorter. An automated sorter used to sort specimens not going to a conveyor-interfaced analyzer or workstation. Such a sorter typically sorts into 30 to 100 different sort groups in racks or carriers. In some systems, the racks are specific to certain analyzers for convenience.
12. Take-out stations. Temporary storage areas for specimens before or after analysis. The take-out station may be the same as the sorter described earlier, where specimens are sorted for manual delivery. However, it may also serve as a holding area (stockyard) for specimens awaiting autoverification of results in case a repeat test is required.
13. Storage and retrieval system. This unit may serve the same function as the take-out station or stockyard—that of holding specimens after analysis in case a specimen is necessary for a repeat test, but it has one major difference. These units are typically refrigerated and hold many more specimens (3000 to 30,000) than the typical take-out station or stockyard. Depending on daily workloads, the laboratory may be able to retain up to 1 week of specimens for possible repeat or additional tests. Specimen containers are loaded and retrieved with a robot.

Automated Specimen Sorting

Several approaches have been used to automatically sort specimens, including (1) a conveyor belt, (2) automated sorter using racks, and (3) stand-alone sorters. Selecting the correct one of these approaches is an extremely important determinant of the overall scheme of automation in any particular laboratory.[10,11]

Integration With a Conveyor System

Three types of conveyor sorting systems have been used. One type uses a continuous loop in which all specimens follow the loop and go past each workstation or analyzer. Specimens are sampled directly by the analytical instrument while on the conveyor, or a robot attached to the workstation removes selected specimens from the conveyor for analysis (Figure 16-5). This approach offers the advantage that it does not require that specimens be aliquoted because specimens pass by all workstations at which tests are performed. However, the continuous loop also has some disadvantages, as specimen throughput is often limited by the slowest direct sampling analyzer on the loop. Exceptions include systems that use bypass

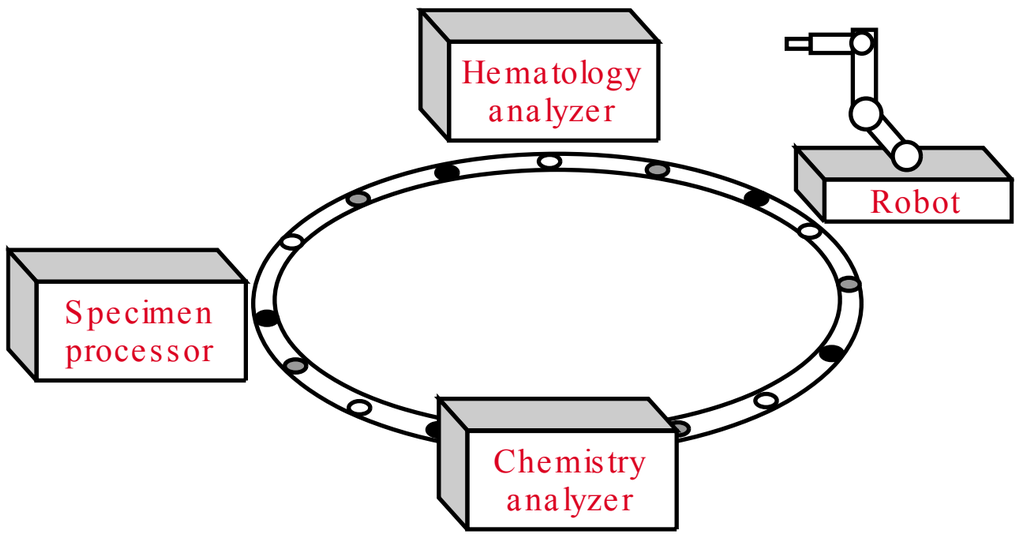

Figure 16-5 Direct sampling from a conveyor track in a loop configuration eliminates the need for separate equipment to sort specimens but may limit the rate of specimen movement on the track to the sampling speed of the slowest workstation. (From Boyd JC, Felder RA, Savory J. Robotics and the changing face of the clinical laboratory. Clin Chem 1996;42:1901-10.)

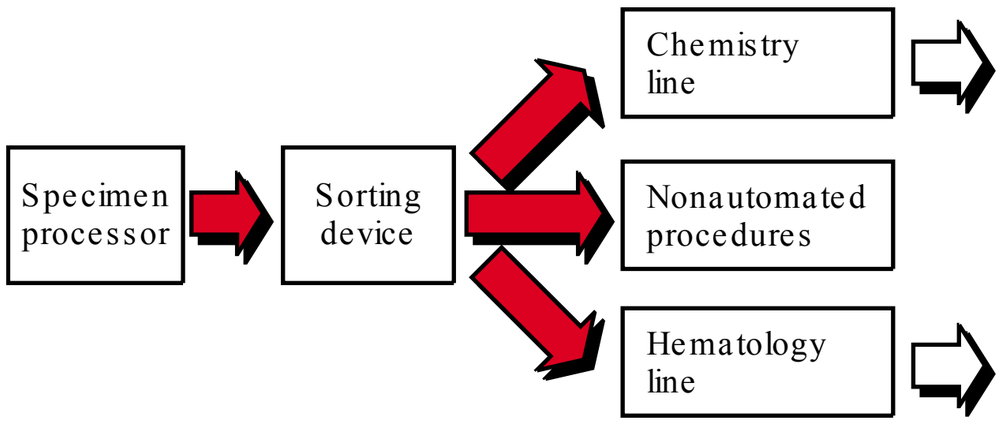

Figure 16-6 Sorting of laboratory specimens before introduction to an automated specimen conveyor system simplifies the design and construction of the conveyor. (From Boyd JC, Felder RA, Savory J. Robotics and the changing *face of* the clinical laboratory. Clin Chem 1996;42:1901-10.)

tracks to enable specimens to bypass stations to get to their correct destinations. It should also be noted that if specimens are removed from their carriers on the line for testing, a system of queuing empty carriers is required to return the tubes to the conveyor.

In a second approach, some automated processing conveyor systems sort specimens into groups according to their destination in the laboratory, such as for hematology or chemistry tests. Downstream from the sorter, separated specimens are routed down a dedicated conveyor line (Figure 16-6). This method follows the approach used in most manual specimen processing areas. The extent of specimen transport via conveyor depends on the activities to be included. For example, these designs may include (1) a centrifuge and aliquoter, (2) an interfaced chemistry or immunochemistry analyzers, (3) an additional sorter, (4) a take-out station, and even (5) a refrigerated storage and retrieval station at the end of the chemistry line. The hematology line may lead directly to hematology and coagulation analyzers and to an automated slide preparation machine.

In the third approach, the sorter is integral to the conveyor system, and specimens are sorted as they are transported (Figure 16-7). The advantages of this approach are that a dedicated specimen sorter is not necessary in the specimen processing system, and that with appropriate specimen transport, the requirement for specimen aliquots may be avoided.

Automated Sorting Into Racks

Some sorters are designed to sort the specimens into racks for transfer to particular laboratory sections or analyzers, as described previously. These systems sort the aliquot and original tubes into racks for manual transport to analyzers or laboratory sections. In some cases, the racks may be specific for a specific analyzer, eliminating additional handling of tubes.

Automated Specimen Storage and Retrieval

Automated capability to store and retrieve specimens on demand is an important aspect of automated specimen delivery systems. A few of the integrated systems described earlier offer specimen storage and retrieval modules as options in their systems. These robotic modules store specimens refrigerated in specific locations that are logged into a database maintained by the specimen delivery system. When a user requests

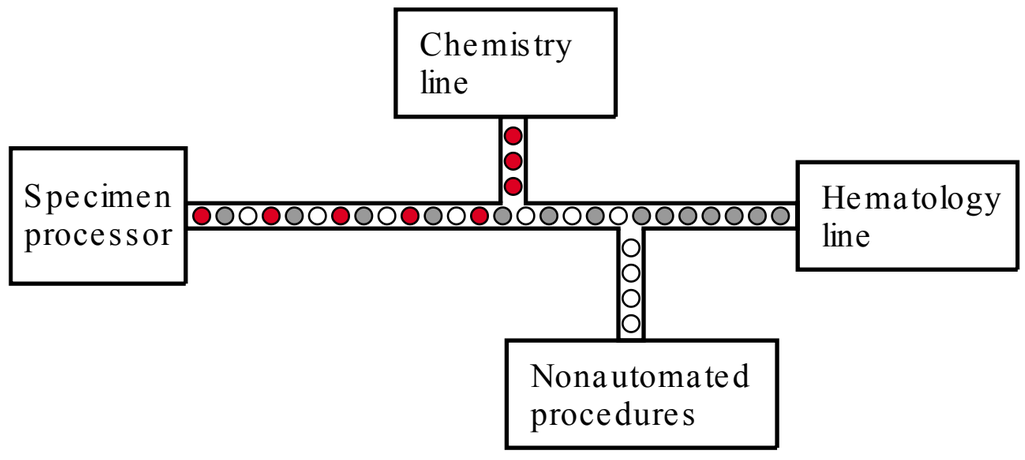

Figure 16-7 Use of the conveyor system to sort specimens dynamically during specimen transport eliminates the requirement for separate equipment to sort specimens but requires a more sophisticated conveyor system with numerous bar code–reading stations and gates to direct specimens to the appropriate workstation. (From Boyd JC, Felder RA, Savory J. Robotics and the changing *face of* the clinical laboratory. Clin Chem 1996;42:1901-10.)

retrieval of a specific specimen, the robot is given commands to retrieve the specimen from the appropriate archived location and to route the specimen to the requested station using the specimen transportation system. Some large reference laboratories have adapted large storage systems commonly used in other industries for use in their own settings.

Practical Considerations

In this section the practical considerations that influence a laboratory's decision to automate part or all of its operations are discussed.

Evaluation of Requirements

Any consideration of total or modular laboratory automation should start with an evaluation of requirements.[16] Such an evaluation begins with mapping of the current laboratory work flow from the arrival of patient specimens through completion of testing and reporting of results. Box 16-4 lists potential work flow steps that should be mapped. Mapping of material (specimen) flows and data flows is directly related to process flow and will assist the laboratory in determining process steps that (1) are bottlenecks, (2) waste labor, and (3) are prone to error.[13] Work-flow mapping thus enables the laboratory to better identify what steps should be considered for automation.

Some laboratorians use 80% as a "rule of thumb" in guiding decisions about automation. Clinical laboratories have many (1) exceptional tests, (2) specimen containers, and (3) handling situations. Nevertheless, if 80% of the specimen containers and handling situations can be standardized and automated, the laboratory will achieve a dramatic reduction in labor and costs, which should be sufficient to justify the investment in automation and the planning and evaluation time involved.

Once the laboratory's workflow has been mapped and its requirements have been identified, alternative solutions are next considered. Vendors are invited to make presentations and to host visits of the laboratory management team at other laboratories where the vendors have successful installations.

BOX 16-4 Clinical Laboratory Steps for Workflow Mapping

Unpacking from transport containers
Presorting
Temperature preservation
Order entry
Document management (requisitions, etc.)
Labeling
Sorting
Centrifugation
Labeling of aliquot tubes
Pouring of aliquots
More sorting
Delivery to laboratory sections
More sorting
Preparing work lists
Decapping
Labeling analyzer-specific tubes for specimens
Pouring or pipetting analyzer-specific specimens
Loading tubes onto analyzers
Performing tests (steps such as extraction, centrifugation, precipitation, dilution, etc., are not specifically listed)
Unloading analyzers
Recapping
Data manipulations (calculations)
Result review and verification
Reporting results
Delivering specimens to archival storage system
Archival storage of specimens
Reflexive testing
Repeat testing, diluting, if necessary
Additional physician-ordered testing
Specimen retrieval for additional or repeat testing
Disposal of expired specimens

It is important at this stage to focus on the requirements identified by the workflow mapping and not allow the vendor to try to sell equipment that may not be necessary.

Problems of Integration

Building a highly integrated laboratory generates many potential problems. Because it is unlikely that a laboratory will use only the equipment of a single equipment manufacturer, integration of instruments and robotic devices from different manufacturers typically is necessary. Decisions must be made concerning which device will be the master controller and which vendor will develop the software that provides overall control of the automation scheme. In addition, individuals or firms that will be responsible for configuration of the automation to the geometry and production schedule of the laboratory must be recruited and trained. Although industrial automation schemes have been developed to solve many of these problems, experience in using these approaches in the very different operating environment of a clinical laboratory is insufficient.

The reader is referred to the CLSI standard AUTO03-A2, which is described in the following section and in particular to the functional control model, which describes the relationships

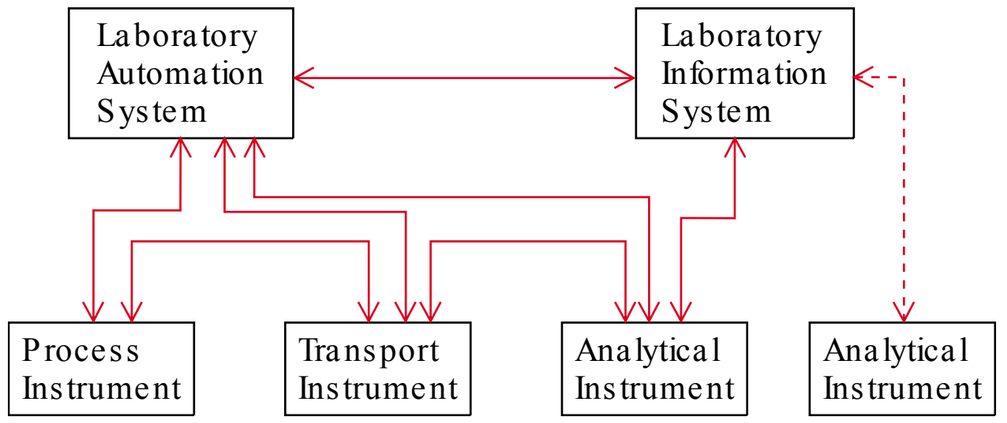

Figure 16-8 Functional Control Model of CLSI AUTO03-A Standard. The solid lines and arrows depict logical information flows supported by the standard. The dotted lines and arrows show logical information flows permitted, but not supported, by the standard. (Clinical and Laboratory Standards Institute. Laboratory automation: communications with automated clinical laboratory systems, instruments, devices, and information systems. CLSI Approved standard AUTO03-A2. 2nd edition. Wayne, PA: Clinical and Laboratory Standards Institute, 2009. Figure reproduced with permission of CLSI.)

between the LIS, the Laboratory Automation System (LAS), and various devices. In this model, and throughout the series of CLSI automation standards,[5-7] the term LAS represents the computer system that controls the automation system, not the actual automation hardware. Most often, it is the LAS that provides the requisite process control software to support automation. The functional control model, which is depicted in Figure 16-8, supports analytical instruments that may be physically attached to the automation system and analyzers that may not be attached but are still interfaced to the LIS. This model does not give dominance to the LIS or the LAS but rather allows essential information flows in either direction to make the most efficient use of the strengths of each system.

Device Integration

One objective of developing an integrated laboratory is to link laboratory instruments and devices into an automated system to maximize the number of functions automated. Automatic specimen introduction requires the development of mechanical interfaces between each laboratory analyzer and devices such as (1) conveyor belts, (2) mobile robots, or (3) robot arms. Enhancements to electronic interfaces for laboratory instruments are necessary to allow (1) remote computer control of front-panel functions, (2) notification of instrument status information, and (3) coordination of the distribution of specimens between instruments. Most existing LIS interfaces with laboratory analyzers provide only the ability to download accession numbers and the tests requested on each specimen and to upload the results generated by the analyzer.

Process Controllers and Software

Process controllers provide computer integration of the many decision-making tasks that occur in the daily activity of a laboratory. Consequently, process control software is needed to coordinate the overall activities of the laboratory. To integrate the various devices in the laboratory, communications with a master controller device need to be established. In addition, communication is needed between (1) the LIS computer,

(2) the LAS computer (that provides process control), (3) laboratory analyzers, and (4) specimen conveyor and specimen manipulation devices, such as automated centrifuges, aliquoters, decappers, etc. The distribution of tasks must be carefully specified when such a communications network is developed.

Other Areas of Automation

In addition to the automated devices described previously, a variety of instruments and processes have been automated and used in the clinical laboratory. They include (1) urine analyzers, (2) cell counters, (3) nucleic acid analyzers, (4) microtiter plate systems, (5) automated pipetting stations, and (6) point-of-care testing analyzers.

Urine Analyzers

Many of the same analytical principles are used for the quantification of serum and urine constituents. It is more difficult, however, to automate testing of urine than serum because of the broad range of concentrations of many urine constituents. This requires a low limit of detection to measure low concentrations, as well as expanded linearity to permit measurement of high concentrations without dilution. This requirement, together with the relatively low demand for urine tests compared with that for serum tests, has restricted the development of analyzers designed specifically for urine constituents. Nevertheless, selected urine analyses are performed on the available analyzers in some institutions.[9]

Cell Counters

Analyzers that perform a complete blood count have been automated through the use of the "Coulter principle," which is based on (1) cell conductivity, (2) light scatter, and (3) flow cytometry. Individual blood cells are analyzed by application of one or more of these techniques. The Coulter principle is based on changes in electrical impedance produced by nonconductive particles suspended in an electrolyte as they pass through a small aperture between electrodes. In the sensing zone of the aperture, the volume of electrolyte displaced by the particle (cell) is measured as a change in voltage that is proportional to the volume of the particle. With careful control of the quantity of electrolyte drawn through the aperture, several thousand particles per second are counted and sized individually. Cells identified by their size include (1) red blood cells, (2) white blood cells, and (3) platelets. Alternating current in the radio frequency range short-circuits the bipolar lipid layer of the cell membrane, allowing energy to penetrate the cell. Information about intracellular structure, including chemical composition and nuclear volume, is collected by this technique.

Flow cytometry typically uses cells stained with a supravital or fluorescent dye that travel in suspension one by one past a laser light source (unstained cells also are measured.) Scattered light and emitted light are collected in front of the light source and at right angles, respectively. Information derived through measurement of light scatter when a cell is struck by the laser beam is then used to estimate (1) cell shape, (2) cell size, (3) cellular granularity, (4) nuclear lobularity, and (5) cell surface structure. Some cell counters classify white cells using the Coulter principle, cell conductivity, and light scattering of unstained cells to differentiate cell types, whereas other cell counters use multiple flow cytometry channels or a combination of (1) flow cytometry, (2) cell conductivity, and (3) light scattering.

Nucleic Acid Analyzers

Automation of the analysis of nucleic acids developed rapidly as an outgrowth of the Human Genome Project.[12] Several manufacturers have developed automation to assist with the isolation of nucleic acids and with analysis of nucleic acids using several amplification schemes and nucleic acid sequencing. Many of these techniques have been miniaturized using chip technology.[4,14] Microfluidic chip-based approaches hold promise for reducing analysis time and reagent consumption, as well as for reducing the costs associated with robotics and laboratory apparatus needed for the macroscale approaches.

Microtiter Plate Systems

Microtiter plate systems are commonly used in immunoassays and nucleic acid analyses. As used for enzyme-linked immunosorbent assays (ELISAs), microtiter plates usually are made of polystyrene and consist of 48 or 96 wells coated with antibody specific for the antigen of interest. After incubation of serum in the microtiter plate well, the well is washed to remove unbound antigen, and a second antibody with conjugated indicator enzyme is added. After a second incubation period, the well is washed to remove the unbound conjugate. An absorbance-producing product is developed by the addition of enzyme substrate, and the reaction is terminated at a specific time. With the development of automated pipetting stations, the liquid handling steps required for microtiter plate assays have been fully automated to make microtiter plate assays a viable technology for carrying out large numbers of immunoassays. Automated pipetting stations have a cartesian robot with a pipette fixed to the end of a probe that moves about a rectangular space. The probe is capable of moving in the X, Y, and Z axes. Liquids may be aspirated and dispensed in any location within the rectangular space.

Automated Pipetting Stations

Pipetting stations may be used to automate an analytical procedure for which an automated analyzer does not exist or cannot be cost justified. Most pipetting robots (1) are relatively easy to program, (2) rarely malfunction, and (3) are capable of delivering aliquots of liquids with extreme precision and accuracy. Multiple-channel pipetting robots allow parallel processing of specimens with 8- or 12-channel probes to handle microtiter plates.

POCT Analyzers

Point-of-care testing (POCT) is a rapidly growing component of laboratory testing.[8] Many of the analyzers developed for this type of testing have been automated (see Chapter 17).

Review Questions

1. Which type of specimen label has resulted in a reduction in preanalytical specimen identification errors and is used extensively in automated specimen identification?
   a. Social Security numbers stamped on all individual specimen containers
   b. Hospital identification numbers written on tubes of blood
   c. Labels containing bar codes that are unique identifiers
   d. Medical accounting numbers written on the lids of all containers
2. The transport of a quantity of analyte or reagent from one specimen reaction into a subsequent one is referred to as:
   a. carry-over.
   b. misdelivery.
   c. indiscrete handling.
   d. batching.
3. A type of analysis in which each specimen is subjected to multiple analytical processes so that a set of test results is obtained on a single specimen is:
   a. batch analysis.
   b. discrete analysis.
   c. sequential analysis.
   d. multiple-channel analysis.
4. In an automated chemistry analyzer, one measurement technique that is commonly used measures diffuse reflected light. This measurement approach is called:
   a. fluorometry.
   b. reflectance photometry.
   c. chemiluminescence.
   d. potentiometry.
5. One serious issue with the use of accelerating/decelerating pneumatic tube systems to deliver specimens to the laboratory is the occurrence of:
   a. hemolysis.
   b. specimen volume loss.
   c. specimen breakage.
   d. clot formation.
6. The initial step in the evaluation of laboratory automation is:
   a. assessment of the integrative ability of several pieces of instrumentation.
   b. determination of which device will be the master controller.
   c. mapping of laboratory work flow.
   d. determining the correct type of process controller required.
7. The most widely used automated type of electrochemical system incorporated into a chemistry analyzer involves:
   a. fluorometry.
   b. nephelometry.
   c. chemiluminescence.
   d. ion-selective electrodes.
8. Elimination or reduction of specimen preparation time occurs when which of the following specimen types is used in a chemistry assay system?
   a. Serum
   b. Whole blood
   c. Urine
   d. Plasma
9. One of the most important benefits of the use of automated systems in a laboratory is the:
   a. reduction of result variability and analysis errors.
   b. need for specialized training for users of a system.
   c. reduction of the workforce required.
   d. ability of the system to choose which type of analysis will be done without user input.
10. The process whereby an analytical instrument performs many tests with only minimal involvement of an analyst is referred to as:
    a. batch analysis.
    b. discrete analysis
    c. automation.
    d. throughput rate.

CHAPTER

17 Point-of-Care Instrumentation

Christopher P. Price, Ph.D., F.R.C.Path., and Andrew St. John, Ph.D., F.F.Sc. (R.C.P.A.)

Objectives

1. Define the following terms:
   - Biosensor
   - Chemosensor
   - Clinical Laboratory Improvement Amendments of 1988 (CLIA-88)
   - Connectivity
   - Dipsticks
   - Immunostrip (immunosensor)
   - Informatics
   - Point-of-care testing
   - Point-of-care testing (POCT)
   - Operator interface
   - Reaction cell
   - Recognition element
   - Sensor
   - Transducer
   - Transducing element
   - Waived test
2. List five advantages of the use of point-of-care testing (POCT).
3. List five requirements of point-of-care testing devices.
4. List the eight key components of a point-of-care testing device.
5. Compare the following in vitro point-of-care testing devices, including design, reaction principles used with each type, examples of each device, result interpretation, and clinical applications:
   - Single-use qualitative strip or cartridge and/or strip
   - Single-use quantitative cartridge or strip tests with a monitoring device
   - Multiple-use cartridge
   - Bench top systems
6. Describe in vivo, ex vivo, and minimally invasive point-of-care-testing devices, including analytical principles, and provide a clinical application of each.
7. Given an analyte, draw an example of an immunostrip format used in a point-of-care testing device and label the components.
8. State the need for and benefits of standardized connectivity for point-of-care testing devices linked to a laboratory information system; state the purpose of the Connectivity Industry Consortium.
9. List and explain the eight steps involved in implementing and managing a point-of-care testing service; list the elements of a training program necessary for POCT personnel.
10. List three quality control methods used with a point-of-care test; state the issues that involve performance of conventional quality control methods on certain POCT devices.

Key Words and Definitions

Biosensor A sensor design in a point-of-care testing device that has a biological or biochemical component as the recognition element.

Chemosensor A sensor design in a point-of-care testing device that detects intrinsic properties of an analyte or that is combined with a transducing element to detect signals produced by the analyte binding to some indicator.

Clinical Laboratory Improvement Amendments of 1988 (CLIA-88) United States federal regulatory standards that apply to all clinical laboratory testing performed on humans in the United States, except clinical trials and basic research.

Connectivity In a clinical laboratory, the linking of an analytical device via an electronic interface to a laboratory information system computer.

Dipsticks Single- or multi-pad measurement devices that quantify from one to several analytes.

Immunostrip (immunosensor) A point-of-care device in which the recognition element is an antibody that binds to the analyte; the binding event is typically detected by an optical mechanism.

Informatics In a clinical sense, the design, management, and study of systems that store and communicate medical information; in the clinical laboratory, this refers to the communication and management of information related to laboratory testing and test interpretation.

Operator interface The part of a device that the operator is required to use for the device to work (e.g., switch on a reader, entry of a patient or sample identification, calibration of the device).

Point-of-care testing (POCT) A mode of testing in which the analysis is performed at a site closer to the patient than the conventional laboratory.

Reaction cell The location in a point-of-care testing device where the analytical reaction takes place.

Recognition element A chemosensor with a transducing element that recognizes the analyte to be measured and produces a signal.

Sensor A component of a point-of-care testing device that identifies a signal produced by the presence of an analyte.

Transducing element A component of a point-of-care testing device such as a chemical indicator or a binding molecule that recognizes the analyte of interest and produces an electrical or optical signal.

Waived test A test that (1) employs methodologies that are so simple and accurate as to render the likelihood of erroneous results negligible; (2) poses no reasonable risk of harm to the patient if the test is performed incorrectly and (3) has been cleared by the Food and Drug Administration for home use. (http://www.aafp.org/; accessed August 13, 2013)

Point-of-care testing (POCT) is a method of clinical laboratory testing in which the analysis is performed at the site close to where healthcare is provided to the patient. Other terms used to describe POCT have included (1) "bed side," (2) "near patient," (3) "physician's office," (4) "extra-laboratory," (5) "decentralized,"(6) "off site," (7) "ancillary," (8) "alternative site" and (9) "unit-use" testing. POCT is performed in a number of different clinical settings (Box 17-1).[10-12] Its main advantages are (1) reduced turnaround time (TAT), (2) reduced risk of error in the testing process (e.g., order being lost, sample being lost, result being lost), (3) reduced risk of a disconnection between the process of testing and clinical decision making (Figure 17-1), and (4) improved health outcomes (Box 17-2).

The following sections of this chapter will describe the technology available for POCT and the organizational factors that complement the technology in delivering reliable healthcare.

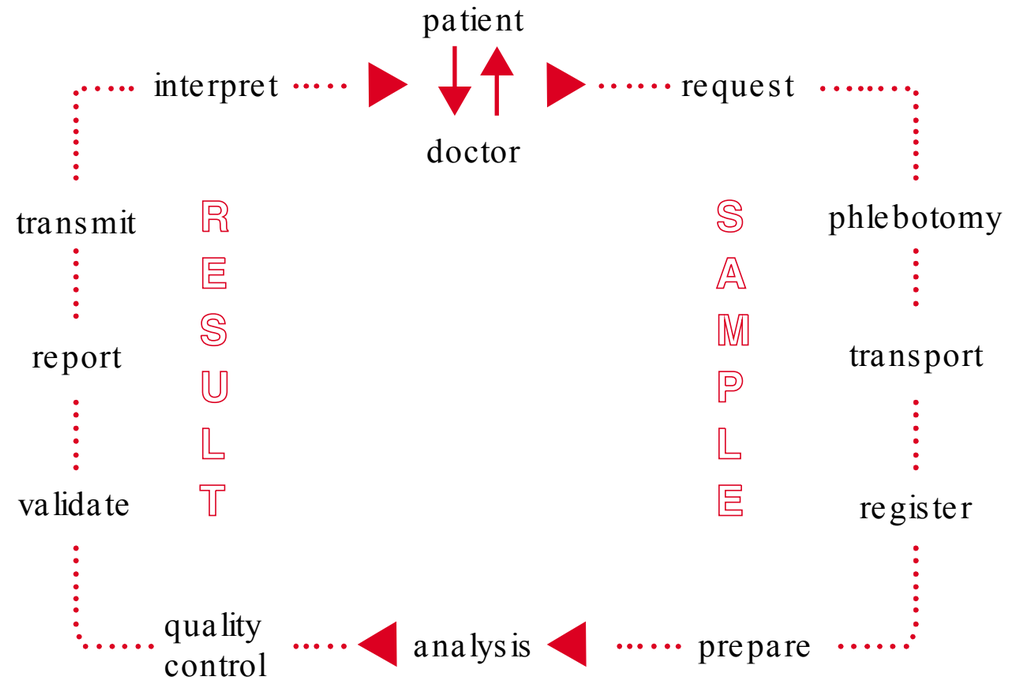

Figure 17-1 A schematic representation of the key steps in requesting, delivering, and using a diagnostic test result.

Analytical and Technological Considerations

Miniaturization has been a long-term trend in clinical diagnostics instrumentation that has resulted in the evolution of POCT devices that measure (1) electrolytes, (2) blood gases, and (3) other analytes. It has led to the development of dry, stable reagents in disposable unit-dose devices. Although the throughput of tests for these devices is low, the time required to produce the results is usually short. In addition, these devices are often small enough to be portable, further enhancing the possibility of "bringing tests closer to the patient."

Topics to be discussed in this section include (1) instrument requirements, (2) instrument and **operator interface** design, (3) examples of POCT devices, and (4) the role of **informatics.** Readers requiring additional information are referred to more comprehensive texts[8,9,11,12] or to the vendors of POCT devices.

Requirements

Characteristics and requirements of POCT devices are listed in Box 17-3.

BOX 17-1 Environments for Which Point-of-Care Testing Might Be Employed

Primary Care
Home
Community pharmacist
Health center (general practice, primary care)
Retail clinic
Workplace clinic
Physician's office and community clinic
Diagnostic and treatment center
Paramedical support vehicle (ambulance, helicopter, aircraft)

Secondary and Tertiary Care
Emergency room
Admissions unit
Ambulatory diagnostic and treatment center
Operating room
Intensive care unit
Ward
Outpatient clinic

BOX 17-2 Advantages of Point-of-Care Testing

Reduced turnaround time (TAT) of test results
Improved patient management
Reduction in the administrative work associated with test requesting
Minimization of delays during sample collection and sample requirement(s)
Reduction in the time delay resulting from transport of the sample to the testing laboratory
Reduction in the time delay resulting from having to log in (register) the sample
Reduction in the time delay that results from entry of a sample into a complex testing facility
Reduction in process errors
Opportunity for more informed discussion with the patient

BOX 17-3 Characteristics/Requirements of a Point-of-Care Testing Analyzer

Reduced errors and enhanced patient care
Results produced in a rapid and timely manner (typically within a minute)
Portable instruments with consumable reagent cartridges
Capability of performing direct specimen analysis on whole blood and urine (nonprocessed samples)
Simple operating procedures (typically a one- or two-step operating protocol)
Flexible test menus
Quantitative results with accuracy and precision comparable with those of the central laboratory
Built-in/integrated calibration and quality control
Ambient storage temperature for reagents
Results provided as hard copy, stored, and available for transmission
Low instrument cost
Service by exchange
Built-in regulatory record keeping

Modified from Maclin E, Mahoney WC. Point-of-care testing technology. J Clin Ligand Assay 1995;18:21-33.

TABLE 17-1 Classification of Types of Point-of-Care Testing Instruments or Devices

Type of Technology	Analytical Principle	Analytes
Single-use, qualitative or semi-quantitative cartridge/strip tests	Reflectance	Urine and blood chemistry
	Lateral-flow or flow-through immunoassays	Infectious disease agents, cardiac markers, hCG
Single-use quantitative cartridge/strip tests with a reader device	Reflectance	Glucose
	Electrochemistry	Glucose
	Reflectance	Blood chemistry
	Light scattering/optical motion	Coagulation
	Lateral-flow, flow-through, or solid phase immunoassays	Cardiac markers, drugs, CRP, allergy and fertility tests
	Immunoturbidimetry	HbA_{1c}, urine albumin
	Spectrophotometry	Blood chemistry
	Electrochemistry	pH, blood gases, electrolytes, metabolites
	Fluorescence, electrochemistry with PCR	Infectious agents
Multiple-use quantitative cartridge/bench top devices	Electrochemistry	pH, blood gases, electrolytes, metabolites
	Fluorescence	pH, blood gases, electrolytes, metabolites
	Multiwavelength spectrophotometry	Hemoglobin species, bilirubin
	Time-resolved fluorescence	Cardiac markers, drugs, CRP
	Electrical impedance	Complete blood count

CRP, C-reactive protein; HbA_{1c}, glycosylated hemoglobin; hCG, human chorionic gonadotropin; PCR, polymerase chain reaction.

Design

Great diversity is evident in the devices used for POCT (Table 17-1). The breadth of technology encompasses a large range of analytes, and many devices use the same analytical principles as those found in conventional laboratory analysers. The key components of POCT device design include (1) the operator interface, (2) bar code identification systems, (3) sample and reagent delivery mechanisms, (4) the **reaction cell**, (5) **sensors**, (6) control and communications systems, (7) data management and storage, and (8) manufacturing requirements. The main objectives of the design are to (1) enable the required reaction to take place that facilitates recognition of the analyte of interest, (2) ensure reliable performance of the device over a specified period of time, and (3) minimize the risk of error associated with use of the device—as well as within a wide range of environmental settings (e.g., temperature, humidity).

Operator Interface

The operator or user interface for a POCT device should (1) require minimal operator interaction, (2) guide the user through the operation, (3) indicate whether any key steps have not been completed correctly, and (4) identify the operator, the patient, and the test to be measured. Advances in information technology and consumer electronics have had a major impact in this area. Other forms of user interface include (1) keypads, (2) bar code readers, and (3) possibly a printer. In some devices, the display is the only means of showing the result, but with the development of mobile telephone and computing technology, displays are rapidly becoming more sophisticated, with touch screens used for many different functions.

Bar Code Identification Systems

Many POCT devices incorporate linear and two dimensional bar codes for a number of purposes. These include (1) identifying the reagent package to the system, (2) incorporating factory calibration data, and (3) programming the instrument to process a particular test or group of tests. In addition to the linear bar codes, two dimensional codes are also used as they have the capability of storing more information than the linear ones. Such codes consist of black square dots arranged in a square grid on a white background, which is read by an imaging device and processed. Information is then extracted from patterns present in both horizontal and vertical components of the image. Some POCT devices use magnetic strips for similar purposes. Other functions of a bar code reader that are of growing importance are to identify both the operator and the patient sample to the system. This provides traceability to the person who performed the test, and it links the results to the correct patient. The latter has assumed increasing importance as part of the focus on patient safety.

Sample

Sample access and delivery of the sample to the (1) actual sensing component of the strip, (2) cassette, (3) cartridge, or (4) fluidic cell are key interactions of the user with the device; in some cases, removal of the sample may also require user intervention. Ideally, after the sample has been added, there should be no further need for operator intervention,[14] and devices are now available that minimize the degree of interaction to the point where a closed tube has simply to be placed in a holder and the instrument automatically performs all other functions.[11]

Reaction Cell

The design of the location where the analytical reaction takes place varies from a simple porous pad to a cell or surface within a chamber. However, to simplify the user interface, it is often necessary to design complexity into the reaction chamber. Advances in fluidics and fabricating techniques have been basic to the development of POCT devices.[7] As analytical reactions have increased in complexity, more reaction cells/zones have been added. Thus in the case of molecular tests, different reaction zones may be required for DNA extraction, the amplification reaction, and probe detection; in these situations, it may be necessary to remove some of the reaction constituents downstream from each zone before the next reaction zone is reached. Reaction temperature requirements may be different for each reaction zone.

Sensors

Much of the focus on POCT devices has involved the advances in sensor design.[16] Various sensor designs have been developed, and both **chemosensors** and **biosensors** may be included (Figure 17-2). Examples of chemosensors include simple ones where the analyte has an intrinsic property, such as fluorescence, that is detected directly with a fluorometer. A popular version of chemosensors includes the addition of a **transducing element** such as a chemical indicator or a binding molecule that recognizes the analyte to be measured and produces a signal, usually electrical or optical. A biosensor has a biological or biochemical component as the **recognition element**. Enzymes are the most common biological element used, followed by antibodies; transduction typically occurs via an optical or electrical signal, although the use of antibody and nucleotide recognition elements is increasing.

Control and Communications Systems

Even the smallest device has a control subsystem that coordinates all the other systems and ensures that all required processes for an analysis take place in the correct order. Operations that require control include (1) insertion or removal of the strip, cartridge, cassette, or reagent; (2) temperature control; (3) sample injection or aspiration; (4) sample detection; (5) reagent addition—especially in a fluid-based system; (6) mixing; (7) timing of the detection process; and (8) waste removal. Fluid movement is often accomplished by mechanical means through pumps or centrifugation, and by fluidic properties, such as surface tension; the latter is often a critical element in the design of simple strip tests and microfabricated systems.[7]

Data Management and Storage

Information technology (IT) is also crucial to POCT devices. IT includes data management of calibration curve data, as well as quality control (QC) limits and patient results. With some systems, data transfer and management take place when the meter or the reader is linked to a small bench top device called a docking station. These and other devices include communication protocols that allow data to be transferred to other data management systems, to electronic medical records, and to other mobile computing devices.[4,5,15]

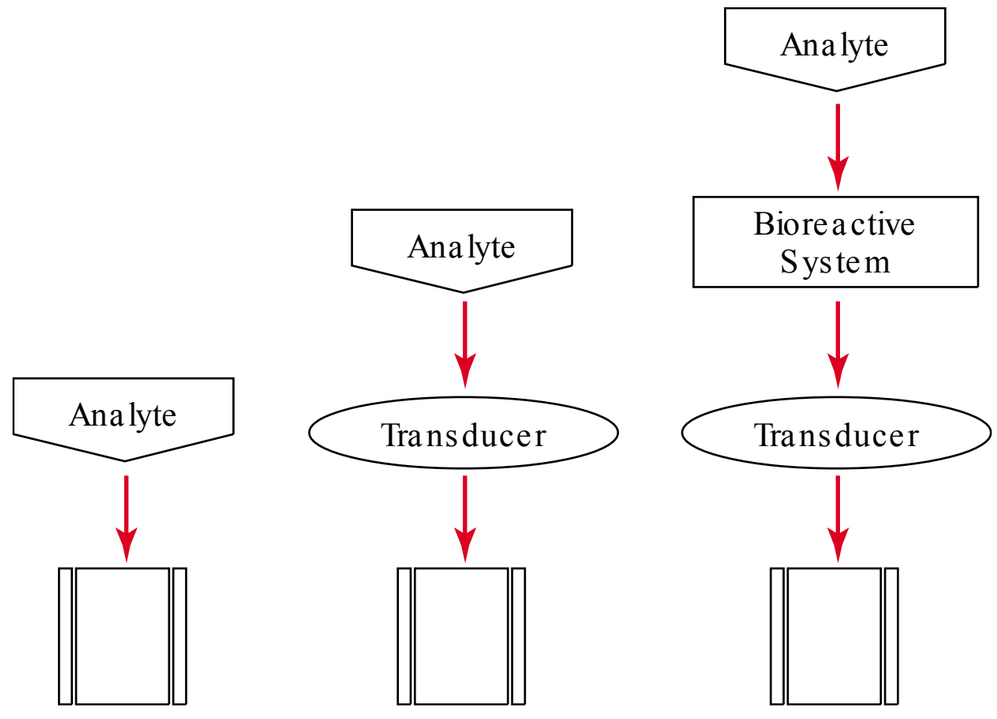

Figure 17-2 Diagram showing the key types of sensor technology used in point-of-care testing (POCT) instruments.

Manufacturing of POCT Devices

Because many POCT devices are used only once and then are discarded, the reproducibility of manufacture is a key requirement, so that consistent performance extends across a large number of strips or devices. The manufacturing process includes steps that are taken to ensure that the devices are reproducible and that they remain stable during transit and storage for a stated period of time.[1]

Examples of POCT Devices

POCT devices are classified as (1) in vitro, (2) in vivo, (3) ex vivo, or (4) minimally invasive.

In Vitro Devices

The diversity of in vitro POCT technology and the range of analytes make it difficult to devise a simple classification that avoids overlap between various technologies. For the purposes of highlighting key or novel POCT technologies, the following discussion classifies various devices largely according to size and complexity: (1) single-use qualitative or semi-quantitative cartridge and/or strip tests, (2) single-use semi-quantitative or fully quantitative cartridge and/or strip tests with a monitoring device, and (3) multiple-use cartridge and bench top systems.

Single-use Qualitative Strip or Cartridge and/or Strip Devices

Many devices fall into this category, including (1) single- or multi-pad urine tests (**dipsticks**) that are read visually; (2) more complex strips that use light reflectance for measurement; and (3) fabricated cassettes or cartridges that incorporate techniques such as immunochromatography and are used as immunosensors.

Dipsticks. Dipsticks are single- or multi-pad measurement devices that are used to quantify up to 10 different urine analytes using reflectance technology.[11] These devices are relatively simple in construction and are composed of a pad of

porous material, such as cellulose, that is impregnated with reagent and then dried.[19]

Complex Strips. More complex pads are composed of several layers, the uppermost of which is a semi-permeable membrane that prevents red cells from entering the matrix. With these devices, a critical operator factor is the need to cover the whole pad with the sample. In addition, because the reactions often do not proceed to completion, it is necessary to time the period between placing the sample on the pad and comparing the resulting color with a color chart. Development of these single-stick devices involves the inclusion of two pads, which are used for measurement of (1) different concentrations of the same analyte, such as hemoglobin and glucose[11,19] and (2) both albumin and creatinine (semi-quantitative) to obtain an albumin/creatinine ratio.[11] A chromatographic device has also been developed for the quantitative measurement of cholesterol, which does not require the use of any instrumentation.[11] Table 17-2 lists some of the tests performed by single- or multi-pad dipsticks and the chemistry used for the analysis.

TABLE 17-2 Examples of Single or Multi-pad Stick Tests

Test	Sample	Chemistry
Acetaminophen	Whole blood	Acyl dehydrogenase
Alanine aminotransferase	Whole blood	Alanine/glutamate
Albumin	Whole blood, urine	Dye binding
Cholesterol	Whole blood	Cholesterol oxidase
Creatinine	Whole blood, urine	Copper complexation
Glucose	Whole blood	Glucose oxidase
Lactate	Whole blood	Lactate dehydrogenase
Uric acid	Whole blood	Uricase
Alcohol	Urine	Alcohol dehydrogenase
Bilirubin	Urine	2,4-Dichloroaniline
Hemoglobin	Urine	Peroxidase activity
Leukocyte esterase	Urine	Pyrrole amino ester hydrolysis
Ketones	Urine	Sodium nitroprusside reaction
Nitrite	Urine	p-Arsanilic acid reaction
pH	Urine	Double indicator principle
Protein	Urine	Protein error of indicators
Specific gravity	Urine	Polyacid pH change
Urobilinogen	Urine	Ehrlich's reaction

Immunostrips. Immunostrips are biosensors in which the recognition agent is an antibody that binds to the analyte. Detection of the binding event or signal transducer is usually accomplished via an optical mechanism, either reflectance or fluorescence spectrophotometry. Immunosensors usually use solid phase technologies in conjunction with (1) flow-through, (2) lateral-flow, or (3) immunochromatography processes. In the flow-through format, a heterogeneous immunoassay takes place in a porous matrix cell that acts as the solid phase. In lateral flow, the separation stage takes place as the sample passes along the porous matrix. [20]

A typical immunoassay format is seen in a flow-through device that has an antibody covalently coupled to the surface of a porous matrix. When the patient sample is added to the matrix, the analyte of interest binds to the antibody. Addition of a second labeled antibody forms a sandwich and traps the label at the position of the first antibody.[12] If the label consists of gold sol particles or colored latex, it is directly visualized or quantified by reflectance spectrophotometry in a separate reader. Another important feature of this type of technology is the incorporation of a built-in quality monitor that indicates positive if all reagents have been stored and the device is operated correctly. In all these different formats, uniform and predictable flow of the sample through or along the solid phase matrix is a major determinant of the reproducibility of the technique. Therefore the choice of matrix and how it interacts with the sample are of particular importance, and advances in the understanding of solid phase and surface chemistry technology have made a major contribution to the development of immunosensors.[11] An example of this technology is shown in Figure 17-3. In this device, the blood sample is added and first flows through a glass fiber fleece, which separates plasma

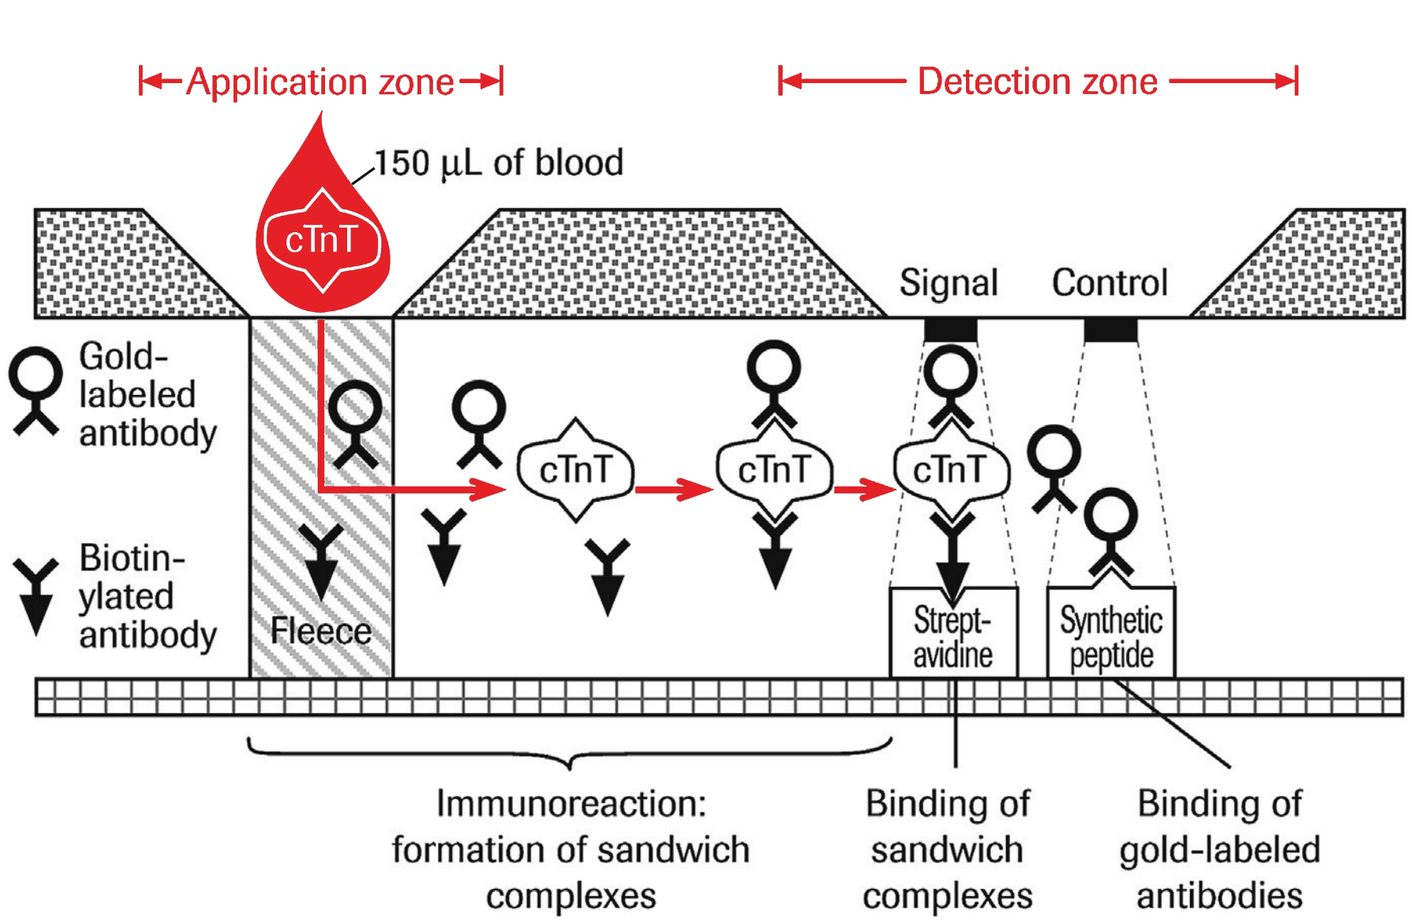

Figure 17-3 Schematic diagram of a lateral-flow immunoassay for troponin T. (Courtesy Roche Diagnostics, Mannheim, Germany.)

from whole blood. Simultaneously, two monoclonal antihuman cardiac troponin T (cTnT) antibodies, one conjugated to biotin and one labeled with gold particles, bind to the troponin T in the sample. The antibody/troponin complex then flows in a lateral direction along the cellulose nitrate test strip until it reaches the capture zone, which contains streptavidin bound to a solid phase. The biotin in the antibody/troponin complex binds to the streptavidin and immobilizes the complex. The complex is then visualized as a purple band by the gold particles attached to one of the antibodies. The unreacted gold-labeled antibody moves farther down the strip, where it is captured by a zone containing a synthetic peptide consisting of the epitope of human cTnT and is visualized as a separate but similar colored band. The presence of this second band serves as an important quality indicator because it shows that the sample has flowed along the test strip and the device has performed correctly.

Single-use Quantitative Cartridge and Strip Tests With a Monitoring Device

The availability of small, compact detectors is a result of advances in modern electronics and miniaturization. An integral part of many of these instruments is a charge-coupled device (CCD) camera that is a multichannel light detector, similar to a photomultiplier tube in a spectrophotometer, but detects much lower levels of light. For example, the Roche Cardiac Reader contains a CCD that quantitates separate lateral-flow immunoassay strips for measurement of (1) troponin T, (2) myoglobin, and (3) d-dimer.

Glucose Measurement. Clinically, POCT is most frequently used to measure glucose. These devices are biosensors because they all use an enzyme such as (1) glucose oxidase (GO), (2) hexokinase (HK), or (3) glucose dehydrogenase (GDH) as the recognition agent with photometric (reflectance) and electrochemical detection.

In general, all modern glucose strips are a form of what is called thick-film technology in that the film is composed of several layers, each having a specific function. When blood is added to a strip, both water and glucose pass into the film or analytical layer; for some photometric systems, erythrocytes must be excluded. These processes are achieved by what is called the separating layer that contains various components, including (1) glass fibers, (2) fleeces, (3) membranes, and (4) special latex formulations. In photometric systems, a spreading layer is important for the fast homogeneous distribution of the sample, whereas electrochemical strips use capillary fill systems. The support layer is usually a thin plastic material that in the case of reflectance-based strips may also have reflective properties. Additional reflectance properties have been achieved through inclusion of substances such as (1) titanium oxide, (2) barium sulfate, and (3) zinc oxide.

With systems that measure reflectance, the relationship between reflectance and the glucose concentration is described by the Kubelka-Munk equation:

$$C\alpha\frac{K}{S}=\frac{(1-R)^2}{2R}$$

where C is the analyte concentration, K is the absorption coefficient, S is the scattering coefficient, and R is the percent of reflectance. In practice, glucose strips are produced in large batches, and, after extensive quality assurance procedures, each batch is given a code that is stored in a magnetic strip on the underside of each test strip. This code describes the performance of the batch, including the calibrating relationship between the photometric or electrochemical signal and the concentration of glucose. In current practice, strips that do not require coding have become more commonplace.

Since their introduction, a steady stream of innovation in the development of glucose meters has been seen, with the goal of making the devices smaller and easier to use with less risk of error and reducing interference from other compounds and effects. The latter includes other (1) reducing substances, (2) low sample oxygen tension, and (3) extremes of hematocrit. A major step in this development process was the use of ferrocene and its derivatives as immobilized mediators in the construction of an electrochemical glucose strip (Figure 17-4). This is composed of an Ag-AgCl reference electrode and a carbon-based active electrode, both manufactured using screen printing technology, with ferrocene or its derivatives contained in the printing ink. The sample is placed in the sample observation window, and the hydrophilic layer serves to direct the sample over the reagent layer. The conversion of glucose is accompanied by reduction of ferrocene and the release of electrons (see Figure 17-4). The introduction of electrochemical technology has facilitated the production of smaller meters that use nonwipe strips. Such meters have less need (1) to clean the instrument optics, (2) produce test results more rapidly, and (3) require smaller sample volumes. Some of these features are now available with photometric glucose meters.

Other Applications. Several immunosensor-based POCT devices have been developed that are capable of measuring a panel of analytes, such as (1) cardiac markers, (2) allergy tests, (3) fertility tests, and (4) drugs of abuse. In these devices, a mixture of antibodies is immobilized at the origin, and complementary antibodies for the various analytes are immobilized

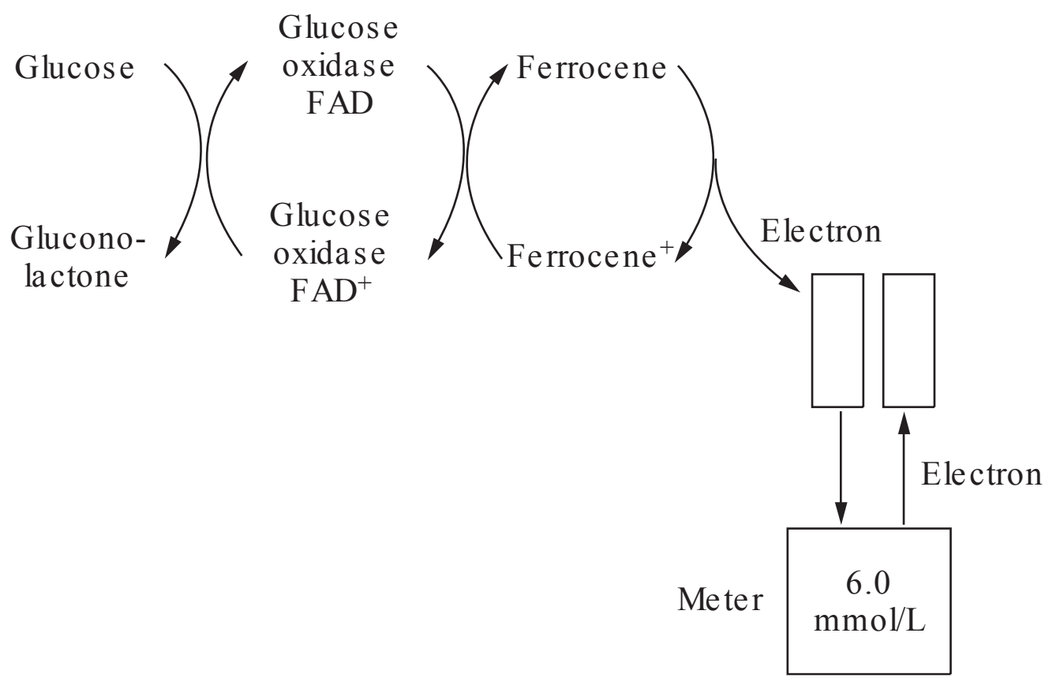

Figure 17-4 Schematic diagram of the reactions taking place in a MediSense electrochemical glucose strip. (Modifed from Henning TP, Cunningham TP. Biosensors for personal diabetes management. In: Ramsay G ed. Commercial biosensors. New York: John Wiley & Sons, 1998:3-46.)

at varying positions along the porous strip. In the case of drugs of abuse, devices are designed such that positive responses are obtained only when the concentration is above a precalibrated cutoff value.[11]

In contrast to the thick-film technology already described, single-use sensors have been constructed using thin-film technology, the most common commercial example being the i-STAT analyser (http://www.abbottpointofcare.com/; accessed August 13, 2013). This handheld blood gas device measures (1) electrolytes, (2) glucose, (3) creatinine, (4) certain coagulation parameters, and (5) cardiac markers. In thin-film sensors, electrodes are wafer structures constructed with thin metal oxide film using microfabrication techniques. The result consists of small, single-use cartridges containing an array of electrochemical sensors that operate in conjunction with a handheld analyzer. Because the sensor layer is very thin, blood permeates this layer quickly, and the sensor cartridge is used immediately after it is unwrapped from its packing. This provides an advantage over some thick-film sensors that require an equilibration or wet-up time before they are used to measure blood samples. A disadvantage of thin-film technology is that manufacturing costs are high because of the need for special clean air facilities. Thus more recently, technology to measure blood gases and related parameters has been devised using less costly smart card technology, where sensors and internal fluidics are incorporated into credit card–sized devices manufactured on a 35-mm tape-on-reel format. This technology is used in conjunction with a handheld analyzer that also has been used for immunoassay measurement.[11]

A number of single-use, quantitative POCT devices are available that employ a cassette or cartridge design rather than lateral-flow strips. One such device separates plasma from red cells, after which the plasma reacts with pads of dry reagents for analytes such as (1) glucose, (2) cholesterol, or (3) triglycerides. The resultant change in absorbance is then measured by a small photometer. Several cassette-based systems have been developed for measurement of hemoglobin. In one such system, (1) red cells are lysed in a minicuvet, (2) hemoglobin is converted to methemoglobin, and (3) methemoglobin is measured at 570 nm; turbidity is corrected for by an additional measurement at 880 nm.

Another type of cartridge design uses a light-scattering immunoassay to measure glycated hemoglobin, together with a photometric assay for total hemoglobin. The cartridge is a relatively complex structure that contains antigen-coated latex particles, antibodies to HbA_{1c}, and lysing reagents that are mixed after the sample is added. Measurement takes place when the cartridge is placed into a temperature-controlled reader, and the analytical performance is sufficient for quantitative monitoring of glycemic control. The size of the device allows it to be used in diabetes clinics, where it is also used for measurement of urinary albumin and creatinine.

POCT devices for monitoring anticoagulant therapy have also been developed for use in clinics or by the patient at home. Historically, early systems used magnets to detect the decrease in sample flow or movement that results from the clotting process, but this required careful timing and a large blood sample, while an alternative technology used optical sensors to monitor the decrease in sample speed as the clot forms. Speckle detection technology whereby an intensity pattern produced by the mutual interference of a set of wavefronts has also been used to measure (1) prothrombin time (PT), (2) activated partial thromboplastin time (APTT), and (3) activated clotting time (ACT). With this approach, the instrument contains an infrared light source that directs a coherent light beam onto the oscillating sample. Movement of red cells in the blood results in refraction of the light to produce an interference or "speckle" pattern that is recorded by the photodetector. This "speckle" pattern changes when the capillary flow slows as the sample clots. The time it takes for this to happen is a measure of the clotting time. Newer detection technologies that have been widely adopted for measurement of the international normalized ratio (INR) in the home and clinic use electrochemical measurements. With the Alere device (http://www.hemosenseinratio.com/; accessed August 13, 2013), clotting is detected by a change in impedance (Figure 17-5), and with a CoaguChek® XS system (www.Roche.com/; accessed August 13, 2013), a change in current is detected. Both devices incorporate built-in QC systems that are activated when a patient sample is placed on the strip.[11]

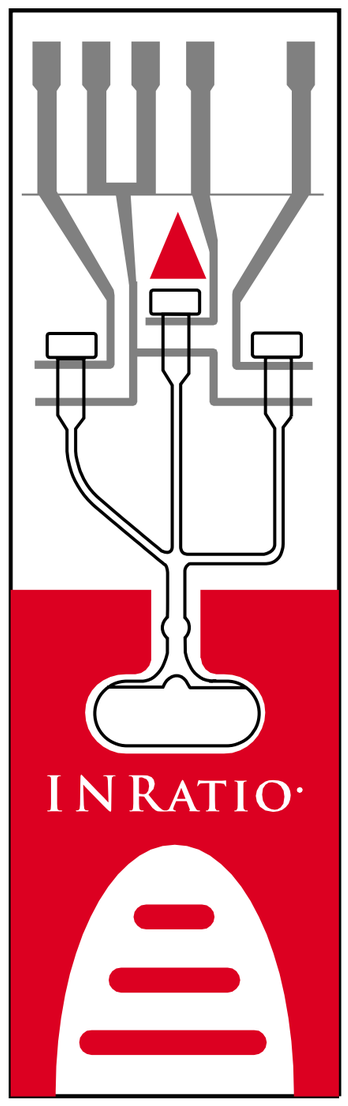

Figure 17-5 Alere INRatio® 2 PT/INR Test Strip. (Used with permission from Alere.)

It should be noted that the sizes of some of the single-use, cartridge-based systems are comparable with certain of the bench top systems. In addition, some of the multiple-use devices incorporate on-board centrifugation. Other small analyzers are used at point-of-care but require preliminary centrifugation of the sample.

Multiple-use Cartridge and Bench Top Systems

Many of the POCT devices in this category are used for critical care testing in locations such as (1) the intensive care unit, (2) the surgical suite, and (3) the emergency room (see Box 17-1). Some of these devices use thick-film sensors or electrodes in strips to measure (1) glucose, (2) lactate, (3) urea, (4) blood gases , and (5) electrolytes incorporating the same technology described previously, but differ in that the sensors are designed to be reusable. They are manufactured from thick films of paste and inks using screen printing techniques to produce individual or multiple sensors. The sensors have been incorporated with reagents and calibrators into a single cartridge or pack, which is placed in the body of a small to medium-sized portable critical care analyzer. Each pack contains reagents sufficient to measure a certain number of samples during a certain time period, after which it is relatively simple to replace.

Other key developments for devices include liquid calibration systems that use a combination of aqueous base solutions and conductance measurements to calibrate the pH and PCO_2 electrodes, with oxygen being calibrated with an oxygen-free solution and room air. In addition, automated QC packages are integrated into these analyzers to ensure that QC samples are analyzed at regular intervals. These comprise packs or bottles of QC material that are contained within the instrument and are sampled at predetermined intervals, with onboard software interpreting the results and generating alerts, if necessary. Such devices have the capability to be remotely monitored and programmed to respond to problems with instruments located long distances from the central laboratory.

Critical care POCT instruments are also available for measuring various hemoglobin species and for performing CO-oximetry determinations. The latter rely upon multiwavelength spectrophotometry, where light absorption by hemolyzed blood is measured at up to 60 or more wavelengths to determine the concentration of the five hemoglobin species. One manufacturer has extended multiwavelength spectrophotometry to measure bilirubin directly in whole blood.[11]

Bench top devices are also available to perform complete blood counts (CBCs) using analytical principles similar to those used with laboratory-based devices. In addition, single-use cartridge technology is now available to provide full white cell differentiation. Immunoassay measurements are now available in a compact device for use in clinics and similar locations. One such device uses dry-coated reagents and time-resolved fluorescence for detection. Results are produced within 20 minutes, and the assay menu includes (1) C-reactive protein (CRP), (2) human chorionic gonadotropin (hCG), and (3) cardiac markers.[11]

In Vivo, Ex Vivo, or Minimally Invasive and Noninvasive Devices

Although most POCT devices are used for in vitro applications, a smaller group is classified as (1) in vivo, (2) ex vivo, or (3) minimally invasive (Table 17-3). In vivo or continuous monitoring applications are those in which the sensing device is inserted into the bloodstream and is used to measure blood gases and glucose using optical or electrochemical technology. Electrochemical sensors are also used in an ex vivo application for the same parameters, the difference being that the sensors are actually external to the body but are present in a closed loop of blood that leaves the body and is then returned downstream from the sensing device. The major application for minimally invasive devices is primarily glucose, such as the Medtronic continuous glucose monitoring system (www.medtronicdiabetes.com/; accessed August 14, 2013), by which glucose measurements in interstitial fluid are transmitted back to a monitor linked to an insulin pump.[11]

TABLE 17-3 Types of Ex Vivo and Noninvasive Point-of-Care Testing Technology

Type of Technology	Analytical Principle	Analytes
In vivo	Optical fluorescence	pH, blood gases
	Electrochemistry	Subcutaneous glucose
Ex vivo	Optical fluorescence	pH, blood gases
	Electrochemistry	pH, blood gases, electrolytes, glucose
Noninvasive	Electrochemistry/iontophoresis	Transcutaneous glucose
	Multiwavelength spectrophotometry	Bilirubin

For noninvasive testing, several POCT devices are available for the transcutaneous measurement of bilirubin in newborn babies.[12]

Informatics and POCT

Most analytical devices used in clinical laboratories are directly linked or connected via an electronic interface to a laboratory information system (LIS). In this progression, many different informatic functions are used, including electronic transfer of data from the analyzers to the LIS and ultimately into a patient's electronic medical record. This provides healthcare professionals with (1) quick, (2) accurate, and (3) appropriate access to the patient's medical history and information.

Considerable effort has been expended to incorporate these informatic processes into POCT devices because of the vital importance of capturing analytical data in a patient's medical record to avoid the errors associated with manual transcription of data. Newer POCT devices have addressed this problem by incorporating the prerequisite hardware and software into their design, and in the last decade so-called **connectivity** standards have been introduced, which facilitate linking of devices to information management systems. Previously, interfacing was very difficult because of multiple proprietary interfaces, but through the efforts of the POCT industry and a Connectivity Industry Consortium (CIC), a set of seamless—"plug and play"—point-of-care communication standards have been developed and subsequently incorporated into a Clinical Laboratory and Standards Institute (CLSI) standard called POCT01-A2.[4] Adherence to these connectivity standards ensures that POCT devices meet critical user requirements, such as (1) bidirectionality,

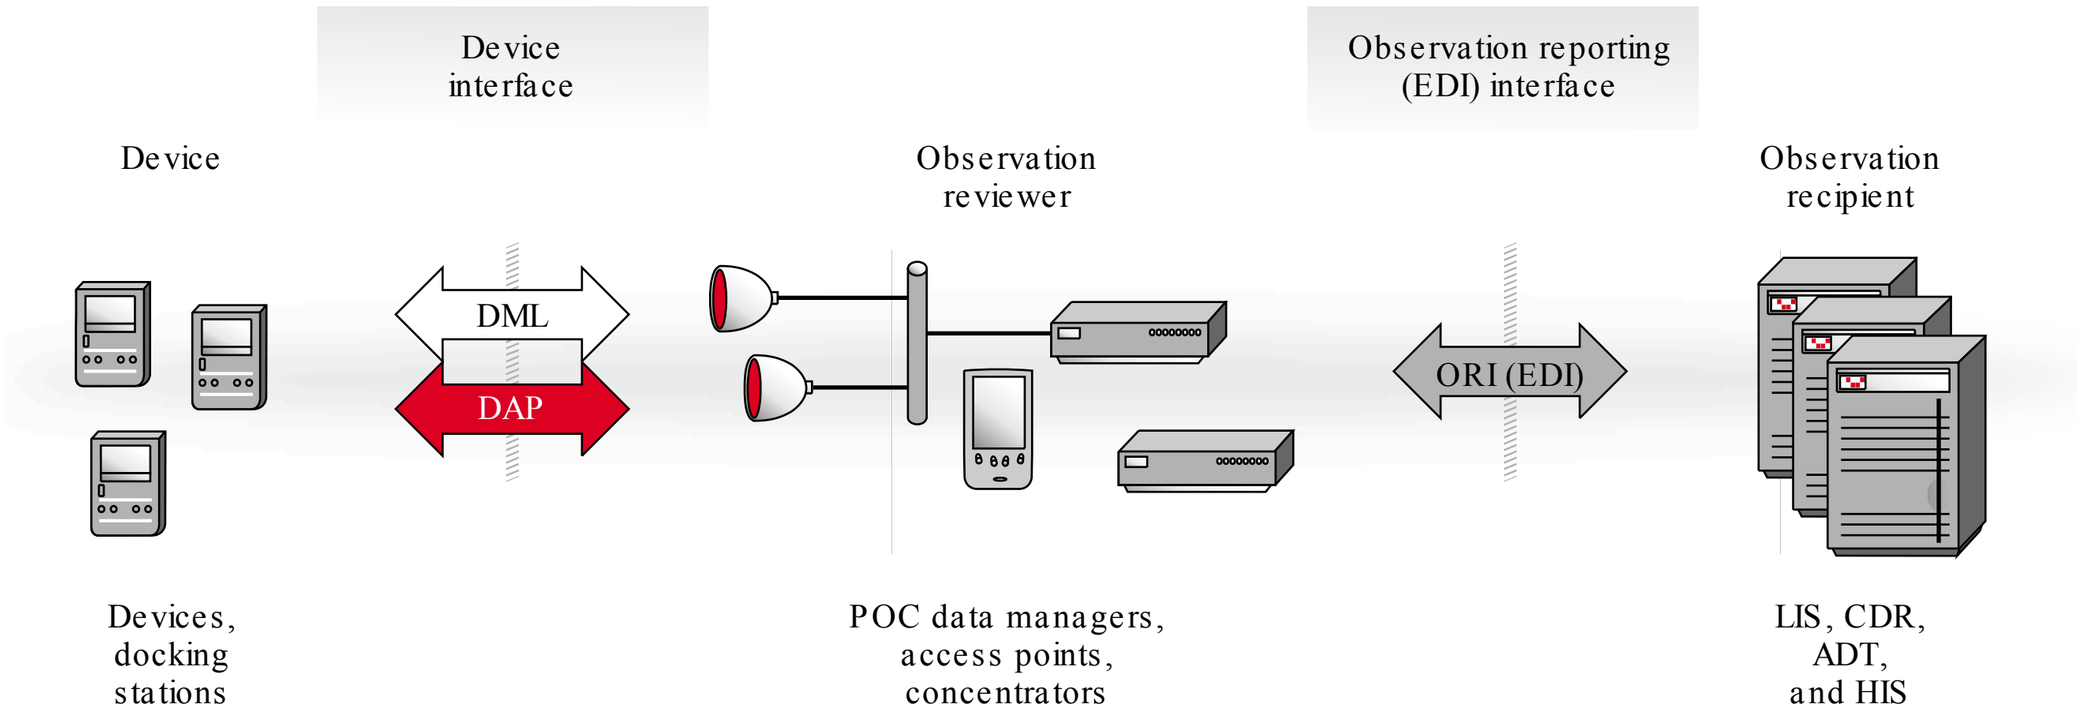

Figure 17-6 Schematic diagram of the interfaces between POCT devices and information systems. (Modifed from Clinical and Laboratory Standards Institute/NCCLS. Point-of-care connectivity: approved Standard CLSI . Approved standard POCT1-A2. Wayne, PA: Clinical and Laboratory Standards Institute, 2006.)

(2) device connection commonality, (3) commercial software intraoperability, (4) security, and (5) QC and/or regulatory compliance.

Description of Connectivity Standards

The CIC connectivity standards are represented simply as the two interfaces between the POCT devices and information systems (Figure 17-6). The device interface passes patient results and QC information between the POCT instrument and devices, such as (1) docking stations, (2) concentrators, (3) terminal servers, and (4) point-of-care data managers. The latter have to be linked to a variety of information systems via the observation reporting interface or the electronic data interface for transmission of ordering information and patient results.

Benefts of POCT Connectivity

Currently, one of the most important benefits of connectivity is that it facilitates the transfer and capture of patient POCT and quality-related data into permanent medical records. In addition, innovations in the area of POCT quality are facilitated by the ability to easily link devices to networks and to those who are ultimately responsible for the device. The potential benefits of POCT connectivity and what users should look for in POCT01-A2[4] compliant devices are described in a CLSI document (POCT02-A[5]. Examples of these benefits are shown in the software products of several POCT device manufacturers, which allow central laboratories to monitor their instruments in remote locations. In conjunction with network technology, remote control software not only allows monitoring of the performance of the device but also enables those responsible for the instrument to carry out some service procedures or even shut the instrument down completely if required. The ability to interface devices more easily with other information systems should enable the development of applications that add value to patient data, such as the use of decision support software to assist with interpretation and other tele-healthcare applications.

Implementation and Management Considerations

The (1) implementation, (2) management, and (3) maintenance of a POCT service in a healthcare facility require the necessary planning, oversight, and inventory control and assurance of the reliability of results through adequate training and QC. Consequently, a number of factors must be considered (Box 17-4).

Establishment of Need

As with general laboratory testing, the decision to implement a POCT service requires (1) establishment of need, (2) consideration of the clinical, operational, and economic benefits, and (3) examination of the costs and changes to the clinical process involved.

Addressing the questions listed in Box 17-5 is useful in establishing the requirement for a POCT service.[13] Answering these questions facilitates identification of the test itself and should also explain why the current service is not meeting the needs of the patient, the clinician, or the healthcare provider.

A risk assessment should be conducted that will focus primarily on the procedures and processes that have to be put in place to ensure continued high quality of service. Issues of concern that need to be addressed when such an assessment is conducted are listed in Box 17-6.

Organization and Implementation of a POCT Coordinating Committee

When organizing and implementing a POCT service, it is important to consult with all involved parties. It is recommended that a POCT coordinating committee be established first. Such a committee is charged with managing the whole process of delivering a high-quality POCT service. The committee should consist of representatives of those who use the service and those who deliver the service, together with a representative of the organization's

BOX 17-4 Factors That Need to Be Considered in the Implementation, Management, and Maintenance of a POCT Service

Establishing need
Organizing and implementing a coordinating committee
Establishing a POCT testing policy and accountability
Procuring equipment and performing its evaluation
Training and certifying operators
Establishing a QC, quality assurance, and audit policy
Ensuring documentation
Establishing accreditation and regulation of POCT policy

BOX 17-5 Assessing the Need for a Point-of-Care Testing Service

Which tests are required?
What TAT is required?
What clinical question is being asked when this test is requested?
What clinical decision is likely to be made upon receipt of the result?
What action is likely to be taken upon receipt of the result?
What outcome should be expected from the action taken?
Why isn't the laboratory able to deliver the required service?
Will POCT provide the required accuracy and precision of the result?
Is staff available to perform the test?
Are adequate facilities available in which to perform the test and store the equipment and reagents?
Will you abide by the organization's POCT policy?
Are operational benefits associated with this POCT strategy?
Are economic benefits derived from this POCT strategy?
Will a change in practice be required to deliver these benefits?
Is it feasible to deliver the changes in practice that might be required?

management team. Users will include (1) physicians, (2) physician assistants, (3) family nurse practitioners, (4) nurses, (5) other healthcare providers, and (6) patients. The providers should include at least one representative from the laboratory and those involved in the use of other diagnostic and therapeutic equipment close to the patient. Typically a laboratory professional will chair such a committee because it is the laboratory that will provide the necessary backup if a service failure should occur; furthermore, the laboratory professional will have received training and developed expertise with the analytical issues that are likely to arise. It is recommended that the committee report to the medical director. The committee should designate members who will take responsibility for overseeing the training and accreditation of all POCT operators, as well as for QC and quality assurance. The work of the committee should be governed by the organization's policy on POCT.[13]

POCT Policy and Accountability

Implementation of a POCT service requires a POCT policy that establishes all of the procedures required to ensure the delivery of a high-quality service, together with the responsibility and accountability of all staff associated with the POCT. This may be (1) part of the organization's total quality management system, (2) part of its clinical governance policy, and (3) required for accreditation purposes.[10] The elements of a POCT policy are listed in Box 17-7.

BOX 17-6 Issues of Concern When a Risk Assessment Is Performed for Consideration of Implementing a POCT Service

Robustness of the POCT device
Quality of the results produced
Competence of the operator of the device
Effectiveness of the process of transmitting results to the caregiver
Competence of the caregiver in interpreting the results provided
Procedures in place to ensure that an accurate record of the results is kept
Identification of what practice changes may have to be made to deliver the benefits that have been identified
Determination of how the staff will be retrained if appropriate
Determination of how the changes in practice will be implemented

Equipment Procurement and Evaluation

After the requirement, the coordination committee, and the policy have been established, the next stage in the process is equipment procurement. This involves first identifying candidate POCT equipment that has the prerequisite analytical and operational capabilities to meet the clinical requirements of a POCT service. As discussed in Chapter 2 and in a CLSI protocol,[3] the performance characteristics of these devices are then determined and compared. In addition, performance requirements of the operator have to be identified and the potential for operator error determined. Independent validation of these analytical and operational characteristics is obtained from (1) the manufacturer, (2) published evaluations performed by government agencies, and (3) reports in the peer-reviewed literature. When performance data are reviewed, particular attention should be paid to the precision and accuracy of measurement, including the concordance between results produced by the POCT device and by a routine laboratory method, because patients are likely to be managed using both analytical systems. This concordance may be difficult to assess, and it may be necessary to seek endorsements from current users of the systems and possibly to conduct some form of internal trial.

An economic assessment of the planned POCT service, including the costs of consumables and servicing, should also be completed. This is likely to be a comparative exercise between the various point-of-care systems under consideration. Any comparison of costs with the laboratory service will only be emphasizing the cost per test, which will not give an accurate assessment of the cost utility of the system. However, it is helpful at this point to have a good assessment of the relative staff costs associated with different systems because these are likely to be key features in the decision-making process. It is probable that the chosen system will be operated by staff already performing a wide range of other duties involving the care of patients, and therefore the amount of time required to operate the device may be critical.

Bibliography

After the comparison data have been obtained, tabulated, and interpreted, a POCT device is selected. The laboratory professional then conducts a short evaluation of the equipment to become familiar with the system. This evaluation will help to determine the content of the training routine that will have to be subsequently developed and whether troubleshooting of problems is required. Such an evaluation should document the concordance between results generated with the device and those provided by the laboratory. All of this information should then be recorded in a logbook associated with the equipment. In addition, the organization may (1) wish to undertake some form of safety check, (2) give the device some form of local code, and (3) enter the code into the local equipment register.

Training and Certification

The confidence of (1) the clinician, (2) the caregiver, and (3) the patient in the results generated by a POCT device depends on the performance and robustness of the instrument and the competence of the operator. Many of the agencies involved in the regulation of healthcare delivery now require that all personnel associated with the delivery of diagnostic results demonstrate their competence through a process of regulation, and this applies equally to POCT personnel. Typically, those healthcare professionals involved in POCT will not have received training in the use of analytical devices as part of their core professional training but may be called upon to operate a number of complex pieces of equipment.

BOX 17-8 The Main Elements of a Point-of-Care Testing Training Program

Understanding the Context of the Test—Pathophysiological Context
- Clinical requirement for the test
- Action taken on basis of result
- Nature of test and method used

Patient Preparation Required—Relevance of Diurnal Variation
- Relevance of drug therapy

Sample Requirement and Specimen Collection

Preparation of Analytical Device—Machine and/or Consumables

Performance of Test

Performance of Quality Control

Documentation of Test Result and Quality Control Result

Reporting of Test Result to Appropriate Personnel

Interpretation of Result and Sources of Advice

Health and Safety Issues (e.g., disposal of sample and test device, cleaning of machine and test area)

The elements of a training program are listed in Box 17-8. In practice, the extent of this program will vary according to how well the complexity of the analytical method has been engineered into the device. Such a program is tailored to meet the needs of the individual and the organization. The program may include (1) formal presentation to groups or on a one-to-one basis, (2) self-directed learning using agreed documentation, or (3) computer-aided learning. For example, several of the current models of blood gas and electrolyte analyzers have onboard computer-aided training modules. Whatever the training strategy employed, it is important to document the satisfactory completion of training and that the individual has been tested and found competent through a combination of questions concerned with understanding and practically demonstrating the skills gained. The latter is achieved by performing tests on a series of QC materials and repeat testing samples that have recently been analyzed (parallel testing). Finally the operator should be observed through the whole procedure involved in the POCT on a minimum of three occasions.

Competence is maintained on a long-term basis through regular practice of skills and continuing education, and it is important to build these features into any education and training program. Regular review of performance in QC and quality assurance programs will provide a means of monitoring and overseeing the competence of operators. However, this is not always sufficient, particularly when operators are employed on irregular shifts or may not always be called upon to perform POCT. In this latter situation, it may be necessary to create specific arrangements by which individuals can undertake tests on QC material. The error log may highlight when problems are arising. However, it is important to encourage an open approach to the assessment of competence so that

operators themselves seek help if they believe that problems are occurring. Such an open approach should be supported with audit and performance review meetings where problems are aired and developments discussed. The regular assessment of competence should be built into a formal program for recertification that will be a requirement of most accreditation programs.[13]

Quality Control, Quality Assurance, and Audit

QC and quality assurance programs provide a formal means of monitoring the quality of a service (see Chapter 7). The internal QC program gives a relatively short-term view and typically compares current performance with that of the previous analysis. External quality assurance is a longer-term process that addresses other issues surrounding the quality of the result. Thus, quality assurance compares the testing performance of different sites and/or different pieces of equipment or methods.[11] An audit is a more retrospective form of analysis of performance that takes a more complete view of the entire process. However, the foundation for ensuring good quality remains a successful training and certification scheme.

Classically, quantitative internal QC involves the analysis of a sample for which the analyte concentration is known and the mean and range of results quoted for the method used. Several challenges are associated with the classical approach to POCT. The first concern to be considered is the frequency of testing—Should a QC sample be analyzed every time that (1) a sample is analyzed, (2) a new operator uses the system, (3) a new lot number of reagents is used, or (4) the system is recalibrated? No consistent agreement has determined the correct approach, and one probably has to be guided by the reproducibility and overall analytical performance of the system. The approach used is also influenced by local circumstances, such as the number and competence of the operators and the frequency with which the system is used. For a bench top and/or multitest analyzer, at least one QC sample should be run a minimum of once per shift—three times a day. Some critical care analyzers are programmed to perform a QC check at intervals set by those responsible for the device.

For single-use POCT disposable devices, this strategy does not completely monitor the quality of the test system. For example, when conventional QC material is analyzed on a unit-use or single-test POCT system, only that testing unit is monitored. Thus it is impossible to test every unit with control material because by definition these are single-test systems, and it is not possible to analyze both control material and a patient sample with the single unit. Under these circumstances, greater dependence is placed on the manufacturing reproducibility of the devices to ensure a good quality service. A 2010 CLSI guideline reports quality management procedures for POCT.[6]

In practice, the user may wish to continue with a QC testing strategy that is similar to that applied for multiuse devices, namely, analyzing a minimum of one QC sample per run during each shift. If testing is infrequent, another approach would be to analyze a QC sample whenever a change is made to the testing system, such as when a different batch of testing materials is used or a different operator is performing the testing. Other QC approaches may be used, but many do not test the whole process. For example, the use of a plastic surrogate reflectance pad as a QC sample will only test the performance of the reflectance meter and does not test the process of sample addition, etc. Similarly, some forms of electronic internal QC do not test the sampling technique but simply the functionality of the cassette and the docking station.[11]

External quality assurance or proficiency testing is a systematic approach to QC monitoring by which standardized samples are analyzed by one or more laboratories to determine the capability of each participant. With this approach, the operator has no knowledge of the analyte concentration, and therefore it is considered closer to a "real testing situation." The results are transmitted to a central authority, who then prepares a report and returns a copy to each participating laboratory. The report will identify the range of results obtained for the complete group of participants and may be classified according to the different methods used by participants in the scheme. The scheme may encompass both laboratory and POCT users, which provides an opportunity to compare results with laboratory-based methods. In practice, external quality assurance or proficiency testing is used in POCT to determine and document long-term performance and the concordance of results between the POCT service and an organization's central laboratory. It is also possible to operate an external quality assurance scheme within a hospital or organizational setting; such a scheme would and should be run by qualified laboratory personnel. This provides the opportunity to compare the results being reported by the laboratory and by other POCT sites within the same organization. This is important when patients are managed in several departments—or when machines break down and samples are taken to other sites for testing. When deteriorating or poor performance is identified in one of these schemes, it is important to document the problem, and then provide and document a solution. It may be necessary as part of this exercise to review some of the patient's notes to ensure that incorrect results have not been reported and inappropriate clinical actions taken. In addition, if the solution highlights a vulnerable feature of the process overall or for one particular operator, a process of retraining must be instituted.

Maintenance and Inventory Control

Implementation and maintenance of a POCT service requires that a supply of devices be maintained at all times and a formal program for doing so employed. The key points in this process are to (1) adhere to the recommended storage conditions, (2) be aware of the stated shelf life of the consumables, and (3) ensure that stocks are released in time for any preanalytical preparation to be accommodated (e.g., thawing). When multiple sites are using the same materials, a central purchasing, supply, and inventory control system should be implemented. This will gain the benefit derived from bulk purchasing and will ensure that individual systems are not supplied unknowingly with different batches of consumables.

The complexity in the maintenance of reusable devices will vary from system to system, but clear guidelines will be

available from the manufacturer and should be adhered to rigorously. Issues that usually require particular vigilance include (1) expiration dates, (2) biocontamination, (3) electrical safety, (4) maintenance of optics, and (5) inadvertent use of inappropriate consumables.

Documentation

Documentation of all aspects of a POCT service is essential and it is critically important to keep an accurate record of (1) test requests, (2) results, and (3) actions taken, as an absolute minimum. Some of the prior issues associated with documentation are now being resolved with the advent of (1) the patient electronic record, (2) electronic requesting, and (3) better connectivity of POCT instrumentation to information systems and the patient record (see earlier discussion). The documentation should extend from the standard operating procedure(s) for the POCT systems to records of training and certification of operators and internal QC and quality assurance, together with error logs and any corrective action taken.

Accreditation and Regulation of POCT

The features of the organization and management of POCT described previously are the same as those associated with the accreditation of any diagnostic services.[2] Accreditation of POCT should be part of the overall accreditation of laboratory medicine services, or indeed part of the accreditation of the full clinical service, as has been the case in many countries, including the United States and the United Kingdom, for a number of years. For example, the U.S. Congress passed the **Clinical Laboratory Improvement Amendments of 1988 (CLIA-88),** which established quality standards for all laboratory testing to ensure (1) accuracy, (2) reliability, and (3) timeliness of patient test results, regardless of where the test was performed. The final CLIA regulations were published in the Federal Register on February 28, 1992. These requirements are based on the complexity of the test, not on the type of laboratory in which the testing is performed. The CLIA regulations list three testing categories: (1) waived, (2) moderate complexity, and (3) high complexity. Of importance to a discussion of POCT is the "waived" category, with a **waived test** defined as a "simple laboratory examination and procedure that have an insignificant risk of an erroneous result" (http://www.cms.gov/; accessed on August 14, 2013). Many POC tests have been categorized as "waived." In addition, CLIA legislation in the United States stipulates that all POCT must meet certain minimum standards.[17,18] In the United States, (1) the Centers for Medicare & Medicaid Services, (2) the Joint Commission, and (3) the College of American Pathologists are responsible for inspecting sites. Each is committed to ensuring compliance with testing regulations for POCT.[8]

Review Questions

1. Are the results obtained from a point-of-care test (POCT) device qualitative, quantitative, or semi-quantitative, or can they be all of these?
   a. Qualitative only
   b. Quantitative only
   c. Semi-quantitative only
   d. All of the above result types can be obtained from a point-of-care test device.
2. Which of the following is not considered an advantage of POCT?
   a. Reduced need for quality control
   b. Reduced turnaround time
   c. Reduced length of time between test results and clinical decisions
   d. Improved health outcomes
3. The most frequently tested analyte that is measured by a point-of-care device is:
   a. arterial blood pH.
   b. glucose.
   c. hemoglobin.
   d. a cardiac marker.
4. One of the benefits for the lab regarding POC testing is a reduction in controllable preanalytical variables and errors. An example of one of these types of variables would be:
   a. not having to run controls.
   b. not performing preventive maintenance on the equipment.
   c. obtaining blood in the wrong type of tube.
   d. the individual's age.
5. With regard to point-of-care testing, examining a urine specimen for the presence (not a specific concentration) of a drug metabolite would likely be performed using a:
   a. single-use quantitative test cartridge.
   b. single-use qualitative test cartridge.
   c. multiple-use test cartridge.
   d. continuous monitoring device.
6. The most common biological recognition element used as a biosensor in a point-of-care device is a(n):
   a. antibody.
   b. antigen.
   c. hormone.
   d. enzyme.
7. To perform quality control on a new lot of multiuse point-of-care devices that are used infrequently, a minimum of one control sample per lot is sufficient to test the whole assay process.
   a. True
   b. False
8. A systematic, long-term approach to quality control of POCT devices that is sometimes referred to as "external" quality control involves enrollment in a proficiency testing program. This type of QC testing involves:
   a. analysis of unknown samples as a sort of test to determine the capability of participants in the program.
   b. testing of a plastic reflectance pad in some POCT devices to test the performance of the reflectance meter.
   c. a standardized program that asks questions of the operators of the POCT.
   d. analysis of the external parts of a POC testing device such as the reagent delivery system.

CHAPTER 18

Amino Acids, Peptides, and Proteins*

Glen L. Hortin, M.D., Ph.D.

Objectives

1. Define the following terms:
   - Acute-phase reaction; acute-phase reactant
   - Ampholyte
   - Amyloid
   - Bence-Jones proteins
   - Complement protein
   - Cryoglobulin
   - Essential amino acid
   - Globulin
   - Immunoglobulin
   - Isoelectric point
   - Paraprotein
   - Peptide
   - Peptide bond
   - Protein
   - Proteinuria
2. Diagram and describe the basic chemical structures of an amino acid and a peptide bond.
3. Explain the metabolism of amino acids and proteins, including sites of formation and breakdown.
4. Describe amino acid and protein analyses, including specimen requirements and quantitative analytical techniques.
5. List the following with regard to proteins:
   - Physiological functions
   - Structural elements
   - Physical properties
6. Explain the principle of serum protein electrophoresis, including a description of properties needed for separation, staining methods, separation techniques, and immunofixation electrophoresis.
7. State the utility and problems of using mass spectrometry and MALDI in the assessment of proteins.
8. Compare plasma and serum with regard to protein concentration.
9. State the formula for calculating globulin concentration; calculate globulin concentration when given appropriate information.
10. List the acute-phase response proteins and the negative acute-phase response proteins.
11. Classify the following plasma proteins as to their function, globulin class (if any), and clinical significance and explain how they are affected by disease, including but not limited to, liver, gastrointestinal, and kidney disease:
    - Prealbumin
    - Retinol-binding protein
    - Albumin
    - HDL, LDL
    - α_1-Antitrypsin
    - α-Fetoprotein
    - Haptoglobin
    - Ceruloplasmin
    - Transferrin
    - C-reactive protein
12. Discuss the complement proteins, including their clinical significance, abundance, pathway involvement, and disease associations.
13. List the immunoglobulin classes. Describe their biochemistry, function, and clinical significance, and explain how they are affected by disease, including multiple myeloma, macroglobulinemia, and lymphoid tumors; discuss free immunoglobulin light chains, including their function, clinical importance, and presence in urine.
14. Explain the presence of protein in urine and describe four types of proteinuria; describe how protein is analyzed in urine.
15. Explain the presence of protein in CSF and the significance of increased CSF protein.
16. Analyze and solve case studies related to amino acids and proteins, including analytical problems, disorders of metabolism, and other disorders.

*The author gratefully acknowledges the previous contributions of A. Myron Johnson, Robert H. Christenson Hassan, M.E. Azzazy, Lawrence M. Silverman, and Elizabeth M. Rohlfs, on which portions of this chapter are based.

Key Words and Definitions

Acute-phase response Body's response to injury or inflammation.

Acute poststreptococcal glomerulonephritis (APSGN) Inflammation of the kidney glomeruli, following a streptococcal infection; also called postinfectious glomerulonephritis.

Amino acid An organic compound containing both amino ($-NH_2$) and carboxyl ($-COOH$) functional groups.

Aminoaciduria An excess of amino acids in the urine.

Amyloidosis A metabolic disease characterized by abnormal deposits of amyloid in the body.

Bence-Jones proteins Small light chains of immunoglobulin found in the urine.

Complement system Complex system of proteins found in blood that combines with antibodies to destroy pathogenic bacteria and other foreign cells.

Essential amino acids Amino acids that are not synthesized by humans and therefore are essential dietary constituents for maintaining health or growth.

Globulin Proteins that precipitate in water and redissolve when the salt concentration is raised.

Hereditary angioedema (HAE) Genetic disorder characterized by recurrent episodes of severe swelling.

Immunoglobulins A family of proteins also known as antibodies that contain highly specific antigen-binding sites consisting of two identical heavy (H) chains encoded on chromosome 14 and two identical light (L) chains encoded on chromosome 2.

Inborn error of metabolism Genetically determined biochemical disorder in which a specific enzyme defect causes a metabolic block in the individual at birth or in later life.

Isoelectric focusing An equilibrium technique that is used to separate charge variants of proteins and is applied to analysis of certain genetic variants of proteins.

Kwashiorkor A form of protein-energy malnutrition produced by severe protein deficiency.

Marasmus A form of protein-energy malnutrition predominantly due to prolonged severe caloric deficit.

Monoclonal gammopathy of undetermined significance (MGUS) A condition in which a paraprotein is found in an individual's blood.

Multiple myeloma A cancer in which antibody-producing plasma cells grow in an uncontrolled and malignant manner.

Paraprotein A monoclonal immunoglobulin produced in excessive amounts in disorders such as multiple myeloma.

Paroxysmal nocturnal hemoglobinuria (PNH) Disease of the blood characterized by complement-induced intravascular hemolytic anemia, red colored urine and thrombosis.

Peptide A compound consisting of two or more amino acids linked in a chain via peptide bonds.

Peptide bond The amide bond formed between the carboxyl group of one amino acid and the amino group of another.

Plasma proteins Proteins present in blood, including carrier proteins, fibrinogen and other coagulation factors, complement components, immunoglobulins, enzyme inhibitors, and many others; most are found in other body fluids but in lower concentrations.

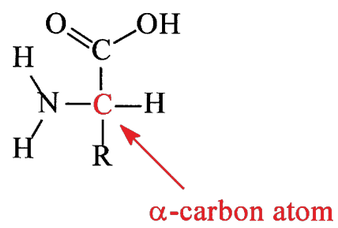
Protein A polymer of amino acids linked by peptide bonds with a specific sequence that folds into a defined structure; any of a group of complex organic compounds that contain carbon, hydrogen, oxygen, nitrogen, and usually sulfur (the characteristic element being nitrogen).

Proteome The total complement of proteins expressed by the genetic material of an organism under a given set of environmental conditions.

Side chain A chemical group that is attached to a core part of the molecule.

Systemic lupus erythematosus (SLE or lupus) A condition that can affect any part of the body.

Waldenström's macroglobulinemia A chronic cancer of the immune system characterized by hyperviscosity, or thickening, of the blood.

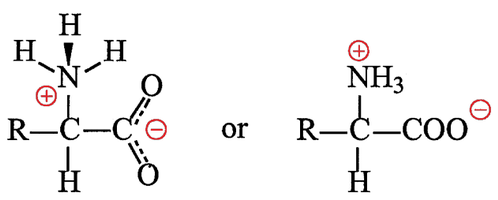


Amino acids, **peptides**, and **proteins** play crucial roles in virtually all biological processes, with amino acids being the basic building block of proteins. In humans, more than 20,000 genes encode peptides and proteins that have diverse structures and functions (www.genome.gov/; accessed August 27, 2013). This chapter includes discussions of (1) amino acids and their analyses, (2) major proteins in biological fluids, and (3) analytical techniques used to analyze proteins.

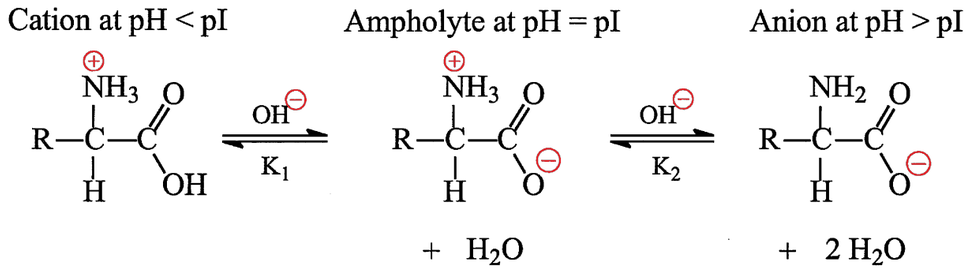
Amino Acids

Amino acids serve as the basic structural units of peptides and proteins; they also have diverse roles in metabolism and neurotransmission. [3] Measurement of amino acids in physiological fluids assists with studies of metabolism and the diagnosis of pathological and inherited disorders (see Chapter 45).

Basic Biochemistry



Amino acids are organic compounds that contain both an amino group ($-NH_2$) and a carboxyl group ($-COOH$). Those that occur in proteins are α−amino acids that are also known as 2-Oxo amino acids. Structurally, the amino group is in the position to the carboxyl group that have the general formula $RCH(NH_2)COOH$, wherein R has varying structures that are often referred to as the **side chain**. This side chain plays a key role in maintaining nitrogen balance in mammals.



Technically, proline is an imino acid not an amino acid, but it is usually grouped with amino acids. Amino acids in physiological fluids also include β-amino acids, such as β-alanine, and γ-amino acids, such as the neurotransmitter γ-aminobutyric acid. Table 18-1 lists the 21 amino acids that are incorporated by ribosomes into proteins with a sequence specified by messenger RNA. Most proteins contain 20 of the 21 amino acids. Selenocysteine is an uncommon amino acid that is incorporated into only a few proteins, where it usually serves as an important residue at catalytic sites of enzymes. With the exception of glycine, all α-amino acids are asymmetrical about the α-carbon, and four different groups are linked to this carbon. Most α-amino acids in humans, including all of the amino acids incorporated into proteins, have the L-configuration.

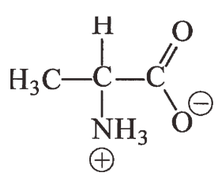
Acid-Base Properties

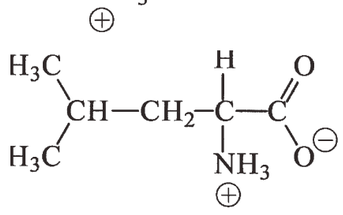
The acid-base properties of amino acids depend on the amino and carboxyl groups attached to the α-carbon and present on any ionizable groups included in the side chains (R). In the physiological pH range of near 7.4, the carboxyl group of an amino acid is dissociated and the amino group protonated, as follows:

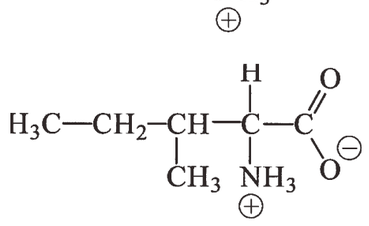
At neutral pH, there is zero net charge as the negative and positive charge balance in what sometimes is termed an ampholyte or zwitterion (see Chapter 11). At low pH, an amino acid has a net positive charge, with both its amino and carboxyl groups protonated ($-NH_3$ and $-COOH$). At high pH, amino acids have a net negative charge, with both amino and carboxyl groups deprotonated. The amino $-NH_3$ is also deprotonated:

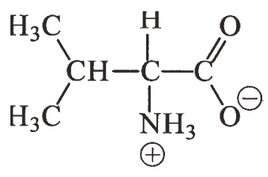
The dissociation constants for the carboxyl group, K_1, and the amino group, K_2, usually are expressed as pK_1 and pK_2, where $pK = -\log K$, in a manner analogous to the notation for pH. A pK is the pH at which equal quantities of the protonated and deprotonated forms of an ionizable group are present. The isoelectric point, pI, is the pH at which a molecule has a net charge of 0. The isoelectric point of a neutral amino acid is the midpoint between the pK's of its amino and carboxyl groups

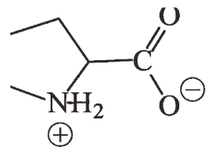
TABLE 18-1 Amino Acids Incorporated Into Protein: Their Properties and Structures

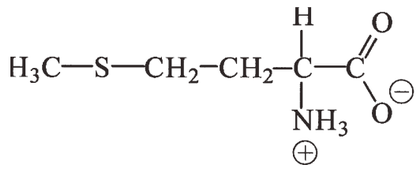


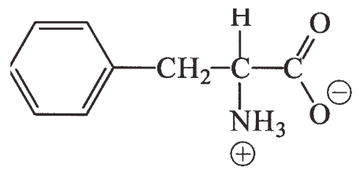


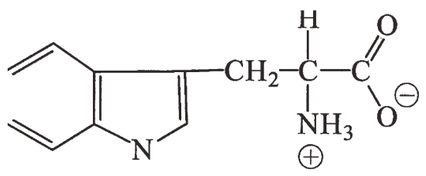


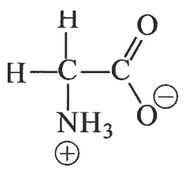


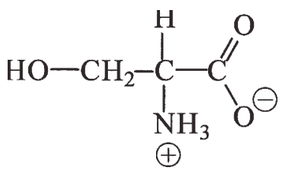


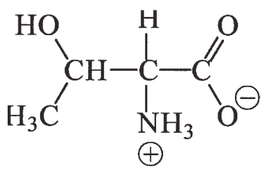


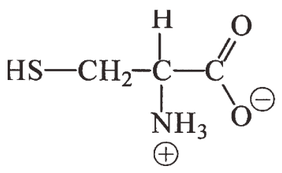


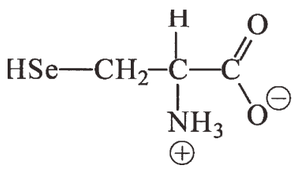


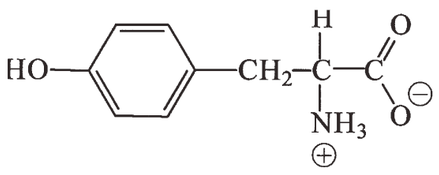


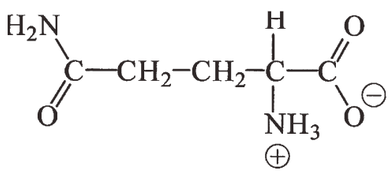


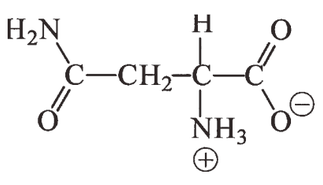


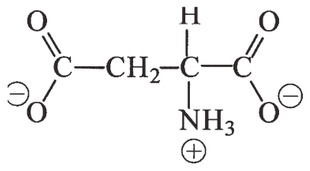


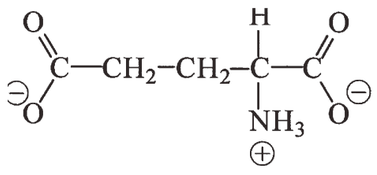


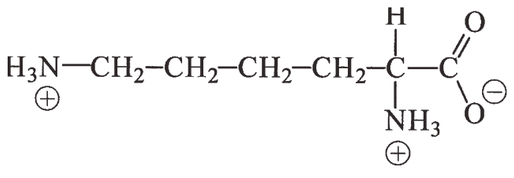


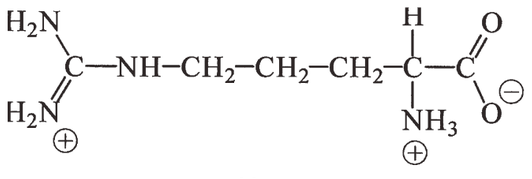


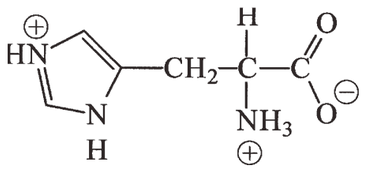


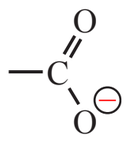


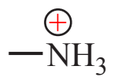


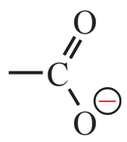


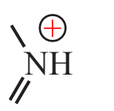


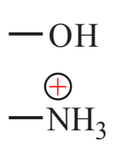


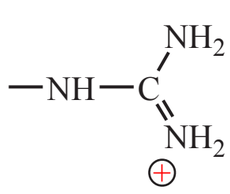












Name and Abbreviation	HI	MW	Structure at pH6 to 7	Comments
Neutral Amino Acids				
Alanine Ala, A	1.8	89.09		Important metabolic substrate in alanine cycle; substrate for ALT
Leucine Leu, L	3.8	131.17		Essential; branched-chain R group; ketogenic; metabolism is faulty in maple syrup urine disease
Isoleucine Ile, I	4.5	131.17		Essential; partly ketogenic; see Leucine above
Valine Val, V	4.2	117.17		Essential; partly ketogenic; see Leucine above
Proline Pro, P	1.6	115.13		Has α-imino rather than α-amino; high content in collagens and can be hydroxylated to hydroxyproline; destabilizes α-helical structures
Methionine Met, M	1.9	149.18		Essential; important as donor of methyl groups; provides sulfur for other sulfur-containing compounds
Phenylalanine Phe, F	2.8	165.19		Essential; elevated concentrations in phenylketonuria as conversion to Tyr is impaired

TABLE 18-1 Amino Acids Incorporated Into Protein: Their Properties and Structures—cont'd

Name and Abbreviation	HI	MW	Structure at pH 6 to 7	Comments
Neutral Amino Acids—cont'd				
Tryptophan Trp, W	−0.9	204.22		Essential; metabolites in carcinoid disease; contains indole ring; precursor of serotonin, melatonin
Glycine Gly, G	−0.4	75.07		No stereoisomer; used in biosynthesis of purines and porphyrins; transfer to bile acids, hippurates, and other conjugates
Serine Ser, S	−0.8	105.09		Source of one-carbon groups for folates; can undergo post-translational addition of phosphate, sugars
Threonine Thr, T	−0.7	119.12		Essential; can undergo post-translational addition of phosphate or sugars
Cysteine Cys, C	2.5	118.16		Sulfhydryl group in active sites of some enzymes; forms disulfides; homocysteine is homologue with side chain one carbon longer
Selenocysteine Sec, U		168.05		Active form of selenium; found in some enzymes involved in oxidation reduction reactions; formed on a specific transfer RNA
Tyrosine Tyr, Y	−1.3	181.19		Usually nonessential; intermediate in synthesis of catecholamines, thyroxine, and melanin; functional phenolic group
Glutamine Gln, Q	−3.5	146.15		Transport form of ammonia; supplies nitrogen atoms used in purine and pyrimidine biosynthesis
Asparagine Asn, N	−3.5	132.12		Attachment site of oligosaccharides in Asn-Xxx-(Ser or Thr) sequences
Acidic Amino Acids				
Aspartic acid Asp, D	−3.5	133.10		Precursor for pyrimidine and purine biosynthesis; a substrate in urea cycle
Glutamic acid Glu, E	−3.5	147.13		Transport form of ammonia γ-glutamyl transfer from glutathione; a neurotransmitter
Basic Amino Acids				
Lysine Lys, K	−3.9	146.19		Essential; side chain has an additional amino group
Arginine Arg, R	−4.5	174.20		Involved in urea synthesis; side chain has a guanidinium group
Histidine His, H	−3.2	155.16		The imidazole group has a pK near physiological pH, so charge can vary with physiological pH change

*A higher value for hydropathy index (HI) indicates greater hydrophobicity of amino acid side chains.

TABLE 18-2 Ionization Constants of Ionizable Groups in Free Amino Acids and in Proteins*

Ionizing Group		Range of pK Values: Free Amino Acids	Range of pK Values: Proteins
Principal carboxyl = pK_1		1.7-2.6	3.0-3.2
α-Amino = pK_2		9.0-10.8	7.6-8.4
Second carboxyls of Glu and Asp		3.8-4.3	3.0-4.5
Imidazole nitrogen of His		6.0	6.0-7.0
Sulfhydryl of Cys		8.3	9.1-10.8
Phenolic hydroxyl of Tyr		10.1	9.2-9.8
ε-Amino of Lys		10.5	9.4-10.6
Guanidinium group of Arg		12.5	11.5-12.6

*The pK value for the primary carboxyl varies from 1.71 for Cys to 2.63 for Thr. The pK for the α-amino group varies from 8.95 for Lys to 10.78 for Cys. In protein chains, the local environment modifies the pK for any given ionizable group. The amino acid symbols are listed in Table 18-1.

(pI = ½[pK_1 = pK_2]). Amino acids also contain several different ionizable groups on their side chains. Table 18-2 lists pK values for various ionizable groups of amino acids. The exact pK values for different groups vary slightly in different amino acids, depending on neighboring groups; in proteins, even greater variation often results from the effects of neighboring amino acids.

Influence of R Groups

The R groups of individual amino acids provide considerable variation in structure and physical properties. Side chains may be (1) acidic, (2) basic, or (3) neutral and vary in size and hydrophobicity. The hydropathy index listed in Table 18-1 is an index of the water solubility of the side chains. Amino acids with charged groups or polar groups like hydroxyl or amide groups in their side chains have high water solubility and low hydropathy. Amino acids with aliphatic or aromatic side chains tend to have low water solubility and high hydropathy. The differing charge and properties of amino acids serve as a basis for their chromatographic separation.

Amino Acid Metabolism

Amino acids are synthesized from α-ketoacids, and later are transaminated from another amino acid, usually glutamate. They participate in many metabolic pathways, in addition to serving as substrates for protein synthesis (see Chapter 37).

Dietary protein usually serves as the primary source of amino acids for protein synthesis. The adult daily requirement for protein intake is about 0.8 g/kg body weight, and demand is higher during (1) growth, (2) pregnancy, (3) lactation, (4) states of protein loss, and (5) many disease states with increased protein breakdown. Endogenous protein turnover serves as another source of free amino acids. In the absence of protein uptake, breakdown of muscle protein serves as a source of amino acids. Eight amino acids used for protein synthesis—(1) isoleucine, (2) leucine, (3) lysine, (4) methionine, (5) phenylalanine, (6) threonine, (7) tryptophan, and (8) valine—are not synthesized by humans and, thus, are considered to be **essential amino acids.** Meat, milk, eggs, and fish contain a full range of essential amino acids. Gelatin is deficient in tryptophan. Individual plant sources may be deficient in (1) lysine, (2) methionine, or (3) tryptophan.

Dietary supply of amino acids has important clinical implications. A diet with adequate calories but low protein intake has been known to lead to **kwashiorkor** (malnutrition due to protein deficiency) with (1) decreased serum albumin, (2) edema, (3) ascites, (4) growth failure, (5) immune deficiency, and (6) apathy. Deficiency of both calories and protein (protein-calorie malnutrition), also termed **marasmus** causes generalized muscle wasting but less edema when compared with kwashiorkor. Inadequate protein nutrition is frequently a problem for (1) surgical, (2) burn, or (3) trauma patients in a catabolic state and for those with decreased food intake. Adequate nutrition is important for immune function and tissue repair. In kidney disease, high protein intake appears to be harmful, and protein restriction has been used as a therapeutic intervention to slow the progress of kidney disease.

Amino acids are important intermediates in many metabolic pathways, including (1) the urea cycle for converting ammonia to urea, (2) the alanine cycle for transferring nitrogen and energy sources from muscle to liver, (3) ammonia generation in the kidney from glutamine and glutamic acid, and (4) glutathione formation to maintain a reducing intracellular environment. Amino acids are precursors for many hormones and signaling molecules, such as (1) thyroid hormones, (2) catecholamines, (3) serotonin, (4) nitric oxide, (5) melatonin, and (6) hydrogen sulfide. Serine is a major source of one-carbon units transferred by tetrahydrofolic acid for purine synthesis and conversion of homocysteine to methionine. Amino acid precursors for purine and pyrimidine synthesis include (1) glycine, (2) aspartic acid, (3) glutamine, and (4) serine. Methionine serves as a methyl donor for many reactions after activation as S-adenosylmethionine. Several amino acids participate in conjugation reactions that serve as excretory pathways and generate products such as glycine or taurine conjugates of bile acids. Cysteine and glutathione form mercapturates with reactive compounds as a protective mechanism. The liver is a very active site in amino acid metabolism and syntheis, as outlined in Figure 18-1. The liver is the primary site for the urea cycle and for uptake of amino acids from the circulation and conversion to a fuel source via transamination. The liver is also a primary source of many of the major plasma proteins in the circulation.

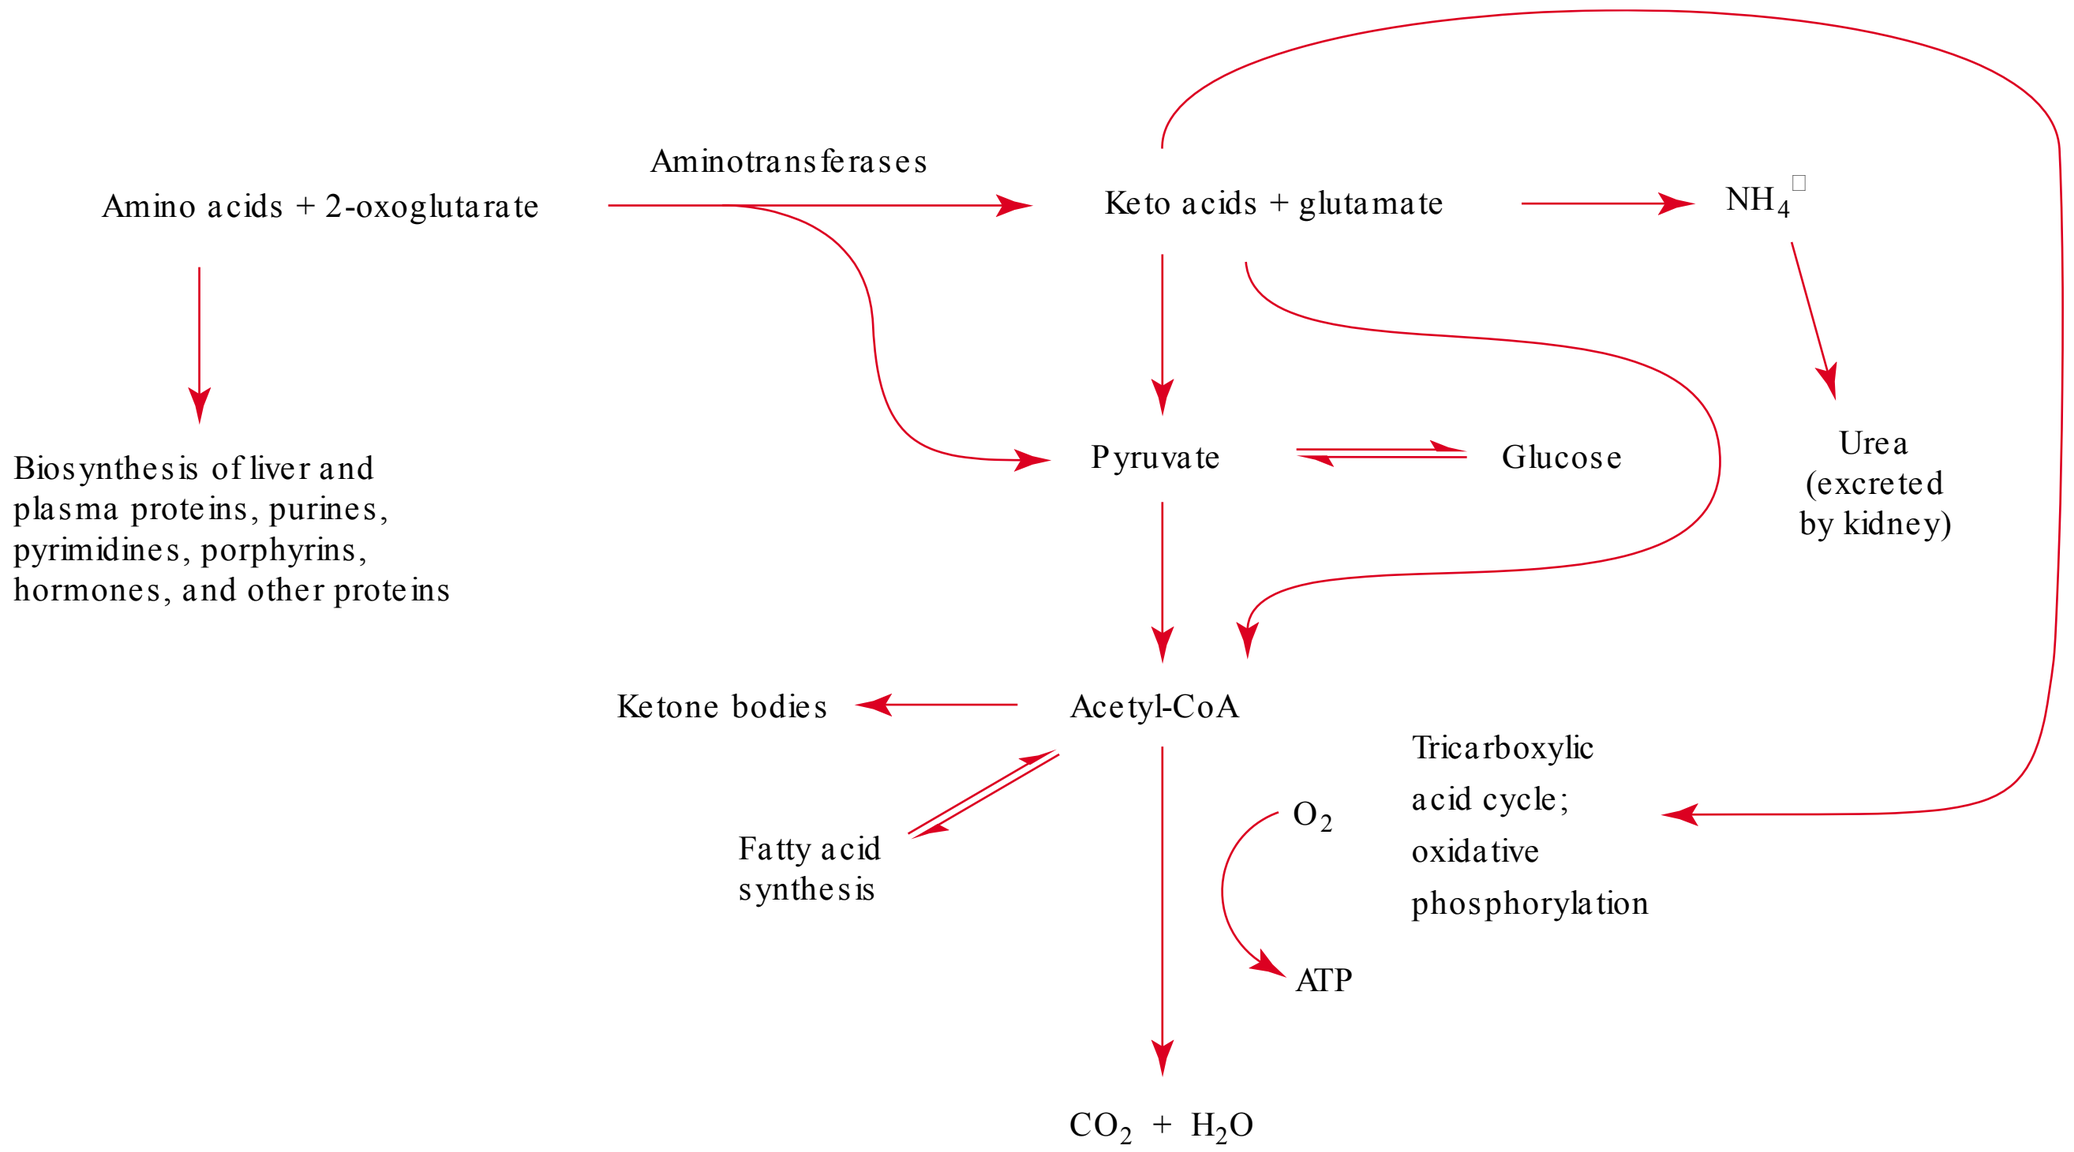


Figure 18-1 A generalized scheme of amino acid metabolism in the liver.

Clinical Implications

Disorders of amino acid metabolism have been assessed by analysis of amino acids in plasma or urine. Increased urinary excretion of amino acids may be primary or secondary. Primary disease is due to an inherited enzyme defect. **Inborn errors of metabolism** are described in Chapter 45. The defect may be located in the pathway by which a specific amino acid is metabolized or in a transport system for an amino acid. Secondary aminoaciduria is due to disease of an organ, such as the liver, which is an active site of amino acid metabolism, or generalized renal tubular dysfunction.

Analysis of Amino Acids

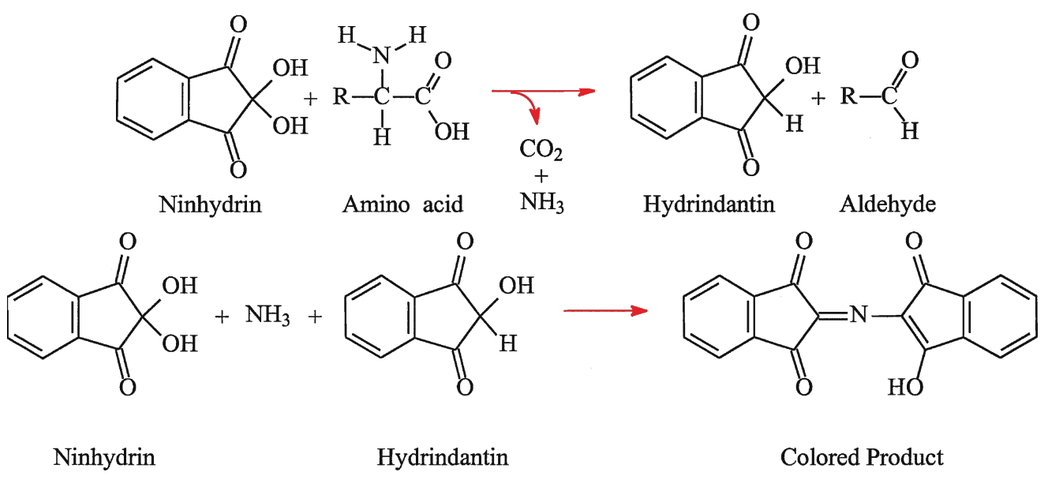
Amino acid concentrations usually are assessed in (1) plasma, (2) urine, or (3) cerebrospinal fluid. Plasma amino acid concentrations vary during the day by about 30%; therefore, it is preferable to collect specimens at the same time during the day if changes are to be monitored. Amino acid concentrations are highest in midafternoon and lowest in early morning. Plasma amino acid concentrations are high during the first days of life, especially in premature neonates, but they tend to be low in infants with birth weight low for gestational age; malnutrition due to placental insufficiency is the cause. Maternal values are low in the first half of pregnancy.

Amino acids are freely filtered through the glomerular membranes of kidneys, but most amino acids are reabsorbed in kidney tubules by saturable transport systems (see Chapters 21 and 35). Increased urinary excretion of one or more amino acids occurs as the result of (1) excessive plasma concentration of an amino acid overwhelming the tubular reuptake (overflow aminoaciduria), (2) tubular injury, or (3) a defect in a reuptake system for an amino acid. Urinary excretion of amino acids varies with age. For example, infants, particularly premature infants, have a generalized aminoaciduria caused by immature reuptake systems. During pregnancy, the renal threshold for many compounds including amino acids is decreased, resulting in increased **aminoaciduria**. In healthy adults, (1) glycine is the most abundant amino acid, followed by (2) histidine, (3) taurine, (4) glutamine, (5) serine, and (6) alanine.

Specimen Requirements

For diagnosis of an inherited disorder of amino acid metabolism, care must be taken to obtain valid and representative samples. For example, individuals should follow a normal diet for 2 to 3 days before collection. Testing for some disorders during newborn screening, such as for phenylketonuria, has been known to fail to detect the disorder if the newborn has had no dietary intake. Blood and urine specimens should be collected simultaneously. Use of heparinized plasma is preferable to use of serum and other anticoagulants. Screening tests for newborns commonly are collected as dried blood spots on filter paper. Because some drugs administered to the mother before she gives birth or to the infant interfere with specimens, all medications should be noted. Most amino acids are stable in blood specimens, except for glutamine, which undergoes cyclization to form pyroglutamic acid (5-oxoproline) with release of ammonia. Specimens should be processed rapidly and frozen rapidly to preserve glutamine. Homocysteine is gradually released from blood cells, so that plasma needs to be separated from whole blood rapidly to obtain accurate

homocysteine measurements. Before analysis, most procedures for analyzing amino acids entail removal of proteins by precipitation or by ultrafiltration. T is yields good recovery of most amino acids. Recovery of tryptophan may vary as the result of protein binding, and substantial amounts of cysteine, homocysteine, and thiol-containing peptides are linked via disulfide bonds to proteins. Recovery of total cysteine and homocysteine requires reduction of specimens before protein removal.



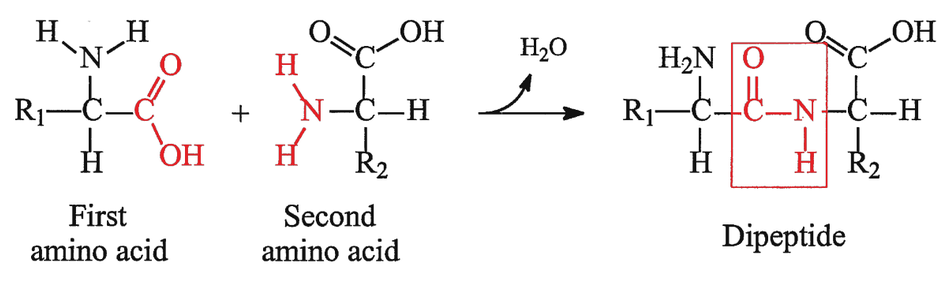
Screening Tests

Historically, a variety of methods have been used to screen newborns for disorders of amino acids in body fluids. T ese have included thin-layer chromatography (TLC) and the Guthrie test. Currently, newborn screening is widely performed on dried blood spots through liquid chromatography–tandem mass spectrometry (see Chapter 45).

Quantitative Tests

Screening tests yield some false-positive or indeterminate results, particularly during screening for relatively rare disorders, such as inherited disorders of amino acid metabolism. Confirmatory diagnostic testing is required on plasma or urine specimens collected for quantitative analysis. Monitoring of patients requires similar quantitative analysis. Also, newborn screening of blood spots may not detect some disorders, such as disorders of urinary amino acid transport.

For many years, quantitative clinical analysis of amino acids was performed mainly by ion exchange chromatography with postcolumn reaction with ninhydrin to generate a product detected by a photometer.



In addition to the ion exchange chromatography/ninhydrin system, a number of other techniques are used, including (1) liquid chromatography–tandem mass spectrometry (LC-MS/MS), (2) reversed-phase high-performance liquid chromatography, (3) capillary electrophoresis (CE), and (4) gas chromatography (GC). T ese procedures usually employ chemical derivatization of amino acids before analysis. Some advantages of these methods versus the ion exchange method include higher throughput and greater analytical specificity. Currently, the main clinical use of amino acid analysis is detection and monitoring of inherited disorders. Selective quantification of plasma homocysteine is the only exception; the plasma concentration of it has been determined by selective (1) enzyme assays, (2) immunoassays, and (3) chromatographic assays. T ese measurements have been used as a marker for deficiency of folic acid or vitamin B_{12} and as a marker associated with increased risk for cardiovascular disease.

Peptides and Proteins

Humans have more than 20,000 genes encoding proteins that serve as major structural elements and as the machinery of life. T e total complement of proteins present at a time in a cell or cell type is known as its **proteome**, and the study of such large-scale data sets defines the field of proteomics, named by analogy to the related field of genomics.[4] Diverse functions of proteins include (1) serving as structural components, (2) facilitating catalysis of chemical reactions, including synthesis of DNA, RNA, and proteins, (3) generating energy through electron transfer, (4) producing motility through contractile elements, (5) serving as ion channels and pumps, (6) acting as carrier molecules, (7) effecting immune defense, (8) serving as receptors, hormones, and cytokines for intercellular communication, and (9) constituting signaling networks for intracellular communication. To perform all of these functions, proteins must have great structural diversity. Diversity from the primary genetic sequence encoding proteins is compounded by (1) variable splicing of messenger RNA, (2) somatic recombination and mutation of selected genes such as those for antibodies, (3) proteolytic processing, and (4) numerous post-translational modifications of proteins.

Basic Biochemistry

Proteins are polymers of amino acids that are linked covalently through an amide linkage that is referred to as the **peptide bond**. T is bond is formed when the α-amino group of one amino acid is linked covalently with the α-carboxyl of a second amino acid (with loss of water) by the protein biosynthetic machinery, as follows:

T e peptide bond is described by the structure in the enclosed area. T e amino acid with the free amino group in the peptide is termed the N-terminal residue and the amino acid with the free carboxyl group is termed the C-terminal residue. Protein synthesis begins with the N-terminal residue and peptides are named from the N-terminal residue. Alanylglycine, for example, is a peptide with alanine as the N-terminal residue and glycine as the C-terminal residue.

Short chains of linked amino acids are designated as (1) dipeptides, (2) tripeptides, (3) tetrapeptides, or (4) pentapeptides according to the number of amino acids. Chains of up to five residues are called oligopeptides. Longer chains (6 to 30 residues) are referred to as polypeptides. When the number of amino acids linked together exceeds 40 or more, the chain is referred to as a protein. T e different side chains found in

amino acids provide peptides and proteins with great diversity in both structure and function. Most peptides in the body, other than a few short peptides such as glutathione, are synthesized as larger precursor proteins, and the peptides are generated by proteolytic cleavage of the precursor.

Structure

The structure of peptides and proteins consists of four elements:

1. Primary structure is the sequence of amino acids in a peptide or protein. Post-translational modifications add to diversity.
2. Secondary structure is the specific organization of segments of the polypeptide backbone into structures that are termed (1) α-helix, (2), β-sheet and (3) β-turn. Random coil refers to segments that lack these structures.
3. Tertiary structure refers to the folding of the chain of amino acids into a three-dimensional structure. This structure may be stabilized by disulfide bonds between cysteine residues. Hydrophobic amino acids tend to fold into the interior, and charged and polar amino acids reside on the surface of the protein. Denaturation refers to the unfolding of proteins and the disruption of secondary and tertiary structures that occur with (1) increased temperature, (2) extremes of pH, (3) organic solvents, and (4) detergents or agents that disrupt hydrogen bonds. Extensive denaturation of proteins leads to irreversible loss of structure and function, and the protein may aggregate or precipitate.
4. Quaternary structure refers to the association of multiple peptide chains. Examples include (1) creatine kinase with two subunits, (2) lactate dehydrogenase with four subunits and (3) hemoglobin with four subunits.

In addition, ligands and prosthetic groups, such as heme in hemoglobin and cytochromes and lipids in lipoproteins, serve as additional structural elements. Proteins without their associated ligands are often referred to as apoproteins (e.g., apotransferrin without iron, apolipoproteins without lipid).

Many proteins are organized as a chain of smaller structural units or domains analogous to a string of beads. Similar domains are found in different proteins, but diversity in structure is achieved by assembly of domains in different combinations and three-dimensional configurations. Proteins have a variety of shapes, ranging from compact globular proteins that are nearly spherical to highly elongated fibrous proteins. Many proteins belong to families of homologous proteins that arose from duplication of ancestral genes. Examples of protein families in humans include the serpin (originally from serine proteinase inhibitor) superfamily with 36 members, including α_1-antitrypsin, α_1-antichymotrypsin, and antithrombin III, and the albumin family with three members, including albumin and α-fetoprotein.

Properties

Proteins have varying physical properties that are used for separation and analysis:

1. Molecular size. Proteins have varying molecular sizes. It is possible to separate proteins from small molecules by dialysis or ultrafiltration. Proteins of varying size are separated by (1) gel filtration chromatography, (2) gradient pore gel electrophoresis, or (3) ultracentrifugation. The size of most proteins increases substantially when they are denatured. Polyacrylamide gel electrophoresis[6] in the presence of the denaturing detergent sodium dodecyl sulfate is a high-resolution technique for separating proteins and estimating their molecular weight. Mass spectrometry separates peptides and proteins by their molecular mass.
2. Differential solubility. Protein solubility is affected by (1) pH, (2) ionic strength, (3) temperature, and (4) the dielectric constant of the solvent. Varying (1) pH, (2) salt concentration, or (3) concentration of an organic solvent like ethyl alcohol, are techniques used to selectively precipitate proteins. This has been used as a preparative technique for albumin and for some globulins.
3. Electrical charge. The variable charge and isoelectric points of proteins enable their separation by electrophoresis, **isoelectric focusing**, and ion exchange chromatography.
4. Differential adsorption. Liquid chromatography is performed in a variety of stationary phases. Reversed-phase chromatography serves as a valuable tool for separating peptides, but some proteins may precipitate or denature in the organic solvents typically used in this technique. Reversed-phase chromatography separates polypeptides and other molecules on the basis of their affinity for a hydrophobic stationary phase.
5. Specific molecular interactions. Highly specific molecular interactions such as binding of (1) an antibody with antigen, (2) a receptor with its ligand, or (3) an enzyme with a selective inhibitor or substrate have been used to bind a protein or a peptide to a stationary phase, while other proteins and peptides are removed. This is is usually termed affinity chromatography. Affinity purification of antibodies or proteins may be used as a preparative technique to prepare specific antibodies or proteins as assay components. Affinity capture is a step in many immunoassay methods.
6. Density. Density gradient ultracentrifugation is used to separate some protein complexes that have a different density when compared with most proteins. This is applies mainly to lipoproteins that have lower density as the result of a high content of lipid (refer to Chapter 23 on lipids and lipoproteins).

Analysis of Proteins

Analysis of proteins includes both qualitative and quantitative analysis.

Quantitative analysis employs a variety of approaches, including (1) physical methods, such as (a) dye binding, (b) direct absorbance measurements, (c) measurement of protein ligands such as lipids or metal ions, (d) selective precipitation, and (e) mass spectrometry; (2) activity measurements for components such as binding protein, protease inhibitors, complement factors, and coagulation factors; and (3) immunoassays. Qualitative analysis of proteins reveals changes in the structure of proteins through techniques such as

(1) electrophoresis, (2) chromatography, (3) genetic analysis, (4) functional assays (coupled with quantitative analysis to identify changes in specific activity), and (5) mass spectrometry.

Measurement of Total Protein Concentration

Measurement of the concentration of protein in solution simply by drying the solution and weighing the residue is a simple technique, but it is inaccurate because of (1) salts, (2) adsorbed water, and (3) other impurities such as carbohydrates or lipids that may remain after drying. Development of reference materials for specific proteins is a challenging task that usually requires extensive purification of the protein and assignment of values by weight or amino acid composition analysis after hydrolysis of the protein. Reference materials are then used to assign values to calibrators for specific assays. Calibration of assays for measuring the total protein content of mixtures may rely on calibration with a single purified protein such as albumin or with a representative mixture of proteins with an assigned calibrator value.

A variety of other methods are used to determine the total protein content of solutions, including the (1) Kjeldahl, (2) biuret, (3) direct spectrophotometric, (4) Folin-Ciocalteu (Lowry), (5) dye-binding, (6) refractometric, and (7) turbidimetric methods.

Kjeldahl Method

In the Kjeldahl method, the sample is digested with acid to convert nitrogen in the protein to ammonium ion, and the ammonium ion is measured. The ammonia nitrogen value is multiplied by a factor of 6.25 (to correct for the average nitrogen content of protein) to calculate total protein. This method is reproducible but (1) time-consuming, (2) inconvenient, and (3) impractical for routine use. Kjeldahl determination, however, still remains a means by which reference materials are characterized and validated. Nitrogen from small compounds such as urea also is measured, so that a precipitation step may be required.

Biuret Method

Under alkaline conditions, Cu^{2+} ions complex with peptide bonds in proteins. Binding shifts the absorption spectrum of Cu^{2+} ions to shorter wavelengths, leading to a color change from blue to violet that has been termed the biuret reaction. The absorbance change from the protein addition is measured spectrophotometrically at a wavelength of approximately 540 nm. The biuret reagent also usually contains tartrate salts to maintain the solubility of Cu^{2+} ions and iodide as an antioxidant. The absorbance change produced is approximately the same for each peptide bond in a polypeptide chain, except for bonds containing proline. Therefore, the absorbance is proportional to the number of peptide bonds and the amount of protein present in the reaction system, unless an unusual content of proline is present. A variety of (1) small compounds, (2) amino acids, (3) dipeptides, and (4) any peptide without proline react to some degree with the biuret reagent. Only the peptide component of glycoproteins reacts. The biuret method has moderate sensitivity and is useful for solutions with high protein concentrations such as serum or plasma. Analysis of serum has been known to be affected slightly by the presence of bilirubin or lipemia, so that a fasting specimen is preferred. Biuret based assays are commonly calibrated with reference solutions of albumin.

Direct Photometric Methods

The absorbance of ultraviolet (UV) light at 200 to 225 nm and 270 to 290 nm has been used to measure the protein content of biological samples. Absorbance of UV light at 280 nm depends primarily on the aromatic rings of tyrosine and tryptophan. Accuracy and specificity suffer from the variable content of these amino acids among individual proteins in a mixture and from the presence in body fluids of (1) free tyrosine, (2) free tryptophan, (3) uric acid, and (4) bilirubin, all of which also absorb light near 280 nm. Peptide bonds are responsible chiefly for UV absorption between 200 and 225 nm (70% at A_{205}); specific absorption by proteins at 200 to 225 nm is 10 to 30 times greater than at 280 nm. Measurement of protein concentration by this method may require removal of low-molecular-weight molecules before absorbance measurements are performed. Absorbance measurements have been used to assess the concentrations of purified proteins with a known extinction coefficient (absorbance per concentration). Also, absorbance measurements are often used to monitor protein and peptide elution in liquid chromatography and protein migration in capillary electrophoresis.

Dye-Binding Methods

Dye-binding methods depend on shifts in the absorbance spectra of dyes when they bind to proteins. Variable binding of dyes to different proteins is a limitation of such methods. Also, calibration with a protein mixture may be difficult to define consistently. Calibration with a pure protein such as albumin may not simulate binding to proteins in complex mixtures such as serum. With use of the dye Coomassie brilliant blue, **immunoglobulins** often give only 60% of the response of an equal concentration of albumin or transferrin. This dye binds peptide chains under acidic conditions, with increased absorbance at 595 nm. Dye-binding methods offer good sensitivity and low interference from small compounds. Assays using the dye pyrogallol red are used for analysis of protein concentrations in dilute fluids such as urine and cerebrospinal fluid.

Folin-Ciocalteu (Lowry) Method

This method is largely of historical interest. It responds to tyrosine and tryptophan content of proteins and was extensively used in the past as a sensitive method for total protein determination.

Refractometry

Refractometry (measurement of refractive index) has been used to rapidly assess high concentrations of protein. Accuracy decreases at protein concentrations <3.5 g/dL, at which salts, glucose, and other low-molecular-weight compounds begin to contribution more to refractive index. Refractometry is used in clinical laboratories more often to assess total solutes in urine specimens than to determine total protein.

Turbidimetric and Nephelometric Methods

Because of their speed and ease, nephelometric and turbidimetric methods are widely used to assay high-abundance proteins (see Chapter 9).

These techniques assess the formation of aggregates when a reagent is added to lower protein solubility or when an antibody is added to a protein. Turbidimetry measures changes in absorbance caused by the formation of aggregates. Many different reagents have been used to aggregate protein for turbidimetric assays, including (1) trichloroacetic acid, (2) sulfosalicylic acid, (3) sulfosalicylic acid combined with sodium sulfate, or (4) benzethonium chloride and (5) benzalkonium salts under alkaline conditions. These reagents form a fine precipitate of uniform, insoluble protein particles, which scatter incident light. Nephelometry measures the light reflected at an angle by the aggregates.

Precipitation methods sometimes have been used qualitatively to assess whether increased protein is present in urine that may be missed by urine dipsticks, which detect mainly albumin.

Analytically, turbidimetric and nephelometric measurements may be performed as an end point (equilibrium) method or as a kinetic (rate) method. Protein and antibodies must be in approximate equivalence for large aggregates to form. If large antigen or antibody excess is present, formation of aggregates is impaired, and falsely low values may be obtained. Limits of detection of turbidimetric and nephelometric assays are improved by the use of particle-enhanced assays, which use antibodies coupled to particles. One limitation of these direct optical methods is that turbid specimens such as lipemic sera may interfere with measurements. Some turbid specimens may need to be cleared of lipids or particulate material by high-speed centrifugation to enable accurate analysis.

Calibration of Total Protein Methods

Bovine or human albumin is used routinely to calibrate biuret methods, which react nearly equivalently with the peptide content of most proteins. Albumin (1) is available in high purity, (2) is highly soluble and stable, (3) is well characterized, and (4) contains no carbohydrate. Calibration of precipitation and dye-binding methods often uses a serum pool, with a normal albumin-to-**globulin** ratio. The total protein concentration of the calibrator is assigned using a biuret or Kjeldahl method. In sulfosalicylic acid precipitation methods, albumin provides about 2.5 times the turbidity that serum globulins do. When trichloroacetic acid precipitation is used, the difference between albumin and globulins is lessened.

Reference Intervals

The total protein concentration of serum obtained from healthy ambulatory adults is about 6.4 to 8.3 g/dL, and for adults at bed rest, 6.0 to 7.8 g/dL. Plasma usually contains a protein concentration about 0.3 g/dL higher (unless diluted with a volume of liquid anticoagulant such as citrate solution) because fibrinogen is removed from plasma when it is clotted to form serum. The reference intervals for neonates and young children and for adults over age 60 are slightly lower.

Electrophoretic Techniques

Electrophoresis is used in clinical laboratories to study and measure qualitative and quantitative changes in the protein content of biological fluids, including serum, urine, and CSF (see Chapter 11). Common electrophoretic techniques for serum include the use of zone electrophoresis on cellulose acetate or agarose gel and the use of capillary zone electrophoresis. The mobility of proteins in zone electrophoresis depends on the ratio of charge to size, so it is a good technique for detecting protein variants that differ in charge. Isoelectric focusing is an equilibrium technique that is useful for separating charge variants of proteins; it has been applied to analysis of genetic variants of proteins such as α_1-antitrypsin and hemoglobin and to analysis of immunoglobulin (Ig) in cerebrospinal fluid. Basic principles of electrophoresis and specialized techniques such as two-dimensional (2D) electrophoresis and blotting techniques are described in Chapter 11.

Serum Protein Electrophoresis

Electrophoretic analysis of serum or plasma typically is performed in clinical laboratories by zone electrophoresis on supports such as sheets of agarose gel or cellulose acetate or in an open capillary tube. In zone electrophoresis, the supports have minimal interaction with the proteins, and proteins migrate according to the ratio of their charge to hydrodynamic size (resistance to migration in the fluid). Usually, serum electrophoresis is performed at pH 8.6 in a low ionic strength buffer. A narrow zone of specimen is added, and a current is applied. Proteins with a negative charge at pH 8.6 move toward the anode (positive pole), and proteins with a positive charge move toward the cathode (negative pole). After electrophoretic separation, proteins on a solid support are stained with dyes such as (1) amido black, (2) Ponceau S, or (3) Coomassie brilliant blue. The intensity of staining individual bands of protein generally is proportional to the amount of protein in a band, although glycoproteins and lipoproteins tend to stain less intensely with commonly used protein stains. Densitometry of the stained bands provides quantitative assessment of each band. Initial methods for serum protein electrophoresis separated serum into four bands, which, from the anodal end, were termed albumin and α-, β-, and γ-globulins. Later improvements in resolution further resolved the α- and β-globulins, each into two components (α_1 and α_2 and β_1 and β_2). Plasma proteins historically were classified according to their mobility on zone electrophoresis. This classification still is often applied to individual proteins and to the naming of proteins. Table 18-3 lists a number of plasma proteins, together with their electrophoretic region.

Special fat stains are needed to visualize lipoproteins that migrate in bands of variable mobility in the(1) α_1-region (high-density lipoprotein [HDL]), (2) the α_2- or pre-β-region (very low-density lipoprotein), and (3) the β_1-region (low-density lipoprotein [LDL]), or that (4) remain at the origin (chylomicrons). Refer to Chapter 23 for a discussion of the lipoproteins

TABLE 18-3 Properties of Selected Plasma Proteins

Electrophoretic Region	Protein	Half-life	pI	MW (daltons)	Comments
	Retinol-binding protein (RBP)	12 h	4.9	21,000	Transports retinol (vitamin A); bound to prealbumin
	Prealbumin (Transthyretin)	48 h	4.7	54,980	Transports thyroid hormones, RBP
Albumin	Albumin	15-19 d	4.7-5.5	66,400	Transports fatty acids, bilirubin, and other compounds; maintains oncotic pressure
α_1	High-density lipoprotein (HDL)	About 5 d		180,000- 360,000	Density >1.063 g/dL; about half protein; apolipoprotein A-I is main protein
	α_1-Antitrypsin (AAT)	4 d	4.8	51,000	Protease inhibitor, especially elastase
	α_1-Acid glycoprotein (AAG; orosomucoid)	5 d	2.7-4	40,000	Binds steroid hormones and cationic drugs
	α_1-Fetoprotein (AFP)	3-6 d	4.8-5.2	69,000	Principal fetal protein; albumin analogue
α_2	Haptoglobin (Hp, HAP)	2 d	4.1 for Hp 1-1	85,000-840,000	Binds hemoglobin; reduced by hemolysis
	α_2-Macroglobulin (AMG)	5 d	5.4	720,000	General protease inhibitor
	Ceruloplasmin (CER)	4-5 d	4.4	132,000	Oxidizes iron to ferric state
β_1	Transferrin (Tf)	7 d	5.7	79,600	Transports iron
	C4	2-3 d	6.0-6.4	206,000	Complement factor
	Low-density lipoprotein (LDL)	About 3 d		About 3×10^6	Density 1.019-1.063 g/mL; about 20% protein; main protein is apolipoprotein B
β_2	C3	2-3 d	5.8	180,000	Complement factor
	β_2-Microglobulin (BMG)	2-5 h	5.8	11,800	Small component of HLA shed from cell surfaces
	IgA	6 d	5.2-6.6	160,000	Major secretory antibody
β-γ border	Fibrinogen	4 d	5.1-6.3	340,000	Forms fibrin clots
γ	IgG	24 d	5.0-9.5	≈150,000	Most abundant antibody
	IgM	5 d	5.1-7.8	900,000	Antibody from primary response
	C-reactive protein (CRP)	20 h	6.2	≈115,000	Nonspecific defense; binds phospholipid

that are major plasma proteins. Efficient visualization of some glycoproteins, such as α_1-acid glycoprotein, requires staining for carbohydrate sidechains.

Applications of capillary electrophoresis rely on direct spectrophotometric detection of proteins at a wavelength of about 200 to 225 nm, rather than staining of a solid support. Proteins migrate through the detector according to their electrophoretic mobility combined with electroendosmotic flow, which is generated by application of an electrical potential. Use of narrow-bore capillaries allows the use of very high voltages that speed separation. Detection of proteins by their ultraviolet absorbance yields better quantitative results and slightly different peak heights for different components than are produced by staining of gels. Low-molecular-weight compounds present in serum at high concentrations, such as radiocontrast dyes, potentially showing up as interfering peaks. Analysis of urine proteins by capillary electrophoresis generally requires some processing of specimens to concentrate proteins and to remove low-molecular-weight compounds that may interfere with analysis, because a smaller amount of protein and a larger number of low-molecular-weight solutes are present in urine.

Figure 18-2 shows comparisons of serum protein electrophoresis (SPE) separations on cellulose acetate and agarose gels with capillary zone electrophoresis (CZE). In this figure, the order of migration of components on the gels and in CZE is shown as reversed, and a marker is added to the CZE analysis to serve as an internal standard. Note that the CZE analysis was completed within 120 seconds. Albumin is the main component in each analysis of the specimen in row A, representing a normal profile. In row B, a second major peak is due to large amounts of a **paraprotein** in the γ-region. Row C shows patterns for a specimen with small amounts of a paraprotein in the γ-region.

The concentrations of many proteins are too low for them to be seen as distinct stained bands, or they are overshadowed by proteins of higher concentrations that migrate near them. However, from changes in intensity of the small number of major bands and in the overall distribution of proteins, it is often possible to interpret patterns as consistent with particular disease processes, such as (1) acute inflammation, (2) nephrotic syndrome, or (3) chronic inflammation. Some examples are shown in Figure 18-3, together with quantitative measurements of selected proteins. In practice, however, these disorders usually are assessed with the use of specific quantitative tests; the main current application of SPE is for the detection or quantification of monoclonal immunoglobulins that occur in disorders such as **multiple myeloma**. Monoclonal immunoglobulins usually appear as sharp bands in the γ- or β-region. They differ from normal immunoglobulins, which migrate as a diffuse zone, mainly in the γ-region, in terms of the sequence and charge heterogeneity of polyclonal immunoglobulins.

Immunofixation Electrophoresis

An example of immunofixation electrophoresis (IFE) is shown in Chapter 15 on immunochemical techniques. IFE relies on

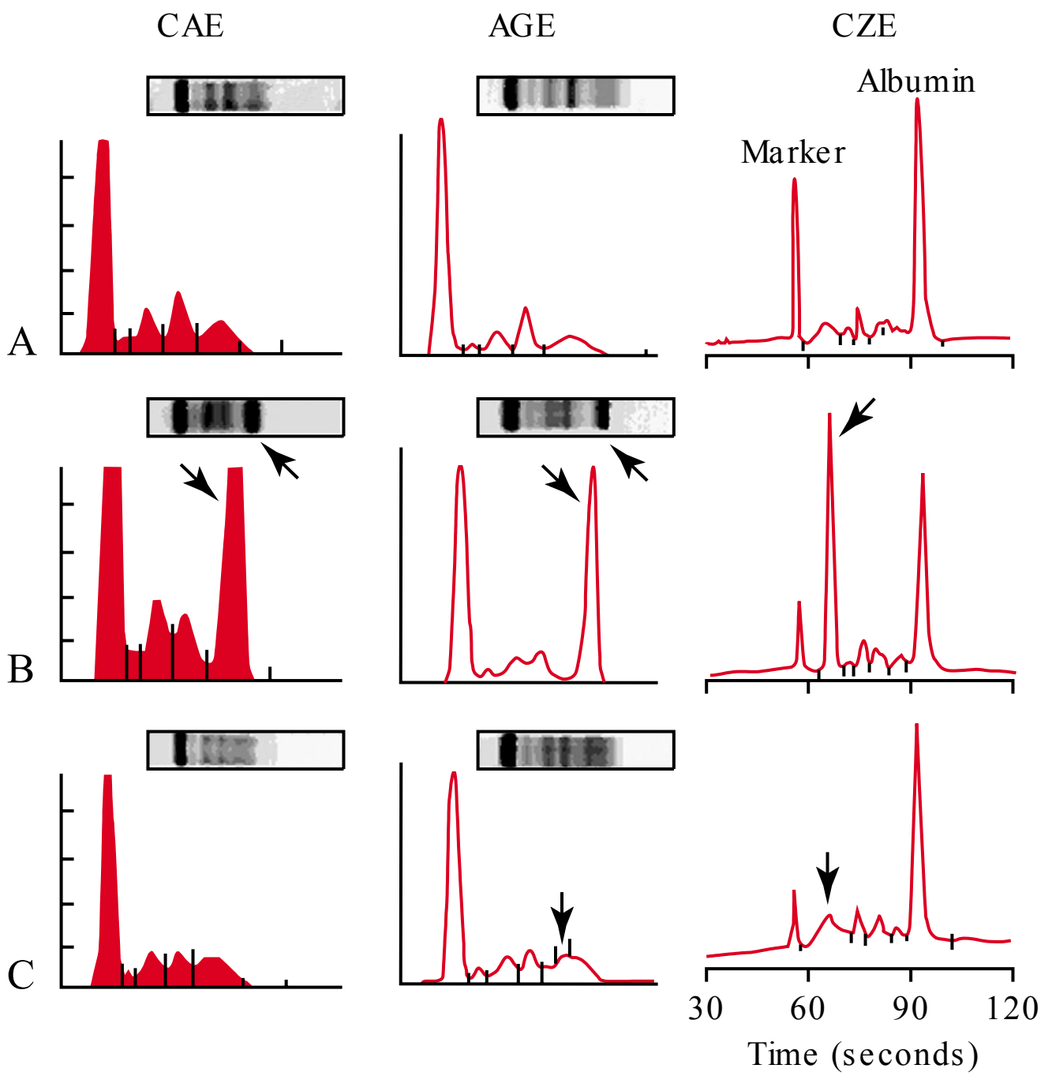


Figure 18-2 Rapid protein electrophoresis of serum protein; comparison with scanning densitometry profles obtained from cellulose acetate (CAE) and agarose (AGE) electrophoresis. A, Normal serum. B, Patient serum containing a large M-protein. C, Patient serum containing a small monoclonal protein. Arrows indicate the position of the monoclonal proteins. (From Karcher RE, Landers JP, Electrophoresis. In: Burtis CA, Ashwood ER, Bruns DE eds. Tietz textbook of clinical chemistry, 5th edition. Philadelphia: WB Saunders, 2012:299.)

the application of specific antibodies directed against classes of immunoglobulin (IgG, IgM, IgA) or κ- and λ-light chains on top of several lanes of an agarose gel after separation of serum proteins. The antibodies form immune precipitates through complexation in the gel with their specific antigens. Other proteins that are not bound by antisera are washed out of the gel, and the remaining bands of immunoprecipitate are stained. Polyclonal immunoglobulins form diffuse bands. Monoclonal immunoglobulins form sharp bands, which react with only a single type of light chain and usually with antibody to a single class of Ig. Sometimes multiple dilutions of serum must be run to provide the right ratio of serum immunoglobulins to antiserum to form an immunoprecipitate in the gel. Antigen and antibody must be approximately equivalent to form an immunoprecipitate. IFE offers more sensitive detection of monoclonal components than is provided by SPE. It also demonstrates the monoclonal nature of immunoglobulins in a band (reactivity with only a single type of light chain and immunoglobulin class) and provides typing of the class of antibody.

Electrophoretic Separation of Urinary Proteins

The procedure for electrophoresis of urine on agarose gel is identical to that for serum, with the exception that usually urine specimens are concentrated about 100-fold before application. Concentration of specimens usually is performed by ultrafiltration, which retains proteins while removing water and low-molecular-weight compounds. Exceptions are specimens with high protein concentrations and procedures modified so by using more sensitive staining methods. Electrophoresis of urine is commonly used to detect the presence of free monoclonal immunoglobulin light chains (also sometimes termed Bence-Jones proteins) or other low-molecular-mass proteins typical of tubular proteinuria.

Mass Spectrometry

General principles of mass spectrometry (MS) are described in Chapter 13. MS relies on the separation of ions in an electrical field in a vacuum. Separations are independent of shape and are based purely on the mass-to-charge ratio (m/z). T is is advantageous for proteins that have complex and varying shapes. The large size and multiple charge states of proteins pose some challenges in MS, however. When electrospray ionization (ESI) is used, small fluid droplets containing a single protein molecule are evaporated to leave an isolated protein ion, which usually is multiply charged, and different ions of the same protein have varying charge (varying z). Therefore, a purified protein yields multiple peaks separated according to their m/z, with multiple values of z. Many proteins also have heterogeneity in m because of variable modifications such as (1) phosphorylation, (2) glycosylation, (3) oxidation, and (4) deamidation. Therefore, many proteins yield a very complex pattern on ESI-MS, and dividing the ions into many peaks lowers the instrument's limit of detection. Analysis of proteins by ESI-MS poses a significant computational problem to "deconvolute" the pattern of multiple peaks into single peaks corresponding to the protein mass. T is has been accomplished and variants in protein structure identified when the mixture is not too complex. An alternative approach in addressing the problem of protein heterogeneity and multiple charge states is to cut proteins into smaller peptides for analysis by MS. Fragmentation of proteins results in some loss of information about the intact protein structure, but peptides are suitable for highly precise qualitative analysis by ESI-MS. Two stages of MS with an intermediary fragmentation step (tandem MS or MS/MS) are used for rapid sequencing of peptides and identification of post-translational modifications. MS has served as a key tool for identifying the sites and structures of the wide range of post-translational modifications of proteins. MS also is used to identify changes in the primary sequence of proteins, although increasingly this is achieved by genetic analysis rather than by direct analysis of the protein.

Accurate quantitative analysis of protein-derived peptides is performed using appropriate internal standards. The quantitative analysis of peptides derived from proteins is being used increasingly as a method of assessing concentrations of proteins. For example, this approach has been used as a reference method for measuring hemoglobin A_{1c} and as a clinical assay for measuring thyroglobulin. Peptides in the circulation, such as C-peptide, are suitable for direct quantitative analysis using appropriate internal

standards. Accurate quantification by MS usually requires some type of internal standardization because efficiency of ionization and fragmentation (in tandem MS) of different components often is quite variable.

An alternative approach to MS analysis of proteins is matrix-assisted laser desorption ionization (MALDI). With this ionization technique, proteins are dried on a target plate, together with a light-absorbing compound that serves as the matrix. A pulse of light from a laser vaporizes some of the matrix, and energy is transferred to the protein, releasing individual protein ions from the surface. This is a relatively "soft" ionization technique, which generates ions without fragmenting large polypeptide chains; for proteins with noncovalently bound subunits, each subunit is released as an individual ion. An important aspect of MALDI ionization is that the ions produced, even for a large molecule such as a protein, usually acquire only a single charge, $z = 1$. Therefore, only a single main peak is obtained for each protein, and it is easy to calculate the mass (m) for m/z when $z = 1$. The challenge presented by proteins is that many mass spectrometers using quadrupoles or ion traps have an upper limit of analysis of 3000 or less for m/z and cannot analyze the large ions generated from proteins by MALDI. Analysis of proteins, then, requires use of a time-of-flight (TOF) mass spectrometer in the combined technique of MALDI-TOF-MS. TOF-MS measures how long an ion takes to move in an electrical field from the target plate to the detector. Light ions arrive faster than heavy ions, and with appropriate calibration, the masses of proteins are determined. This is technique has been used to analyze proteins with a molecular weight of 100 kDa or more, although resolution declines for larger molecules. MALDI-TOF-MS is also used to analyze complex mixtures and to determine precisely the mass of small proteins and peptides; it has been used to examine the patterns of peptides and small proteins in biological fluids. The power of this approach has been widely applied in clinical laboratories for identification of bacteria that are isolated by culture techniques. Bacteria can be identified rapidly when the pattern of proteins from an individual colony is compared with an extensive database of patterns.

Plasma and Serum Proteins

As discussed in Chapter 6, plasma is the fluid portion of the blood in which the cells are suspended. It differs from serum in that it contains fibrinogen and related proteins that are removed from serum when blood clots. The major protein components in plasma are often considered collectively as the **plasma proteins**.[1] Many proteins have similar concentrations in serum and plasma. Serum has lower viscosity and about 5% lower total protein concentration owing mainly to loss of fibrinogen during clotting of plasma to form serum. Serum is depleted of fibrinogen and some coagulation factors, and increased numbers of some factors are released from platelets and peptides generated during coagulation. Serum and plasma are sometimes considered to consist of two fractions—albumin, which makes up slightly more than half of the total protein, and the other proteins, which are classified as **globulins**. The concentration of globulins usually is calculated as follows:

$$\text{Globulins (g/dL)} = \text{Total protein (g/dL)} - \text{Albumin (g/dL)}$$

Globulins tend to be characterized as proteins that precipitate in water (such as dialysis of serum vs. water) and that redissolve when the salt concentration is raised. Proteins with this characteristic sometimes are termed euglobulins. Albumin remains soluble at low ionic strength. The solubility characteristics of globulins must be considered when serum or plasma is diluted extensively with water. Sometimes precipitation of protein may occur if water rather than saline is used for dilutions.

The most abundant plasma proteins are mainly proteins secreted by the liver or by B lymphocytes. Table 18-3 lists characteristics of a number of the major plasma proteins, organized according to their electrophoretic mobility in zone electrophoresis at pH 8.6. The reference intervals for several of these proteins are listed in Table 18-4 and are based on calibration with European Reference Material ERM-DA470.

For most clinical applications, quantitative changes in specific proteins are the major diagnostic indicator. In a few cases, qualitative changes assessed by techniques such as electrophoresis serve as diagnostic indicators. Plasma proteins are variably distributed between the intravascular space and the larger extravascular space. Large proteins are more likely to be retained in the intravascular space. Small proteins and peptides are distributed more evenly between intravascular and extravascular

TABLE 18-4 Interim Consensus Reference Intervals for 14 Plasma Proteins in Human Serum Referenced to ERM-DA470*

Protein	g/L	mg/dL
α_1-Acid glycoprotein	0.5-1.2	50-120
Albumin	35-52	3500-5200
α_1-Antitrypsin	0.9-2.0	90-200
C3*	0.9-1.8†	90-180†
C4	0.1-0.4	10-40
Ceruloplasmin	0.2-0.6	20-60
C-reactive protein	<0.005	<0.5
Haptoglobin	0.3-2.0	30-200
IgA	0.7-4.0	70-400
IgG	7-16	700-1600
IgM	0.4-2.3	40-230
Prealbumin (transthyretin)	0.2-0.4	20-40
α_2-Macroglobulin	1.3-3.0	130-300
Transferrin	2.0-3.6	200-360

These reference intervals apply to adults between 20 and 60 years of age.
*ERM-DA470 (European Reference Material, Clinical [D] Proteins [A]) was formerly known as Certified Reference Material 470 (CRM470).
†Values are slightly lower in fresh samples (assayed <8 h after draw).
From Dati F, Schumann G, Thomas L, et al. Consensus of a group of professional societies and diagnostic companies on guidelines for interim reference intervals for 14 proteins in serum based on the standardization against the IFCC/BCR/CAP reference material (CRM470). Eur J Clin Chem Clin Biochem 1996; 34:517-20.

spaces. A slight redistribution of fluid is noted with movement from lying down to standing up. Consequently, plasma protein concentrations are slightly lower when collected from a patient who is lying down, because of the higher intravascular volume. If a tourniquet is applied for a prolonged time, a slight hemoconcentration is noted along with an increase in both cellular and protein components in the vein, while fluid passes into the extravascular space. The state of hydration of a patient may also slightly affect the concentration of all plasma proteins. Dehydration leads to increased protein concentration.

Several physiological and pathological factors, such as (1) nutritional status, (2) liver function, (3) physiological changes, and (4) therapeutic changes in steroid hormone concentrations, selectively affect the concentrations of subsets of plasma protein. One of the most important factors affecting clinical measurements of plasma protein concentrations in disease is the **acute-phase response** (APR). The APR is a systemic response to (1) infection, (2) tissue injury, or (3) inflammatory processes,[2] resulting in fever, increased white blood cell count, and changes in the concentration of many plasma proteins.* The proteins affected are known as acute-phase proteins (APPs). Proteins such as (1) α_1-antitrypsin, (2) α_1-acid glycoprotein, (3) haptoglobin, (4) ceruloplasmin, (5) C4, (6) C3, (7) fibrinogen, (8) C-reactive protein (CRP),[9] and (9) serum amyloid A show increased concentrations in response to an APR and are known as positive APPs. In extreme cases, concentrations of CRP and serum amyloid A have been known to increase up to 1000-fold from a low initial baseline value. The concentration of other plasma proteins, including (1) transthyretin, (2) albumin, and (3) transferrin, are decreased and they are known as negative APPs. Changes in plasma protein concentrations are triggered by interleukin-6 (IL-6) and other cytokines. Plasma concentrations of individual APR proteins change at different rates after the initial trigger. Procalcitonin is a rapidly responding APP that has been applied as an indicator of whether patients are at risk for bacterial infection. In practice, measurement of APPs assists in detection of inflammation, and sequential measurements of proteins such as CRP are used to monitor the progress of the inflammation or its response to treatment. Increased erythrocyte sedimentation rate (ESR) provides an alternative means of measuring inflammatory responses. Fibrinogen concentrations are considered to be a major determinant of ESR; therefore ESR probably reflects changes in fibrinogen concentration in the APR.

Chronic infection often yields a different pattern of plasma proteins than is seen in acute infection. In chronic infection, such as infection with hepatitis B or C and tuberculosis, immunoglobulins are often increased.

Concentrations of plasma proteins depend on their (1) rates of synthesis, (2) extracellular distribution, and (3) rates of clearance. Proteins and peptides substantially smaller than albumin are cleared from the circulation by glomerular filtration, unless they are bound to larger carriers, such as small apolipoproteins bound to lipoprotein particles or retinol-binding protein bound to prealbumin. Peptides and small proteins with half-lives of about 2 hours are cleared under conditions of normal kidney function, and they accumulate to higher concentrations in kidney failure. Examples of small proteins that accumulate in kidney failure are (1) β_2-microglobulin, (2) cystatin C, (3) Ig light chains, (4) complement factor D, and (5) retinol-binding protein. Some bioactive peptides in plasma, such as (1) insulin, (2) intact parathyroid hormone, and (3) kinins, have circulating half-lives of only a few minutes, indicating receptor-mediated clearance or degradation by peptidases. Proteins of the size of albumin or larger generally have a half-life with an upper limit of about 7 days as determined by pinocytosis (introduction of fluids into a cell) and degradation of proteins by cells. Two exceptions to this are albumin and IgG, which have a receptor-mediated process that recycles these proteins from pinocytotic vesicles. The recycling mechanism extends the half-lives of these proteins several-fold. Many proteins are subject to uptake by specific receptors or to degradation by proteolysis. Half-lives well under 7 days for a large protein suggest the presence of clearance mechanisms in addition to pinocytosis.

*In 1992, the Consensus Conference Committee of the American College of Chest Physicians/Society of Critical Care Medicine produced and promulgated guidelines that recommend that the term "Systemic Inflammatory Response System (SIRS)" be used instead of "Acute Phase Reaction (APR)." Further information on this issue can be found in Chapter 27.

Individual Plasma Proteins

Prealbumin (Transthyretin) and Retinol-Binding Protein (RBP)

Prealbumin and retinol-binding protein (RBP) are transport proteins. RBP is bound to prealbumin, which was named for its electrophoretic mobility. In 1981, the term transthyretin was proposed for prealbumin to reflect its binding and transport of thyroid hormones and RBP. Both prealbumin and transthyretin are commonly used terms.

Biochemistry and Function

Prealbumin is a nonglycosylated protein (molecular mass, 55 kDa) composed of four identical subunits that associate to form a hollow core containing T_3- and T_4-binding sites. It binds and transports approximately 10% of both hormones. Prealbumin binding of one hormone molecule decreases the binding affinity of the second (a process known as negative cooperativity) so that only one site is normally occupied. Prealbumin is synthesized in the liver and to a lesser extent in the choroid plexus of the central nervous system, accounting for the relatively high concentration of prealbumin in CSF. Its synthesis is stimulated by (1) glucocorticosteroid hormones, (2) androgens, and (3) many nonsteroidal anti-inflammatory drugs (NSAIDs), including aspirin.

RBP is a small (21 kDa), monomeric transport protein for all-trans-retinol, the active form of vitamin A. RBP synthesis requires zinc, and retinol is required for its transport out of the Golgi apparatus. When circulating in the plasma, RBP is present in a 1:1 complex with prealbumin, slowing glomerular filtration of RBP. Uptake of retinol by target cells is followed by dissociation of the prealbumin/RBP complex and clearance of apoRBP (RBP without retinol) from the circulation by the kidneys. RBP is reabsorbed by the proximal renal tubular cells and catabolized. RBP has a usual half-life of only about 12 hours, but it is extended in renal failure.

Clinical Significance

If vitamin A intake is adequate and renal function is normal, concentrations of prealbumin and RBP tend to rise and fall in parallel. Serum RBP is increased in chronic renal disease, including diabetic nephropathy, as the result of decreased renal clearance. Interest in RBP has been stimulated by recognition that it is synthesized by adipose tissue and that excretion of RBP may be increased, together with other products of fat cells such as leptin, in syndromes of insulin resistance. Concentrations of both prealbumin and RBP are increased with corticosteroid or NSAID therapy and in Hodgkin disease.

Decreased concentrations of RBP are seen primarily with (1) liver disease, (2) protein malnutrition, and (3) the APR. Zinc deficiency is characterized by low serum concentrations of both RBP and vitamin A. The short half-life of RBP allows its concentration to respond rapidly to changes in nutrition.

Prealbumin concentrations are often used as an indicator of protein nutrition because of its relatively short half-life and high proportion of essential amino acids. It responds much more rapidly to nutritional changes than do proteins such as albumin. Concentrations fall in (1) inflammation and malignancy (2) cirrhosis of the liver and (3) protein-losing diseases of the gut or kidneys. Prealbumin is a negative APP. Therefore, a sensitive APP such as CRP should be assayed along with prealbumin when concentrations are used to estimate nutritional status. History and physical examination are additional important aspects of nutritional assessment.

Several genetic variants of prealbumin have been described, some of which are associated with increased (familial euthyroid hyperthyroxinemia) or decreased T_3 and T_4 binding. Several variants aggregate to form amyloid fibrils in various tissues. These autosomal dominant hereditary amyloidoses can have various clinical presentations and sites of amyloid deposition, including the heart, the peripheral nerves, and the brain. Variants have been identified by mass spectrometry or by genetic analysis.

Laboratory Considerations

Prealbumin migrates as a minor band anodal to albumin on routine serum electrophoresis. Prealbumin and RBP usually are measured by immunoturbidimetric or immunonephelometric methods. The adult reference interval for RBP is 3.0 to 6.0 mg/dL, and for prealbumin, 20 to 40 mg/dL (see Table 18-4). On the basis of these reference intervals, approximately three times as many prealbumin molecules as RBP molecules have been identified, so that less than half of the prealbumin molecules are complexed with RBP.

Albumin

Albumin is a nonglycosylated protein of 585 amino acids with calculated molecular weight of 66,438 Da. It is the most abundant protein in plasma from midgestation until death, usually accounting for slightly more than one-half of plasma protein mass. Because of its high plasma concentration and medium size, albumin is the major contributor to colloidal oncotic pressure (COP) in the vascular space. This force helps to retain fluid within the vascular space, and albumin solutions sometimes have been infused to assist in maintaining intravascular volume. When albumin concentrations are decreased, the tendency for fluid to go into extravascular spaces and to produce edema is increased. Albumin is the major protein component of most extravascular body fluids, including (1) CSF, (2) interstitial fluid, (3) urine, and (4) amniotic fluid. Approximately 60% of the total body albumin is found in the extravascular space, although the concentration is higher in the vascular space (plasma concentration). Albumin is highly soluble in water because of its high abundance of charged amino acids. It has a net charge of about −12 at neutral pH. At normal concentrations, albumin contributes about 6 to 10 mmol/L to the anion gap. Low albumin concentrations contribute to a decreased anion gap.

Biochemistry and Function

Albumin is synthesized by the hepatic parenchymal cells. The synthetic reserve of the liver is substantial; in the nephrotic syndrome, the synthetic rate has been known to increase to threefold above normal. The synthesis of albumin is controlled primarily by COP and secondarily by protein intake. Catabolism occurs primarily by pinocytosis in all tissues, but albumin, together with IgG, has a half-life that is extended by about two- to fourfold because of the action of the neonatal IgG receptor that selectively recycles these two proteins from pinocytosed fluids. The usual half-life of albumin is 15 to 19 days. Most other plasma proteins have half-lives of 7 days or less. Albumin has multiple functions, including maintenance of COP and binding and transport of a large number of compounds, including (1) free fatty acids, (2) bilirubin, (3) calcium, (4) thyroid and steroid hormones, (5) drugs, and (6) thiol-containing compounds.

More than 80 genetic variants of albumin have been reported. Many variants have altered electrophoretic migration, resulting in so-called bisalbuminemia (two bands for albumin), for heterozygotes. Bound drugs and metabolites also may change the electrophoretic migration of albumin. A few variants have increased binding affinities for thyroxine (T_4). Affected individuals have increased serum T_4 but are euthyroid and have normal thyrotropin concentrations.

Clinical Significance

Increased concentrations of albumin are seen with dehydration or prolonged tourniquet time or with specimen evaporation before analysis. Therefore high albumin concentrations suggest problems with patient hydration or specimen handling. Decreased concentrations are seen in a multitude of clinical conditions.

Analbuminemia. Only about 20 families with this rare genetic deficiency have been reported. Individuals with analbuminemia have plasma albumin concentrations less than 0.5 g/L. Symptoms often are absent or consist of mild edema and dyslipidemia.

Inflammation. Albumin is a negative APP and acute inflammation and chronic inflammation are common causes of hypoalbuminemia. Inflammatory processes decrease plasma

albumin by (1) increasing capillary permeability, allowing more albumin to enter the extravascular space, (2) decreasing hepatic synthesis of albumin in response to factors such as IL-6, (3) stimulating catabolism, and (4) slowing synthesis in response to COP contributions of positive APPs.

Hepatic Disease. The liver has synthetic capacity to maintain albumin concentration until parenchymal damage results in greater than 50% loss of function. Additional mechanisms may contribute to decreased albumin concentrations in many cases of liver disease, including (1) nutritional deficiency, (2) increased distribution into the extravascular space, and (3) direct inhibition of synthesis by toxins such as alcohol.

Urinary Loss. Normally, the glomerular filtration barrier efficiently prevents entry into the urinary ultrafiltrate by proteins the size of albumin or larger. Usually, only 1 to 2 g/d of albumin pass through the glomerular barrier, and 99.9% of albumin in the glomerular ultrafiltrate is taken up by the proximal tubules of the kidney, where it is degraded. Only about 10 mg/d of albumin is normally excreted in urine. Small increases in albumin excretion to >30 mg/d indicate early stages of glomerular or tubular injury and risk of progression to more severe kidney disease. This has been termed microalbuminuria. (Note: "micro" refers to excretion of small amounts, not a smaller form, of albumin). Nonpathological increases in urine albumin excretion sometimes are observed with postural changes, strenuous exercise, and fever. Collection of first or second voided urine specimens in the morning may minimize postural effects. Severe glomerular injury produces the nephrotic syndrome, which is characterized by excretion of >3.5 g/d of protein, which is mainly albumin. In the nephrotic syndrome, the kidney maintains some size selectivity. Concentrations less than 200 kDa of protein such as albumin generally are substantially decreased, even though hepatic production is increased. Concentrations of a few very large proteins, such as α_2-macroglobulin (AMG) and apolipoprotein B–containing lipoproteins, are increased.

Gastrointestinal Loss. Inflammatory disease of the intestinal tract is associated with increased gastrointestinal (GI) loss of albumin with, losses of albumin being as great as renal losses in the nephrotic syndrome.

Protein-Energy Malnutrition (Marasmus). Albumin concentrations help to detect and monitor protein nutritional status. Responses to dietary intake are slow because of the long half-life of albumin. The APR often has to be considered as a potential complicating factor in patients with low albumin concentrations.

Burn Injury. Patients with burn injury have been observed to experience severe loss of albumin from wounds. Severely decreased albumin concentrations with massive burn injuries probably are related to combined effects of epithelial losses, accelerated catabolism, and the APR.

Edema and Ascites. Edema and ascites usually are secondary to increased vascular permeability, rather than to hypoalbuminemia per se. Plasma albumin concentrations are decreased as a result of redistribution of albumin into extravascular spaces.

Laboratory Considerations

Most clinical laboratories assay albumin in plasma or serum samples using dye-binding methods, which rely on a shift in the absorption spectrum of dyes such as bromcresol green (BCG) or purple (BCP) upon albumin binding. The affinity of these dyes is higher for albumin than for other proteins, and partial specificity is provided for albumin. BCP generally is slightly more specific for albumin and yields lower values than BCG, particularly in patients with kidney disease. Albumin concentration is considered an important indicator of adequate nutrition in patients with kidney failure. Nutritional supplementation usually is recommended for patients with kidney failure and albumin <4 g/dL as determined by a BCG method. The dye-binding assays tend to have decreased accuracy when the serum protein pattern is abnormal. Immunoturbidimetry and nephelometry offer greater specificity and accuracy for albumin measurement, along with the lowered limits of detection needed for specimens with low albumin concentrations, such as urine and cerebrospinal fluid. Albumin concentrations can be calculated from densitometric scans of electrophoretic patterns, together with total protein measurements, but this approach usually is associated with lower accuracy and precision. Reference intervals are listed in Table 18-4.

High-Density Lipoprotein

High-density lipoprotein (HDL) formerly was termed α-lipoprotein on the basis of its electrophoretic mobility (see Chapter 23 for a more detailed discussion of lipoproteins), but it is not visualized satisfactorily by protein stains. It is characterized by high density (>1.063 g/mL) because of its content of about 50% protein and phospholipid as a major lipid component. Apolipoprotein A-I of 29 kDa is the major protein, although small amounts of many other proteins are present. High concentrations of HDL, usually measured as the cholesterol in HDL or as apolipoprotein A-I, lower the risk of cardiovascular disease. Apolipoprotein A-I is a negative APP that is considered to have anti-inflammatory properties. In inflammatory states, the composition of HDL may change as amounts of apolipoprotein A-I decline, and it may be replaced by serum amyloid A.

α_1-Acid Glycoprotein (AAG)

α_1-Acid glycoprotein (AAG), also known as orosomucoid, is a member of the lipocalin family of proteins that bind lipophilic substances. AAG actually consists of two proteins that are products of closely homologous genes, which differ in only 21 out of 183 amino acid residues.

Biochemistry and Function

AAG contains 183 amino acids and a total molecular mass of about 40 kDa, of which approximately 45% is carbohydrate, including about 12% sialic acid. The oligosaccharide structures and charge of AAG change slightly with inflammation, as do many proteins. It is synthesized mainly by hepatic parenchymal cells. Intact AAG has a half-life of about 3 days, but when sialic acid is lost from its oligosaccharides, it is

cleared within a few minutes by hepatic asialoglycoprotein receptors.

AAG binds a variety of lipophilic hormones, such as progesterone, and basic drugs, including (1) propranolol, (2) quinidine, (3) chlorpromazine, (4) cocaine, and (5) benzodiazepines. Binding of drugs to AAG increases the plasma drug concentration while reducing the proportion of drug that is free and bioactive. Because AAG concentrations may change several-fold in the APR, interpretation of total drug concentrations for some drugs requires measurement of AAG or alternative measures of free rather than total drug concentrations.

Clinical Significance

AAG is a positive APP. Plasma concentrations often increase several-fold in APRs, especially in GI inflammatory disease and malignant neoplasms. Concentrations are increased by corticosteroids and by some NSAIDs. Estrogens (e.g., from pregnancy, from oral contraception) decrease synthesis of AAG. Concentrations also are low in protein-losing syndromes, such as nephrotic syndrome.

Laboratory Considerations

Although AAG is one of the highest-concentration proteins in the α_1-globulin region, on routine serum electrophoresis, it does not stain satisfactorily with protein stains because of its high CHO content. It is visualized with the use of periodic acid–Schiff or other carbohydrate stains. AAG usually is quantified by immunochemical methods, including turbidimetry and nephelometry. Reference intervals are listed in Table 18-4.

α_1-Antitrypsin

α_1-Antitrypsin (AAT) is a serpin (serine proteinase inhibitor) that inactivates serine proteases such as neutrophil elastase that are structurally related to trypsin.[10] Other serpins include (1) α_1-antichymotrypsin, (2) α_2-antiplasmin, (3) antithrombin III, and (4) C1 inhibitor.

Biochemistry and Function

AAT is synthesized primarily by hepatic parenchymal cells. On a molar basis, AAT is the highest-concentration protease inhibitor in plasma. It acts as a suicide substrate of serine proteases and remains covalently attached to the protease. The complex of AAT with proteases is removed from the circulation rapidly by specific receptors. Physiologically, it is the most important inhibitor of leukocyte elastase, as released by neutrophils. If a deficiency of AAT is present, unchecked action of the leukocyte elastase cleaves elastin, which is important for maintaining the architecture of lung tissue. Loss of elastin leads to emphysema. Smoking serves as a cofactor by stimulating inflammation and neutrophil infiltration in the lungs and by lowering AAT activity by oxidizing a methionine residue in AAT, which is the reactive site residue in the inhibitor.

At least 75 genetic variants of AAT are known, several of which are associated with low serum concentrations. The common wild phenotype is designated PiMM ("Pi" for protease inhibitor); the most common deficiency genotypes of clinical importance are PiZZ and SZ. Other genotypes include PiMZ and PiSS. In many populations, 10% or more of individuals are heterozygous for AAT variants. Most clinical disorders occur in individuals with two variant alleles. AAT deficiency is decreased by about 85% in individuals who are PiZZ and by about 63% for PiSZ. AAT variants have a disorder of protein folding that leads to intracellular aggregation and decreased secretion of AAT.

Clinical Significance

AAT concentrations are elevated by the APR and by estrogens (pregnancy, oral contraception). AAT concentrations are secondarily low in individuals with (1) neonatal respiratory distress syndrome, (2) severe pancreatitis, and (3) protein-losing disorders. Decreased AAT concentrations due to genetic deficiency are associated with high risk for developing basilar pulmonary emphysema (in contrast to the apical disease present in other forms of emphysema). Onset of disease is usually much earlier than for most other forms of emphysema, with changes beginning in the second to fourth decades of life in 90% of PiZZ individuals. The process is promoted by smoking. Severe genetic deficiency occurs with a frequency of about 1 in 3000.

Genetic deficiency of AAT also is associated with diseases of the liver, including (1) neonatal cholestasis, (2) cirrhosis, and (3) hepatocellular carcinoma. About 10% of infants with PiZZ or PiZnull genotypes have prolonged obstructive jaundice, and 2% progress to liver failure in childhood. Early histologic differentiation of cholestasis from AAT deficiency and biliary atresia is challenging. Liver disease with AAT variants is associated with risk for progression to hepatocellular carcinoma. Hepatic injury in AAT deficiency probably is related to intracellular aggregation of AAT variants.

Laboratory Considerations

Quantitative testing of AAT is recommended for patients with onset or family history of chronic obstructive pulmonary disease before age 45. AAT usually is quantified by immunoturbidimetry or immunonephelometry. Reference intervals for AAT are listed in Table 18-4. Phenotyping of AAT usually is performed by isoelectric focusing. Genotyping assays detect common variants of AAT.

AAT usually is the major constituent of the α_1-globulin band on routine clinical serum electrophoresis. AAG and α-lipoprotein also are included in the α_1-globulin band but do not stain well with peptide stains because of their high contents of CHO and lipid, respectively. Decreases in the α_1-band suggest a decrease in AAT or variants of AAT with altered mobility.

α-Fetoprotein

α-Fetoprotein (AFP) is the most abundant plasma protein in early embryonic life. AFP is homologous to albumin but differs in having about 4% carbohydrate. Its molecular mass is about 70 kDa. AFP usually is present at very low concentrations after the neonatal period, and highly sensitive immunoassays are required for analysis. The serum concentration of AFP serves as a tumor marker for hepatocellular and germ

cell carcinoma (refer to Chapter 20 on tumor markers). Maternal serum concentrations are analyzed as indicators of fetal trisomy of chromosome 18 or 21 (refer to Chapter 44 for a description of testing in pregnancy).

Haptoglobin

Haptoglobin (Hp) is an α_2-glycoprotein that binds free hemoglobin (Hb). It is synthesized by the liver and consists of equal numbers of α- and β-subunits in variable proportions depending on genotype. Each αβ pair in Hp binds an αβ dimer from Hb.

Biochemistry and Function

Hp is synthesized as a single peptide chain by hepatocytes and is cleaved into α- and β-chains. Hp is polymorphic because of the variable occurrence of two types of α-chain—α^1 and α^2. Three Hp genotypes—designated Hp1-1, Hp 2-1, and Hp 2-2—result from the combination of two genes for α^1, one each for α^1 and α^2, or 2 α^2 genes. Hp 1-1 consists of two each of α- and β-chains with a total molecular weight of about 85 kDA, Hp 1-2 consists of multiple forms ranging from 85 kDa to 300 kDa, and Hp 2-2 has larger multimers ranging from 170 to 900 kDa.

Hp 1-1 genotype has a frequency of about 50% in some African and indigenous South American populations but less than 20% in most North American and Asian populations. The Hp 1-1 genotype is associated with decreased risk of cardiovascular disease that may be related to a (1) higher concentration, (2) Hb affinity, and (3) greater extracellular distribution. Hp/Hb complexes are rapidly bound by receptors on reticuloendothelial cells. Because Hp is removed from the circulation and is degraded after complexing with Hb, Hp concentration drops severely when intravascular hemolysis occurs, so that Hp measurement assists in identifying hemolytic disorders. Hp has a capacity to bind only about 1% of the Hb in red cells at usual hematocrits and Hp concentrations. Hemolysis of specimens during or after blood collection does not decrease amounts of Hp, so that Hp measurement sometimes helps to distinguish in vivo from in vitro hemolysis.

Binding of Hb by Hp prevents renal clearance of Hb and loss of iron, and hematuria will occur only after Hp is depleted. Hp binding of Hb also prevents toxic effects of Hb on kidney tubules. A consequence of Hp depletion in chronic hemolytic states, such as sickle cell disease, is that the plasma concentration of Hb increases, and the Hb acts as a scavenger of the physiologically important vasodilator, nitric oxide. Free Hb in the circulation therefore contributes to vascular disorders such as pulmonary hypertension.

Clinical Significance

Hp concentrations are increased by (1) glucocorticosteroids, (2) androgens, and (3) many NSAIDs. It is a weak and late-reacting APP. Hp concentrations are elevated in selective protein-losing syndromes, such as nephrotic syndrome, in individuals with the Hp 2-1 or 2-2 genotype, which produces Hp with a high molecular weight. Biliary obstruction in the absence of severe hepatocellular disease is associated with significantly increased Hp concentrations, and most forms of liver disease are associated with decreased amounts of Hp. Concentrations of Hp are low during pregnancy and are very low in the neonatal period. Reference intervals for Hp vary with genotype—57 to 227 mg/dL in Hp 1-1, 44 to 183 mg/dL in Hp2-1, and 38 to 150 mg/dL in Hp 2-2. The adult reference intervals for undefined genotypes are listed in Table 18-4.

Laboratory Considerations

Immunoturbidimetry and immunonephelometry usually are employed for clinical assays of Hp. Traditionally, Hp was measured by assaying peroxidase activity after serum was mixed with an excess of Hb, the so-called Hb-binding capacity (BC). On average, approximately 1 mg Hb is bound by 1.5 mg Hp. Hp and α_2-macroglobulin (AMG) constitute the major α_2-globulins on serum zone electrophoresis.

α_2-Macroglobulin

AMG is a major plasma proteinase inhibitor. Unlike AAT and most other proteinase inhibitors, it is a very large molecule (molecular mass, ≈725 kDa) that does not diffuse from the plasma space into extracellular fluids in significant amounts.

Biochemistry and Function

AMG inhibits many different classes of proteinases, including those with (1) serine, (2) cysteine, and (3) metal ions in their catalytic sites. AMG is homologous to complement components C3 and C4, and, like those proteins, it contains an internal thioester bond that is activated by proteolytic cleavage and reacts to bind covalently with proteases. Intact AMG has a half-life of several days, but it is cleared rapidly by a hepatic receptor when it is cleaved by a protease.

Clinical Significance

AMG is synthesized by the liver. Estrogen increases AMG concentrations, so that women of childbearing age demonstrate higher concentrations than men of the same age. Concentrations in infants and children are two to three times adult concentrations. High AMG concentrations in children may delay symptoms resulting from deficiency of antithrombin III or C1 inhibitor. AMG is not an APR in humans, and concentration stays fairly constant during the APR. AMG tends to increase in the nephrotic syndrome, while most other plasma proteins decrease; the liver increases synthesis of all proteins, but loss of proteins exceeds production, except for very large proteins, which still are retained by the impaired glomerular filtration barrier. Decreased plasma concentrations of AMG often are seen in individuals with severe acute pancreatitis or with advanced carcinoma of the prostate. Although genetic variants of AMG have been noted, they have no known clinical significance.

Laboratory Considerations

AMG and Hp together constitute the major α_2-globulins on serum zone electrophoresis. In the newborn period, and after in vivo hemolysis, AMG alone is the major contributor to this zone. AMG usually is quantified by immunoturbidimetry or immunonephelometry. The reference intervals for AMG are listed in Table 18-4.

Ceruloplasmin

Ceruloplasmin (Cp) is an α_2-globulin that contains approximately 95% of the total serum copper, giving Cp a blue color. When Cp concentrations are significantly elevated (e.g., during pregnancy) or the normal yellow pigments of plasma are decreased, plasma may have a greenish tint.

Biochemistry and Function

Cp is synthesized primarily by the liver. Copper is added to the peptide chain by an intracellular ATPase and is essential for the normal folding of the polypeptide chain. ApoCp synthesized in the absence of copper or the ATPase is degraded primarily intracellularly, and decreased amounts are released into the circulation.

The primary physiological role of Cp is catalysis of reduction and oxidation (redox) reactions. Cp is vitally important in regulating the ionic state of iron, oxidizing Fe^{2+} to Fe^{3+} (from the ferrous to the ferric states), thus permitting incorporation of the iron into transferrin. The copper in Cp serves as an electron receptor in this reaction, going from Cu^{2+} to Cu^{+}. In the absence of this reaction, iron cannot be mobilized efficiently from tissue stores into circulation on transferrin. Although Cp contains primarily plasma copper, albumin and transcuprein probably serve as the most important copper transport proteins.

Clinical Significance

Cp is a weak, late-reacting positive APP. Concentrations are increased significantly by estrogens, as in pregnancy or with the use of oral contraceptives. Primary genetic deficiency of Cp is rare and results in iron deposition in tissue, similar to hereditary hemochromatosis, because of impaired export of iron from tissues into transferrin. Individuals have normal tissue copper but increased tissue iron stores and decreased serum iron. Secondary deficiency of Cp due to decreased incorporation of Cu^{2+} into apoCp during synthesis is more common than primary deficiency. Secondary deficiency may be due to (1) dietary copper insufficiency (including malabsorption), (2) inability to transport Cu^{2+} from the GI epithelium into the circulation (as in Menkes disease), or (3) defective incorporation of Cu^{2+} into the developing Cp molecule (as in Wilson disease). Cp concentrations also may be low in cases of blood loss or GI or renal protein-losing syndromes. Dietary deficiency, secondary to nutritional copper deficiency, is associated with (1) neutropenia, (2) thrombocytopenia, (3) low serum iron, and hypochromic, normocytic, or microcytic (4) anemia that does not respond to iron therapy.

Wilson disease, or hepatolenticular degeneration, differs from dietary deficiency in that total body copper is increased significantly and deposited in tissues, including the (1) hepatic parenchymal cells, (2) the brain, and (3) the periphery of the iris (resulting in the characteristic Kayser-Fleischer rings). Copper is absorbed from the diet and is transported to the liver, but the absence of a specific ATPase impairs incorporation of copper into Cp. Symptoms in individuals with Wilson disease usually begin in the second or third decade of life and include (1) hepatitis, (2) neurological disorders, and (3) renal tubular dysfunction. Mutations that completely destroy the ATPase function may be associated with the onset of liver disease as early as 3 years of age. Treatment of Wilson disease aims to remove tissue copper through chelation with agents such as penicillamine or trientene and inhibition of dietary copper uptake with supplemental zinc.

Laboratory Considerations

Cp usually is measured by immunoturbidimetry or immunonephelometry. Cp functional activity is measured in oxidase assays. It is subject to oxidation and proteolysis during storage that may affect immunoreactivity. T is lability poses problems with (1) calibrators, (2) control materials, and (3) patient samples. Serum or plasma should be separated from blood as soon as possible, and specimens should be refrigerated for up to 3 days or frozen at below −70 °C for prolonged storage. The adult reference intervals for Cp are listed in Table 18-4. Plasma concentrations of Cp are low at birth, increase to peak concentrations at 2 or 3 years of age, and decline slowly until adolescence, when adult concentrations are reached.

Transferrin

Transferrin (TRF), or siderophilin, is the major plasma transport protein for iron (see Chapter 28). TRF accounts for most of the total iron-binding capacity (TIBC) of plasma; one molecule binds two ferric ions that physiologically are generated by oxidation of ferrous ion by Cp. The TRF-Fe^3 complex then transports iron to cells for incorporation into cytochromes, Hb, and myoglobin, and to storage sites, such as the liver and the reticuloendothelial system. Virtually every cell type has surface receptors for TRF.

Biochemistry and Function

TRF is synthesized primarily in the liver and usually migrates in the β-region on routine clinical electrophoresis of serum. Plasma concentrations are regulated primarily by availability of iron, with plasma concentrations rising with iron deficiency and falling with adequacy of iron. As with albumin, about one-half of the TRF exists outside the vascular compartment in extracellular fluids.

Clinical Significance

Evaluation of plasma TRF concentrations aids in the differential diagnosis of anemia and in monitoring of treatment for iron deficiency anemia. In cases of iron deficiency, the TRF concentration is increased, but the protein has low saturation with iron. In anemia of chronic disease instead of deficiency of iron, TRF concentration may be normal or low, but the protein is highly saturated with iron. In iron-overload states, such as hereditary hemochromatosis, TRF concentration is normal, but iron saturation often exceeds 55%—considerably above reference values. Interpretation of serum iron and iron saturation is complicated by large diurnal variation. Serum iron concentration usually is highest in the morning and decreases markedly in the evening. Saturation >100% may be observed with parenteral iron infusion or with toxic overdoses of iron,

for which high saturation may be a sign of severe overdose. High concentrations of TRF are present in pregnancy and during estrogen administration.

TRF is a negative APP, and low concentrations occur in inflammation or malignancy. Decreased synthesis occurs with chronic liver disease or protein malnutrition. Protein loss, such as that seen in the nephrotic syndrome or in protein-losing enteropathy, also causes low concentrations. In the rare disorder congenital atransferrinemia, a very low concentration of TRF is accompanied by iron overload and severe hypochromic anemia that is resistant to iron therapy.

Laboratory Considerations

The availability of simple photometric assays for TIBC, or the ability to calculate TIBC from assays of iron plus unsaturated iron binding capacity (UIBC) where TIBC = UIBC + iron, is used to estimate functional TRF. TIBC also is used to estimate TRF by the following equation:

$$\text{TRF (mg/dL)} = 0.70 \times \text{TIBC (}\mu\text{g/dL)}$$

or

$$\text{TIBC} = 1.43 \times \text{Tf}$$

TRF is more accurately quantified by immunochemical methods, including immunoturbidimetry and immunonephelometry, and these measurements have been used to calculate the TIBC. As was noted previously, TRF migrates in the β_1-region on routine serum electrophoresis, where it usually is the major component, but genetic variants may cause changes in mobility. Reference intervals are listed in Table 18-4.

Carbohydrate-deficient TRF (CDT) is a form of TRF that has decreased or absent glycosylation. CDT usually is a minor component of TRF (<2%), but amounts of CDT are often increased in congenital disorders of glycosylation that affect the glycosylation of many proteins. Amounts of CDT also are increased in individuals with chronic alcohol abuse, and quantitative analysis of CDT may serve as a marker for alcohol abuse. CDT migrates in the β_2-region during zone electrophoresis rather than in the usual β_1-region for TRF because of the lower negative charge. CDT is a major fraction of TRF in CSF, and it has been used as an indicator of whether clear fluids coming from the ear or nasal passages represent leakage of CSF. Electrophoretic analysis often has been used for this analysis, with the β_2-TRF band serving as a marker for CSF.

Low-Density Lipoprotein

Low-density lipoprotein (LDL) is often termed β-lipoprotein on the basis of its electrophoretic mobility. (Refer to Chapter 23 for a more extensive discussion of lipoproteins). LDL has a density between 1.019 and 1.063 g/mL when separated by density gradient ultracentrifugation. It consists of about 80% lipid and 20% protein. Cholesterol ester is the main lipid component, and apolipoprotein B is the main protein. Apolipoprotein B is a large protein of 500 kDa, which is very hydrophobic and inserts into the lipid particle similarly to an intrinsic membrane protein. Increases in LDL concentration confer increased risk of cardiovascular disease. Concentrations of LDL are assessed by calculation of LDL cholesterol that are based on other lipid measurements, direct quantification of LDL cholesterol, or quantification of apolipoprotein B. One apolipoprotein B is usually present per LDL particle, so that measurement of apolipoprotein B serves as a measure of the number of LDL particles.

β_2-Microglobulin

β_2-Microglobulin (BMG) is a low-molecular-mass (11.8 kDa) protein found on the cell surfaces of all nucleated cells; small amounts are shed into plasma.

Biochemistry and Function

BMG, the light or β-chain of the human leukocyte antigens (HLAs), consists of a single polypeptide chain with no carbohydrate. Some BMG is shed into the plasma, particularly by lymphocytes and tumor cells. The small size of BMG allows it to be filtered through the glomerular membrane, but typically less than 1% of the filtered BMG is excreted in the urine. The remainder of the BMG is reabsorbed and catabolized in the proximal tubules of the kidneys.

Clinical Significance

High plasma concentrations of BMG are present in individuals with (1) renal failure, (2) inflammation, and (3) neoplasms, especially those associated with B lymphocytes. Urinary BMG is used as a marker for renal tubular function. (See later section on urinary proteins.) Measurement of plasma BMG has been used as a staging criterion for multiple myeloma, with higher BMG representing more advanced disease. In patients with chronic lymphocytic leukemia, high BMG concentrations are a prognostic marker for decreased survival.

Rapid clearance of BMG typically keeps the plasma concentration low. The reference interval is 0.7 to 1.8 mg/L. However, the concentration increases substantially in renal failure, to concentrations of up to about 40 mg/L. BMG concentrations in patients with renal failure and efficiency of BMG clearance during dialysis treatment are clinically significant because BMG can deposit as amyloid, leading to systemic **amyloidosis** in many patients on long-term dialysis.[7]

Fibrinogen

Fibrinogen, the terminal component of the coagulation system, aggregates to form a fibrous network when it is cleaved by the protease thrombin. Maintaining adequate concentrations of fibrinogen is important for preventing bleeding. Fibrinogen is a positive APP.

Biochemistry and Function

Fibrinogen is a highly elongated protein that consists of six polypeptide chains joined by disulfide bonds. Two each of Aα-, Bβ-, and γ-chains are the products of separate genes. The total molecular mass is about 340 kDa. Removal of small A- and B-fibrinopeptides from the Aα- and Bβ-chains by thrombin causes fibrinogen to aggregate into long fibers of fibrin. Fibrin has binding sites for platelets, and other cells such as red cells become entrapped in the fibrous network of fibrin as

a clot forms. Contractile elements in platelets gradually cause the clot to retract (clot retraction) and to squeeze serum out of the clot. Fibrin monomers then slowly become covalently cross-linked by the action of a transglutaminase (coagulation factor XIIIa), which makes a clot firmer and more rigid.

Clinical Significance

Low plasma concentrations occur as the result of consumption from extensive bleeding or dysregulation of the coagulation system, such as disseminated intravascular coagulation. Functional disorders of fibrinogen (dysfibrinogenemia) may be seen with liver disease or as a rare inherited disorder. Fibrinogen is a positive APP. It is one of the major contributors to plasma viscosity because of its large size and highly elongated structure, and it accounts for the higher viscosity of plasma relative to serum (which has fibrinogen removed). High plasma concentrations of fibrinogen on a chronic basis are associated with increased risk of cardiovascular disease, which may relate to increased plasma viscosity or the increased tendency for thrombosis.

Laboratory Considerations

Fibrinogen typically is measured by functional clotting assays. It is also measured by immunoturbidimetric methods or by turbidimetric methods based on the addition of precipitating reagents. Plasma concentrations of fibrinogen are normally in the interval of about 150 to 350 mg/dL but vary slightly with the method of analysis. Fragments of fibrin generated by the protease plasmin, such as fibrin-degradation products or d-dimer, are measured as indicators of increased thrombosis, suggesting the presence of pulmonary embolism or venous thrombosis. If fibrinogen is not completely removed from serum, it may give a band on serum protein electrophoresis at the anodal end of the γ-region that is mistaken for a paraprotein. T is may occur if the patient is receiving anticoagulation, or if the specimen is contaminated with an inhibitor of coagulation such as heparin. T e pseudoparaprotein band from fibrinogen will not show any corresponding band on immunofixation electrophoresis, indicating that the band does not consist of immunoglobulins.

C-Reactive Protein

C-reactive protein (CRP) is a substance found in the sera of acutely ill individuals that is able to bind the cell wall C-polysaccharide of Streptococcus pneumoniae. It is an early positive APR and exhibits some of the most dramatic increases in concentration. It has been used extensively as a marker of inflammation.

Biochemistry and Function

CRP consists of five identical, nonglycosylated subunits of 23 kDa that associate to form a disc-shaped structure. Its pentameric structure leads to the family name pentraxin for CRP and related proteins. CRP is synthesized by the liver. Functions of CRP include protecting against foreign organisms and assisting in clearing tissue debris. CRP binds a variety of compounds in the presence of Ca^2: (1) polysaccharides present in many bacteria, fungi, and protozoans; (2) phosphorylcholine; (3) phosphatidylcholines, such as lecithin; and (4) polyanions, such as nucleic acids. In the absence of Ca^2, CRP binds polycations, such as histones. Complexation of CRP activates the classic complement pathway starting at C1q, thus initiating (1) opsonization, (2) phagocytosis, and (3) lysis of invading organisms, such as bacteria and viruses. CRP also helps to clear tissue debris from damaged tissue.

Clinical Significance

CRP is one of the strongest-reacting APPs, with plasma concentrations rising dramatically after (1) myocardial infarction, (2) stress, (3) trauma, (4) infection, (5) inflammation, (6) surgery, or (7) neoplastic proliferation. CRP begins to rise within 6 to 12 hours of the onset of any of these stimuli and usually peaks within 48 hours. CRP concentration may increase more than 1000-fold from a low initial baseline. Bacterial infection usually is a stronger stimulus than viral infection, and CRP has been used as a marker for bacterial infection in newborns. CRP measurements are used as an indicator of inflammatory processes, and they are used to assess the activity of disorders such as rheumatoid arthritis and Crohn disease. For unknown reasons, CRP responses to some inflammatory disorders such as systemic lupus erythematosus and ulcerative colitis are mild.

Epidemiological studies demonstrate that slightly increased serum CRP concentrations are associated with increased risk of cardiovascular disease. T ese slight increases in CRP may reflect low-grade chronic inflammation associated with atherosclerosis. T is application of CRP requires assays with detection limits of about 1 mg/L, which often are referred to as high-sensitivity CRP (hsCRP) assays. CRP >2.0 mg/L has been suggested as an indicator of increased cardiovascular risk. Separate assays with a higher measuring range are commonly used to measure CRP in cases of infection or severe inflammation.

Laboratory Considerations

CRP is normally present in plasma at concentrations <5 mg/L. High concentrations of CRP in inflammatory states are measured with direct immunoturbidimetric or immunonephelometric assays using antibody to CRP. Assays to measure basal CRP in healthy subjects usually require different technologies to achieve lower detection limits; hsCRP assays include (1) particle-enhanced immunoturbidimetry or nephelometry, or (2) sandwich immunoassays with fluorescence or chemiluminescent detection. CRP migrates on cellulose acetate or agarose gel electrophoresis anywhere from the slow-γ- to mid-β-regions, depending on the calcium ion content of the buffer. Serum concentrations are too low to show as a stained band except in an extreme APR.

Complement Proteins

Complement is a complex system of proteins found in normal blood plasma that combines with antibodies to destroy pathogenic bacteria and other foreign cells. It helps or "complements" the ability of antibodies and phagocytic cells to clear pathogens from an organism. It consists of at least 20 proteins

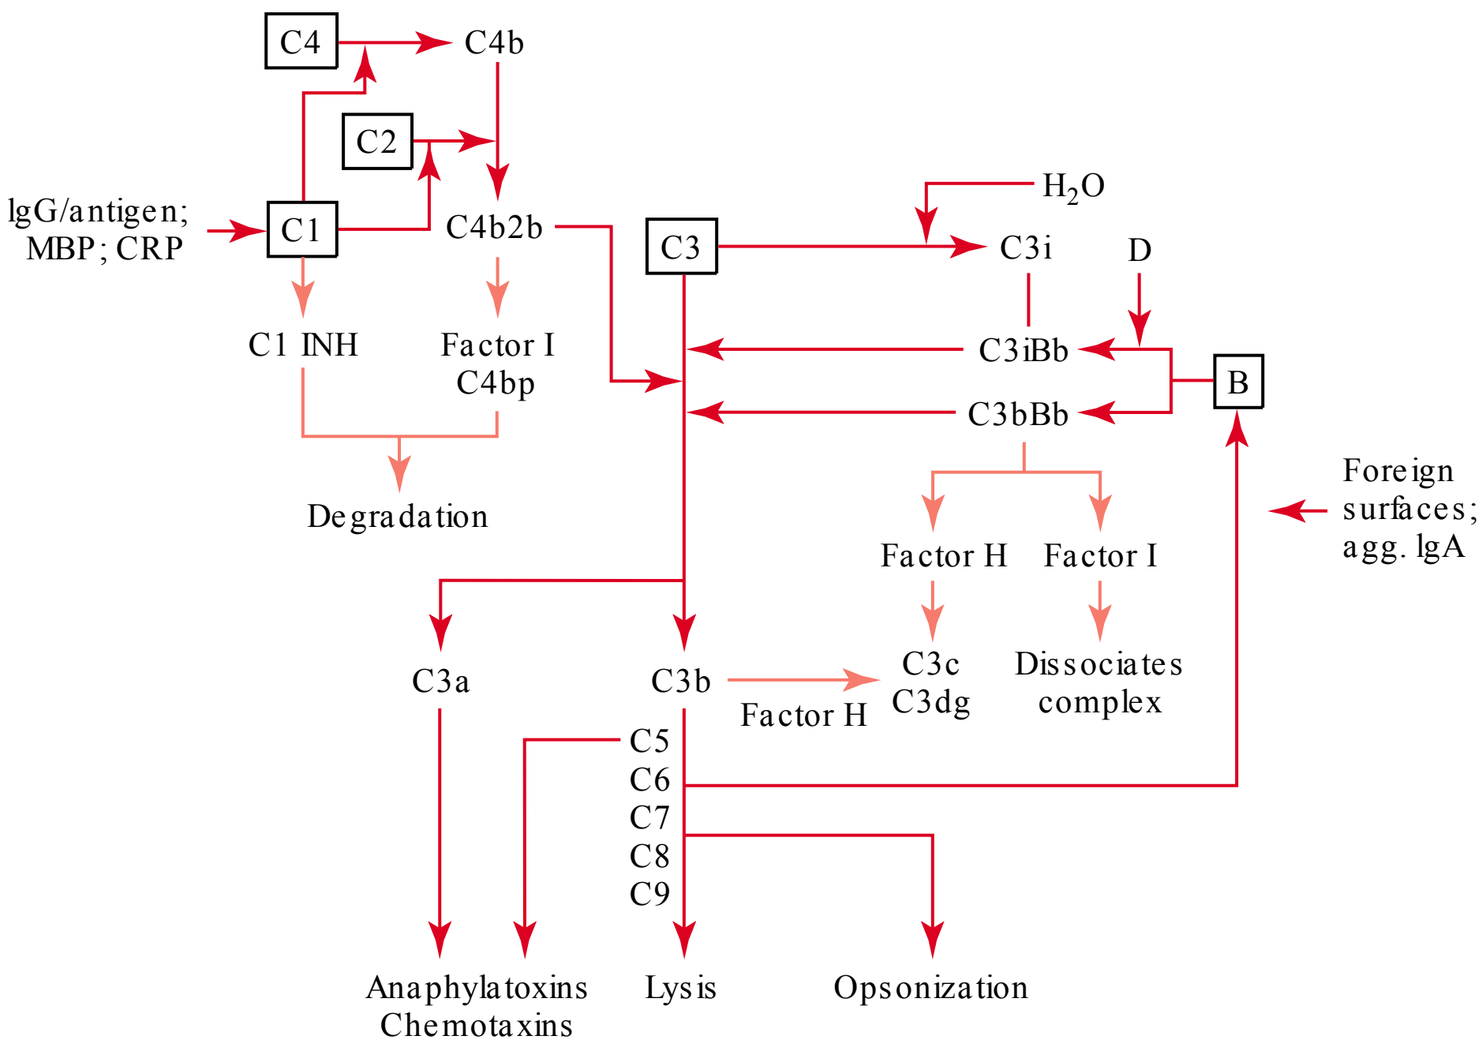

Figure 18-4 Overview of the Complement Cascades. Activation via the classical pathway and the lectin pathway is shown on the left and via the alternative pathway on the right. Gradual activation by spontaneous hydrolysis of C3 to C3i is shown at the center top. Direct activation of C3 by neutrophil and plasma proteases also may occur. The control mechanisms are shaded. (Courtesy J.W. Whicher, with modifcations.)

in plasma and a number of cellular receptors and regulators on cell surfaces; some of the interactions of major components are diagrammed in Figure 18-4.[11] Complement proteins are divided into six groups by function:

1. The classic pathway, which includes C1, C4, C2, and C3 (in order of activation).
2. The alternative pathway, which includes C3, factors B and D, and properdin.
3. The lectin pathway, which includes mannan-binding protein (MBP), ficolins, and associated proteases.
4. The membrane attack complex, which includes C5 through C9 and inserts into cell membranes and lyses cells.
5. Inhibitors and inactivators of the previous pathways, including C1 inhibitor, factors H and I, and C4-binding protein (C4bp).
6. Cellular receptors and regulators for activated or cell-bound components.

The classic pathway is activated primarily by complexes of immunoglobulins with antigen or bacteria or other ligands with CRP (see Figure 18-4), whereas the alternative pathway is activated by (1) bacterial lipopolysaccharides, (2) cellular proteases, and (3) cobra venom. The lectin pathway is activated by binding of ficolins and MBP to mannose-rich oligosaccharides that are present in the cell walls of many microorganisms. Activation of the classic pathway through C3 also activates the alternative pathway, which amplifies the production of effector molecules. Other mechanisms also may activate the **complement system**, including the action of proteases released by leukocytes and other inflammatory cells. The common step involved is the activation of C3 to C3b.

A number of the complement components are proteases. Each of the three pathways of complement activation consists of a cascade of several protease zymogens, including C1r, C1s, C2, factor D, factor B, and MBP-associated serine protease-I and -II. Zymogens are activated by cleavage of preceding factors in a pathway. Multiple factors act to control the protease activities. The protease inhibitor C1 inhibitor is an important regulator, as are the binding proteins factor H and C4bp and the protease factor I, which breaks down activated complement factors.

During activation, many complement components are cleaved by proteases into two fragments—in general, (1) one larger fragment that binds to various surfaces, such as bacterial membranes, plus (2) a smaller fragment that may become active in chemotaxis (movement or orientation of an organism or cell along a chemical concentration gradient) and vascular permeability. The larger fragments are designated by a lowercase "b," and the smaller fragments by a lowercase "a." The larger fragments may contain a binding site for cell membranes and immune complexes or a protease that then activates the next component(s). Thus, the active, cell-bound fragment of C3 is C3b, whereas the anaphylotoxin peptide C3a is released into the surrounding fluid. Inactivated fragments are designated by the letter "i" (e.g., C3bi). Both C4 and C3 contain an internal thioester bond that is activated by cleavage to C4b and C3b and that reacts to form a covalent bond with neighboring molecules such as components of a cell surface. Surface-bound C4b and C3b then direct further complement targeting to that site.

Activation of the (1) classic, (2) lectin, or (3) alternative pathways, with or without activation of the membrane attack complex, produces effector molecules that initiate inflammation and facilitate elimination of antigens by lysis (disintegration of a cell by rupture of the cell wall or membrane) or by phagocytosis (engulfing and ingestion of bacteria or other foreign bodies by phagocytes). The complement system is a major mediator of inflammation. Increased vascular permeability permits the passage of further antibody, complement, and phagocytes into the extravascular space, which helps kill and remove infectious agents and immune complexes.

Biochemistry and Function

Plasma complement components are synthesized mainly by the liver, although small quantities are synthesized by monocytes and other cell types. C3, the most abundant complement component, is a common component of the three pathways of complement activation. C3 is a large protein of about 180,000 Da that is homologous to C4, C5, and AMG. A reactive thioester bond in C3, C4, and AMG plays a central role in binding these proteins covalently to neighboring targets when they are activated. T e thioester is not completely stable, and gradual hydrolysis of the thioester in C3 continuously generates small amounts of C3i in plasma, leading to a low rate of complement activation. Slow ongoing activation of complement factors would lead to accumulation of complement factors on cells such as red blood cells and might cause their lysis or clearance when factors are not present on cell surfaces to promote removal of complement bound to cell surfaces. A few of these factors include (1) decay-accelerating factor (DAF or CD55), (2) protectin (CD59), (3) membrane cofactor protein (MCP), and (4) complement receptor 1. Deficiencies of DAF and protectin result in increased red cell lysis in the disorder **paroxysmal nocturnal hematuria**, and demonstrate the important role of these proteins. Complement regulatory factors on cell surfaces help to prevent destruction of endogenous cells at the same time that nearby foreign cells are destroyed by complement. Plasma factors also help turn off complement activation. Factor H and C4bp are binding proteins for C4b and C3b that serve as cofactors in the cleavage of C4b and C3b by factor I and help to dissociate complexes of complement factors.

Clinical Signif cance

T e clinical importance of the complement system is demonstrated by the disease associations present in inherited or secondary deficiencies of various components. Several complement proteins, notably C3 and C4, are increased in number after an APR; however, they are weak and late-reacting APPs. C1, C1 inhibitor, C3, C3 proactivator (factor B), and C4 are the components most often measured for clinical purposes because their concentrations are important in relatively common disease states, and because assays are available readily. Activity of the complete classic pathway, often termed total hemolytic complement or CH_{50} is measured by the extent of lysis of antibody-coated red cells or liposomes.

Both genetic variants and deficiencies of nearly each complement component have been described. Deficiencies in particular may be associated with disease. For example, genetic deficiency of C2 and C4 typically is associated with (1) autoimmune immune complex diseases such as **systemic lupus erythematosus** (SLE), (2) polymyositis, and (3) glomerulonephritis. Partial deficiency of C4 is common. Two closely related genes encode C4, so four alleles are present. About 10% of the population has a deficiency in two of the four alleles. In contrast, the rare deficiency of C3 is associated with infection, often severe, with encapsulated bacteria. Deficiency of any of the membrane complex components (C5 through C9) is associated with recurrent and severe neisserial infection. Heterozygous deficiency of C1 inhibitor results in **hereditary angioedema (HAE)**, with excessive activation of complement factors. HAE is characterized by recurrent attacks of (1) subcutaneous, (2) laryngeal, (3) bronchial, and (4) GI edema, which may be life threatening. Decreased C4 concentrations have been used to screen for the disorder; if C1 inhibitor concentrations are normal in individuals with clinical symptoms and decreased C4, functional assays should be performed. Some cases of HAE have adequate quantities of C1 inhibitor, but the protein has mutations that decrease activity. Genetic deficiency of MBP occurs in up to 5% of the population and may increase susceptibility to infection in infancy, when antibody concentrations are low. MBP deficiency appears to have little effect on adults, unless severe immunosuppression is present.

Secondary decreases in components occur as a result of consumption. T e classic examples of this are depletion of C4 in HAE and of C3 and C4 in **acute poststreptococcal glomerulonephritis**. In diseases such as SLE and other disorders associated with formation of immune complexes, differentiation of genetic and secondary deficiency may require (1) family studies, (2) phenotyping, (3) DNA analysis, or (4) combinations of these.

Coagulation Proteins

T e coagulation system is a complex system designed to prevent bleeding from injuries by forming blood clots. (For more detail on this process, the reader is directed to Chapter 59, Higgins RA, Kitchen S, Olson JD. Hemostasis In: Burtis CA, Ashwood ER, Bruns DE eds. Tietz textbook of clinical chemistry, 5th edition. Philadelphia: WB Saunders, 2012:2083-128.) T is process requires careful regulation and balance between hemostasis (formation of clots where needed) and thrombosis (pathological clotting) leading to [1] venous thrombosis, [2] pulmonary emboli, [3] strokes, and [4] myocardial infarction. T e coagulation system has been divided functionally into intrinsic and extrinsic pathways, which merge into a final common pathway, generating fibrin (see Figure 59-2; Higgins RA, Kitchen S, Olson JD. Hemostasis. In: Burtis CA, Ashwood ER, Bruns DE eds. Tietz textbook of clinical chemistry, 5th edition. Philadelphia: WB Saunders, 2012:2085). T e intrinsic pathway is activated by negatively charged surfaces and is assessed by a clot-based assay, activated partial thromboplastin time (APTT). T e intrinsic pathway is activated by tissue factor released by tissue injury and is assessed by prothrombin time (PT) clotting assays. T e pathways are cascades of protease zymogens that are sequentially activated by factor V and factor VIII, which serve as cofactors to organize protease activity. Not shown on the pathway are inhibitors such as antithrombin III that help to prevent uncontrolled action of the proteases.

A number of clotting factors such as fibrinogen are consumed or entrapped in the clot during clotting of blood to form serum. T erefore, plasma for coagulation testing usually is collected with one part of 3.2% sodium citrate (109 mmol/L) as anticoagulant per nine parts of blood. Citrate inactivates coagulation by chelating calcium required for activity of coagulation factors. Clotting assays add back calcium and other activators of clotting and measure the time required to form a clot. Clotting assays are used to measure activity of complete pathways or

of individual factors. Clotting assays are also frequently used to monitor the action of the anticoagulants Coumadin and heparin. Selective factors and inhibitors also are measured in direct enzyme activity assays with the use of selective chromogenic substrates. Chromogenic substrates have come into increased use to measure functional concentrations of low-molecular-weight heparin by determining the inhibition of factor Xa.

Coagulation factors are synthesized mainly by the liver. Fibrinogen, the most abundant factor, is described in a preceding section. Other factors are present at more than 10-fold lower concentrations and are not visualized as major bands on protein electrophoresis. Factor concentrations have been observed to be low as the result of (1) hereditary deficiencies, (2) consumption by active clotting, (3) liver disease, or (4) anticoagulant therapy. Some hereditary disorders lead to excessive bleeding, such as (1) hemophilia A, (2) factor VIII deficiency, (3) hemophilia B, and (4) factor IX deficiency. Others lead to risk of thrombosis, such as (1) factor V Leiden, (2) antithrombin III deficiency, and (3) protein C deficiency. Usually, specific factor concentrations are assessed by functional assays, with activity assessed as a percentage versus reference plasma. Liver disease has been known to result in lower factor concentrations that commonly are identified using the PT assay. T is assay is also used to monitor the anticoagulant activity of Coumadin. Coumadin blocks a post-translational modification—the carboxylation of glutamic acid side chains to form γ-carboxyglutamic acid—of several coagulation factors (prothrombin and factors VII, IX, and X). Vitamin K is a cofactor in this reaction. Factors lacking γ-carboxyglutamic acid have a decreased ability to bind calcium and to function in the coagulation pathways. PT assay results are commonly reported in seconds and as an international normalized ratio (INR), which helps in standardizing results obtained with different batches of reagents.

Immunoglobulins

Immunoglobulins (antibodies) are a family of proteins that contain highly specific antigen-binding sites. Synthesis of immunoglobulins is stimulated by foreign immunogens, leading to immunoglobulins that selectively bind foreign molecules or organisms (see Chapter 15). Regulatory mechanisms usually suppress formation of autoantibodies against the body's own structures and failure of regulatory mechanisms and production of autoantibodies contributes to autoimmune disease. Each of five classes of Ig is characterized by sequence heterogeneity of antigen-binding sites that allows binding of a diverse variety of molecules with high specificity.

Basic Biochemistry and Function

All immunoglobulins include one or more basic units consisting of two identical heavy (H) chains encoded on chromosome 14 and two identical light (L) chains encoded on chromosome 2 (see Figure 15-1, Chapter 15, for a diagram of IgG structure) that are joined by disulfide bonds. Each of the four chains has a variable and one or more constant domains. Two variable domains, one from the light chain and one from the heavy chain, together form an antigen-binding site. Extensive diversity in the variable domains is generated by somatic recombination and mutation of the Ig genes. Constant domains of immunoglobulins have little sequence diversity, and these domains provide sites for complement activation and receptor binding, as well as a structure to hold the variable domains together to form antigen binding sites. Ig light chains usually are produced in slight excess of heavy chains and are of two types—kappa (κ) and lambda (λ)—defined by different constant domains. Each B lymphocyte or clone of B lymphocytes synthesizes Ig with a single type of light chain and a single set of variable domain sequences, which binds a specific antigen. Usually, about twice as many lymphocytes synthesize immunoglobulins containing κ-light chains as λ-light chains

Immunoglobulins are synthesized by cells of B-lymphocyte lineage. Immature B-lymphocytes have surface-bound IgM. Upon binding of a target antigen, immature B lymphocytes proliferate and develop into a clone of plasma cells. Secretion of IgM is the primary response to antigenic stimulation. With further maturation of plasma cells, splicing of heavy chain constant domains yields class switching as Ig production switches from IgM to IgG and IgA. Later exposure of B cells activates memory B cells, and this yields a more rapid and a larger secondary or anamnestic response with IgG secretion. As an example, initial vaccination may require two or more doses, and a single booster dose at a later time is adequate to generate a strong antibody response.

Individual Immunoglobulins

T e five classes of immunoglobulins are (1) IgG, (2) IgM, (3) IgA, (4) IgD, and (5) IgE; they vary in the constant domains of their heavy chains.

Immunoglobulin G (IgG)

IgG is the most abundant class of Ig, making up 70% to 75% of total Ig. Of this amount, 65% is extravascular and 35% is found in plasma. IgG consists of two γ-heavy chains and two light chains. Its molecular weight is about 150 kDa, including about 3% carbohydrate from one oligosaccharide chain on each heavy chain. During zone electrophoresis, IgG migrates broadly in the γ- and slow β-regions as a result of heterogeneity of the IgG molecules.

IgG includes four subclasses—IgG_1, IgG_2, IgG_3, and IgG_4. T eir circulating half-life is approximately 22 days, which is much longer than the half-life of most plasma proteins. IgG_1 and IgG_3 strongly activate complement via the classical pathway. IgG_2 weakly activates complement, and IgG_4 does not activate complement. Clustering of multiple IgG molecules is required to activate complement. IgG_1 and IgG_3 bind Fc receptors on phagocytic cells and cross the placenta via receptor-mediated active transport. IgG_1 is the major neonatal Ig, with concentrations similar to maternal concentrations. Transport of maternal IgG into the fetal circulation sometimes causes lysis of fetal red cells (hemolytic disease of the newborn) when the mother generates antibodies to fetal red cell antigens. Neonates have low production of Ig as the result of immaturity of their immune systems, and IgG concentrations fall early in infancy as maternally acquired Ig is cleared.

Immunoglobulin M

Immunoglobulin M (IgM) is produced at early stages of B-cell development. In the immature immune system of neonates, IgM is the major immunoglobulin synthesized. In adults, it accounts for only 5% to 10% of total circulating Ig. IgM as a membrane receptor molecule is monomeric, but most of the serum IgM is a pentamer, which contains five monomers, similar to IgG linked via disulfides to the small J chain. Plasma cell malignancies may secrete monomeric IgM, in addition to, or instead of, pentamers. The high molecular weight of IgM (970 kDa; ~10% carbohydrate) prevents its ready passage into extravascular spaces. IgM is not transported across the placenta and, therefore, is not involved in hemolytic disease of neonates. It activates complement even more efficiently than IgG; binding of one IgM molecule may be adequate to activate complement. In rare hyper-IgM syndromes, class switching to IgG and IgA is deficient. Affected patients have deficiency of IgG and IgA and increased susceptibility to infection.

Immunoglobulin A

Approximately 10% to 15% of serum immunoglobulin is immunoglobulin A (IgA), which contains 10% carbohydrate and has a molecular weight of 160 kDa and a half-life of 6 days. Two subclasses have been identified—IgA_1 and IgA_2. In its monomeric form, its structure is similar to that of IgG, but 10% to 15% of IgA in serum is dimeric, particularly IgA_2, which is more resistant than IgA_1 to destruction by some pathogenic bacteria. On electrophoresis, IgA migrates near the junction of the β- and γ-regions, anodal to most IgG.

Secretory IgA is found in (1) tears, (2) sweat, (3) saliva, (4) milk, (5) colostrum, (6) gastrointestinal secretions, and (7) bronchial secretions. It has a molecular mass of 380 kDa and consists of two monomers of IgA—a secretory component (molecular mass, 70 kDa) and a J chain (15.6 kDa). It is synthesized mainly by plasma cells in the mucous membranes of the gut and bronchi and in the ductules of the lactating breast. The secretory component helps transport secretory IgA across mucosal epithelium and into secretions. Secretory IgA is more abundant than IgG in colostrum and milk and may help protect neonates from intestinal infection. IgA also activates complement by the alternative pathway, but the exact role of IgA in plasma is not clear.

Immunoglobulin D

Immunoglobulin D (IgD) accounts for less than 1% of plasma Ig. It is monomeric, contains about 12% carbohydrate, and has a molecular mass of 184 kDa. Its structure is similar to that of IgG. Like IgM, IgD can occur as a surface receptor for antigen on B lymphocytes, but its primary function is unknown.

Immunoglobulin E

Immunoglobulin E (IgE) is so rapidly and firmly bound to mast cells that only trace amounts of it are normally present in serum. IgE contains 15% carbohydrate and has a molecular mass of 188 kDa. Its structure is similar to that of IgG. IgE binds to mast cells via binding sites on its Fc region. When the antigen (allergen) cross-links two surface-bound IgE molecules, the mast cell is stimulated to release histamine and other vasoactive amines. These compounds increase vascular permeability and smooth muscle contraction, thereby mediating type 1 hypersensitivity reactions such as (1) hay fever, (2) asthma, (3) urticaria, and (4) eczema. A rare regulatory disorder, Job's syndrome, leads to increased production of IgE, eczema, and recurrent infection. IgE molecules specific for particular allergens are measured by sensitive immunoassays using immobilized allergens to capture specific IgEs. These assays help identify the triggers for allergic responses in different individuals. The total concentration of IgE may be increased in allergic disorders.

Free Immunoglobulin Light Chains

Light chains usually are synthesized in slight excess over quantities required for intact immunoglobulins. Consequently, small quantities of free light chains, representing only about 0.1% of total Ig, usually are present in serum or plasma. Amounts in plasma usually are kept low by rapid renal clearance of these small proteins. Free κ-light chains (23 kDa) are cleared about three times faster than free λ-light chains (which form a disulfide-linked dimer of 46 kDa), which have a usual half-life of 4 to 6 hours. Consequently, even though production of κ-light chains is about twice as great as that of λ-light chains, the plasma concentration of free λ-light chains usually is higher, except in renal failure. Free light chains are not functional, but immunoassays specific for free light chains, commonly measuring the ratio of free κ:free λ light chains, are very sensitive indicators of disorders of Ig synthesis such as multiple myeloma, where clones are synthesizing increased amounts of Ig with either κ- or λ-light chains. Because free light chains are cleared by the kidneys, urine provides a specimen proportionally enriched in free light chains relative to plasma, and analysis of urine provides more sensitive detection of monoclonal free light chains than analysis of serum.

Clinical Significance

Typically, serum contains a heterogeneous, polyclonal mixture of immunoglobulins, with varying amino acid sequences and binding specificities. Benign or malignant proliferation of one such clone produces a high concentration of a single monoclonal antibody, which may appear as a sharp, narrow band on protein electrophoresis. Unbalanced production of free light chains might also lead to a second band, representing a free light chain. If a few clones proliferate, several sharp bands (e.g., the oligoclonal bands seen in electrophoresis of CSF) may be noted in (1) demyelinating diseases such as multiple sclerosis, (2) serum following successful bone marrow transplantation, or (3) early response to such organisms as Streptococcus pneumoniae. Disease may be associated with a decrease or an increase in normal polyclonal immunoglobulins or with an increase in one or more monoclonal immunoglobulins.

Immunoglobulin Deficiency

Immune defense depends on four complex, interactive systems: (1) cell-mediated immunity (T lymphocytes), (2) antibodies (immunoglobulins), (3) the phagocytic system, and

(4) the complement system. T e last two systems are nonspecific in that they have no immunological memory for the antigen. Immunodef ciency states may be the result of a deficiency of a single factor or of combinations affecting multiple systems and factors. Immunodeficiency results in increased susceptibility to infections that usually do not cause disease in people with normal immune systems.

Deficiency of IgG and other immunoglobulins may be secondary to protein loss or to depletion of B lymphocytes; primary deficiencies may result from genetic disorders. Infants have transient physiological IgG immunodeficiency, with a baseline concentration observed at about 3 months of age. Concentrations of maternal IgG, transferred across the placenta, rise rapidly in the fetus during the last half of pregnancy. After birth, concentrations of IgG gradually decline and then begin to rise as the infant slowly begins to produce IgG (Figure 18-5). A delay in IgG production may be associated with increased infection rates. Neonates who are particularly at risk include premature infants, who start with less maternal IgG and may have slower initiation of IgG synthesis. Monitoring of IgG concentrations is used to assess this problem. Rising serum IgM and salivary IgA concentrations at 6 weeks of age suggest a favorable prognosis. Contact of the neonate with environmental antigens normally causes B lymphocytes to begin to multiply and IgM concentrations to start to rise, followed weeks to months later by increased concentrations of IgA and IgG.

T e diagnosis of an immunoglobulin deficiency state is clinically important because replacement therapy with IgG is possible. Selective deficiency of individual IgG subclasses is not rare, and deficiency of IgG_2 may confer slightly increased risk of infection by encapsulated bacteria. IgA deficiency occurs in about 1 in 500 whites and less frequently in Asian populations. IgA deficiency usually is not associated with severe infection, but risk of infection with Giardia or other non–life-threatening organisms may be increased. IgA deficiency may lead to false-negative assays for IgA autoantibodies that are indicators of celiac disease. IgA-deficient individuals have some risk of anaphylaxis if they receive blood products that contain IgA. A variety of uncommon genetic disorders are associated with decreased production of IgG, which leads to increased risk of pyogenic infection. Severe combined immunodeficiency is one example of a disorder in which IgG production is decreased.

Polyclonal Hyperimmunoglobulinemia

Polyclonal increases in plasma immunoglobulins constitute the normal response to infection. IgG response predominates in most autoimmune responses; IgA in (1) skin, (2) gut, (3) respiratory, and (4) renal infections; and IgM in primary viral infections and with bloodstream parasites, such as malaria. Chronic bacterial infections may cause an increase in serum concentration of all immunoglobulins. Selective changes in Ig concentrations assist in the differential diagnosis of liver disease and of intrauterine infection. In (1) primary biliary cirrhosis, the IgM concentration is greatly increased; (2) chronic active hepatitis, IgG and sometimes IgM are increased; and (3) portal cirrhosis, IgA and sometimes IgG are increased. In intrauterine infection, production of IgM by the fetus is increased, as is the IgM concentration in the umbilical cord blood.

Monoclonal Immunoglobulins (Paraproteins)

A single clone of plasma cells produces Ig molecules with a single amino acid sequence. If the clone expands greatly, the concentration of its monoclonal Ig in the patient's serum may produce a discrete band on electrophoresis, often referred to as an M-spike or M-protein, visible against the diffuse polyclonal background. T ese monoclonal immunoglobulins, termed paraproteins, may be (1) intact Ig, (2) polymers of Ig, (3) free light chains or heavy chains, or (4) fragments of immunoglobulins. About 60% of paraproteins are associated with plasma cell malignancies (multiple myeloma or solitary plasmacytoma), and approximately 15% are due to overproduction by B lymphocytes, mainly in lymph nodes of patients with (1) lymphomas, (2) chronic lymphocytic leukemia, (3) Waldenström's macroglobulinemia, or (4) heavy chain disease. Up to 25% of paraproteins are benign and have been termed **monoclonal gammopathy of undetermined signif cance** (MGUS). MGUS is characterized by (1) paraprotein concentrations <3 g/dL, (2) <10% clonal plasma cells in bone marrow,

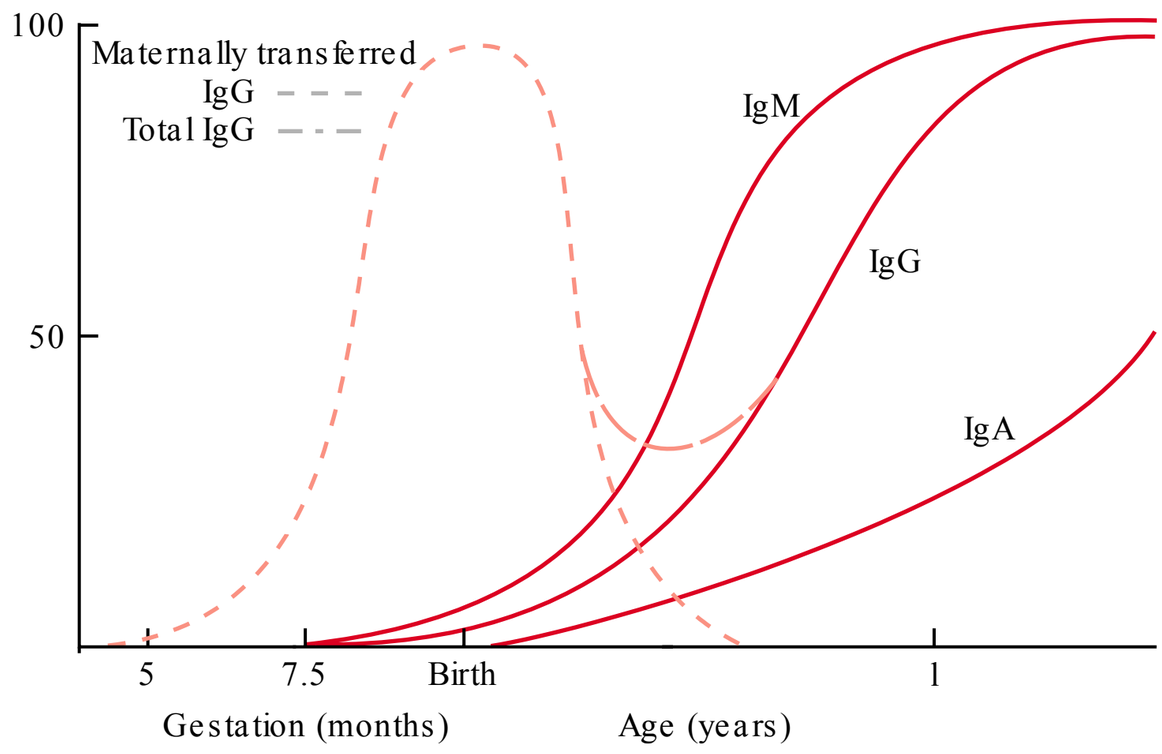

Figure 18-5 Serum immunoglobulin concentrations as percent of mean adult concentrations before birth and for the frst year of life.

and (3) lack of evidence of paraprotein-related organ injury. The incidence of MGUS increases with age, with 1% incidence reported for people 50 to 70 years of age and 3% incidence for those over the age of 70. Occurrence of MGUS is associated with increased risk of progression to multiple myeloma that should be monitored. Multiple myeloma appears to be preceded in most cases by MGUS.

The primary clinical interest in identifying paraproteins involves the detection or monitoring of proliferative disorders of B lymphocytes. However, from the viewpoint of the laboratory, paraproteins also are significant as a potential, unpredictable interference with many assays. Paraproteins may aggregate or precipitate in a variety of photometric reactions and hematology analyzers. Occasionally, specimens with paraproteins form gels that plug sample probes and disable automated analyzers (see later section on cryoglobulins).

Many patients with paraproteins have nonspecific presentations such as (1) anemia, (2) low or high globulins, (3) hypercalcemia, or (4) infection. The concentration of polyclonal Ig often is decreased when a paraprotein is present, accounting for increased susceptibility to infection. Identification and typing of paraproteins in serum usually are based on protein electrophoresis and immunofixation electrophoresis of serum or urine,[5] as described in a later section. Analysis of urine is helpful mainly in identifying patients with monoclonal urinary light chains, which are sometimes referred to as **Bence-Jones proteins**. This is term originally referred to a subset of free light chains in urine that precipitated upon heating to 50 °C to 60 °C and redissolved upon further heating to 90 °C to 100 °C. Introduction of capillary electrophoresis and assays for free light chains has led to several alternative approaches for detecting paraproteins. Serum protein electrophoresis combined with analysis of free light chains in serum appears to have a diagnostic yield similar to use of immunofixation electrophoresis. Analysis of free light chains tends to detect residual disease or recurrence at lower concentrations than does immunofixation. The prognosis of paraproteins generally depends on (1) the type of disorder producing the paraprotein, (2) the class of the paraprotein, and (3) its concentration. The concentration of paraprotein at the time of diagnosis usually correlates with the extent of disease. The rate of increase in concentration is indicative of expansion of the clone producing the paraprotein.

Multiple Myeloma. Multiple myeloma is a malignant neoplasm, usually of a single clone of plasma cells. The plasma cells usually proliferate diffusely throughout the bone marrow, but occasionally they form a solitary tumor called a plasmacytoma. Osteolytic bone lesions are produced, and the other bone marrow cells are reduced so that platelets, red cells, and neutrophils may be decreased. Normal plasma cells are inhibited; consequently, synthesis of other immunoglobulins is reduced, and recurrent infections may occur. The incidence of multiple myeloma is low in individuals younger than 60 years and increases with age. Patients may have local symptoms of a bone lesion, such as pain or fracture, but more often have nonspecific symptoms, such as (1) weight loss, (2) anemia, (3) hemorrhage, (4) repeated infections, or (5) renal failure. Significant diagnostic features include (1) detection of neoplastic plasma cells in bone marrow aspirates, (2) radiological findings of osteolytic lesions, and (3) identification of a paraprotein in serum or urine. All patients with suggestive symptoms should be screened for paraproteins; less than 1% of patients with multiple myeloma do not have detectable paraproteins. Table 18-5 lists the paraproteins that are associated with multiple myeloma and some of their characteristic findings.

Lymphoid Tumors. Lymphoid tumors such as lymphomas or chronic lymphocytic leukemias, arise from less mature stages in B-lymphocyte development. About one in five cases produce paraproteins, usually of the IgM class.

Waldenström's Macroglobulinemia (WM). Waldenström's macroglobulinemia is a malignant proliferation of plasmacytoid cells producing IgM. It differs from multiple myeloma in terms of (1) biology, (2) outcome, and (3) treatment. Clonal expansion in WM involves more immature B lymphocytes. IgM is a high-molecular-weight protein, and IgM paraproteins cause hyperviscosity that may require treatment by plasma exchange. Serum viscosity measurement helps to assess this problem. Monoclonal IgM also may behave as a cryoglobulin.

Heavy Chain Disease. Heavy chain disease is a rare disorder in which a free Ig heavy chain is produced. Heavy chains

TABLE 18-5 Monoclonal Immunoglobulins (Paraproteins) in Multiple Myeloma

Plasma Paraprotein	Incidence (%)	Age of Occurrence (Mean)	Incidence of Light Chain Proteinuria (%)	Comments
IgG	50	65	60	Patients more susceptible to immunodeficiency; paraproteins reach highest concentrations
IgA	25	65	70	Tend to have hypercalcemia and amyloidosis; paraprotein often in β-region
Free Ig light chains (Bence-Jones)	20	56	100	Often renal failure; bone lesions; amyloidosis; poor prognosis
IgD	2	57	100	90% λ-type; often have amyloidosis, renal failure; poor prognosis
IgM	1	—	100	May have hyperviscosity
IgE	0.1	—	Most	—
Biclonal	1	—	—	—
None detected	<1	—	0	Usually decreased normal immunoglobulins

are shorter than usual and lack a segment that links them to light chains. The most common form is α-chain disease (the heavy chain of IgA), which may be associated with intestinal infiltration with clonal lymphocytes, possibly resulting in malabsorption.

Cryoglobulinemia. Cryoglobulins are serum proteins or protein complexes that precipitate at temperatures lower than normal core body temperature.[8] Precipitation of cryoglobulins in tissues results in vasculitis and ischemic injury to peripheral tissues at a lower temperature. Patients must be kept in a warm environment until treatment lowers cryoglobulin concentrations. Type I cryoglobulins consist of monoclonal immunoglobulins, often IgM. Occasionally, specimens with high paraprotein concentrations will gel, and the gel will plug sample probes of automated analyzers. Most cryoglobulin complexes consist of polyclonal immunoglobulins with a monoclonal Ig (type II cryoglobulin) or polyclonal immunoglobulins without a monoclonal component (type III). Polyclonal cryoglobulins often present with chronic infection, particularly with hepatitis C. Laboratory testing for cryoglobulins requires (1) transport, (2) clotting, and (3) centrifugation of specimens at temperatures near body temperature to avoid loss of cryoglobulins during clotting or centrifugation. For cryoglobulin analysis, serum usually is refrigerated for 7 days and centrifuged. Cryoglobulins precipitated in the cold should redissolve when warmed back to 37 °C, whereas cryofibrinogen will not redissolve when warmed. Unusual solubility properties of cryoglobulins and paraproteins may result in unpredictable interferences in photometric assays, and precipitated cryoglobulins may interfere with automated hematology analyzers.

Amyloidosis. Amyloidosis is a pathological process in which proteins are deposited in tissues as aggregates, termed amyloid, that form β-sheet structures. Depending on the site of deposition, amyloidosis has been observed to result in (1) kidney failure, (2) heart failure, (3) peripheral neuropathies, and (4) other disorders. The aggregates are stable filamentous structures resistant to proteolysis and normal clearance mechanisms, so they accumulate over time. Formation of amyloid occurs when production of (1) specific proteins, (2) genetic variants of proteins, or (3) fragments of proteins that are prone to aggregation is increased. At least 26 different proteins are identified as primary components of amyloid. Amyloidoses have often been classified according to sites or clinical presentation of tissue injury, but it may be more useful to classify amyloidosis according to the primary component in amyloid deposits. Amyloidosis cannot be diagnosed by analysis of plasma proteins because it is a process that occurs in tissues. Diagnosis is made by analysis of tissues obtained from (1) fat aspirates, (2) rectal biopsy specimens, or (3) biopsy specimens of affected tissues. The β-sheet structure of amyloid has characteristic staining with Congo red dye. Genetic variants of several proteins, including (1) prealbumin, (2) apolipoproteins A-I and A-II, (3) fibrinogen, (4) gelsolin, (5) cystatin C, and (6) other proteins, are associated with amyloidosis that has widely varying clinical presentation depending on the main site of amyloid deposition. Amyloidosis may be suspected if one of these protein variants is detected. Amyloidosis occurs as the result of increased concentrations of a number of proteins including (1) Ig light chain paraproteins (AL amyloidosis), (2) BMG in renal failure (Aβ2 amyloidosis), and (3) serum amyloid A (AA amyloidosis). The latter protein is increased up to 1000-fold in chronic inflammatory conditions such as (1) rheumatoid arthritis, (2) tuberculosis, (3) osteomyelitis, (4) renal and gastric carcinomas, and (5) Hodgkin lymphoma. Amyloid produced by serum amyloid A deposition accumulates gradually in a variety of tissues, including (1) kidney, (2) liver, and (4) spleen. Patients with chronic renal failure or chronic inflammatory states are at high risk for amyloidosis.

Proteins in Other Body Fluids

In addition to plasma, proteins of clinical interest are found in several other body fluids and tissues, including (1) urine, (2) CSF, (3) amniotic fluid, (4) saliva, (5) feces, and (6) pleural and peritoneal fluids.

Urinary Proteins

Urine usually represents a fluid with much lower protein concentration than plasma. Urine represents, in part, an ultrafiltrate of plasma, with most of the plasma proteins, particularly the larger proteins, removed by the combined action of glomerular filtration and tubular uptake of protein. The urinary epithelium adds a few proteins, such as Tamm-Horsfall protein, that are not present in plasma. Analysis of urinary proteins is performed mainly to diagnose kidney disease (see Chapter 35) or disorders with paraprotein production. Four basic causes of increased urinary protein excretion (proteinuria) are known: (1) glomerular injury, (2) tubular injury, (3) overflow proteinuria of low-molecular-weight proteins, and (4) postrenal proteinuria.

Glomerular Proteinuria. Glomerular proteinuria sometimes is referred to as albuminuria, because albumin is the major protein. Many disease processes produce glomerular injury, including (1) diabetes, (2) SLE, (3) IgA nephropathy, (4) various forms of glomerulonephritis, and (5) hepatitis and human immunodeficiency virus (HIV) infections. Urine dipsticks detect the markedly increased urinary protein excretion when major glomerular injury occurs. The dipstick test for protein relies on a pad coated with a pH indicator dye such as tetrabromphenol blue, together with a citrate buffer at pH 3. The dye changes color in the presence of protein with a lower detection limit of about 15 to 30 mg/dL. The test is more sensitive to albumin than globulins. Positive dipstick reactions for protein are often followed by quantitative assays for urine protein. A variety of methods are used, including pyrogallol red dye-binding assays and benzethonium chloride turbidity assays. Normal urinary protein excretion is <150 mg/d. Excretion of >1 g/d of protein usually indicates glomerular injury. Excretion of >3.5 g/d protein is a criterion for the nephrotic syndrome, which is also characterized by (1) hypoalbuminemia, (2) hypercholesterolemia, and (3) edema.

Early stages of glomerular injury are characterized by modestly increased urinary albumin excretion of 30 to 300 mg/d, also termed microalbuminuria, which is a risk factor for progression of kidney disease in diabetes. Urine albumin (often

called microalbumin) assays usually rely on immunoturbidimetric or immunonephelometric methods to achieve adequate sensitivity and specificity. Because of the inconvenience and problems associated with collecting 24-hour urine specimens, urine albumin usually is measured on random urine specimens and expressed as a ratio versus creatinine to correct for the degree of urine dilution. A reference value of 30 mg albumin/g creatinine has often been used, although females tend to have slightly higher values because of their lower rates of creatinine excretion. For this reason, guidelines recommend using a reference value of 23 mg/g for males and 32 mg/g for females. Increased albumin excretion has been used as a staging criterion for chronic renal disease and is a risk factor for increased overall mortality.

Proteinuria due to pathological processes must be distinguished from *f*unctional or benign proteinuria that occurs with (1) exercise, (2) fever, and (3) exposure to cold. Protein excretion rates are less than 1 g/d. Postural or orthostatic proteinuria, associated with the upright position, is also a form of functional proteinuria, but excretion may exceed 1 g/d. Orthostatic proteinuria complicates assessment of otherwise symptomless patients. If transient, it is probably benign; persistence of proteinuria suggests underlying renal disease. Analysis of random urine specimens collected in the morning, such as the first voided specimen of the day, may minimize the effects of orthostatic proteinuria. In normal pregnancy, protein excretion may increase slightly (<300 mg/d). Urinary protein is tested in pregnancy as an indicator of preeclampsia, which is characterized by an increase in blood pressure and proteinuria >300 mg/d. Identification of preeclampsia is important in that it can progress to eclampsia, a severe hypertensive crisis in pregnancy.

Tubular Proteinuria. In tubular proteinuria, low-molecular-weight proteins appear in the urine as a result of decreased reabsorption by the proximal tubules. Tubular proteinuria may be caused by (1) hereditary disorders of tubular function such as Fanconi syndrome; (2) toxicity from compounds such as (a) aminoglycosides, (b) cyclosporine, (c) tacrolimus, (d) amphotericin B, (e) radiocontrast dyes, (f) cisplatin, and (g) ethylene glycol; (3) poisoning with heavy metals such as cadmium and lead; (4) ischemia due to obstruction of blood flow or decreased blood flow in shock or heart failure; or (5) toxicity from overload with proteins such as free Ig light chains, hemoglobin, or myoglobin. When tubular proteinuria occurs alone, albumin excretion may not increase sufficiently to give a positive dipstick reaction. More specific tests are required to detect simple tubular proteinuria. Agarose electrophoresis of urine from af icted patients gives a characteristic pattern, with prominent α- and β-bands and a relatively faint albumin band. Electrophoretic methods use gradient pore gels or other methods that separate on the basis of size, such as sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE).

Quantitative immunoassays for low-molecular-weight proteins such as BMG help identify increased excretion as an indicator of tubular injury in disorders such as poisoning with lead or other heavy metals. One problem with measurement of BMG is that it is unstable at a urine pH <6. For this reason, a variety of other low-molecular-weight proteins, such as cystatin C and α_1-microglobulin, have been considered markers for tubular injury. Some proteins made by the tubules also are potential markers, including (1) N-acetyl-β-glucosaminidase (NAG), (2) kidney injury molecule-1 (KIM-1), and (3) neutrophil gelatinase-associated lipocalin (NGAL). Synthesis of the latter two markers is induced by tubular injury. T ese markers have not been widely used in clinical practice, but researchers are interested in finding better markers for acute kidney injury than serum creatinine, which responds by rising relatively slowly after kidney injury.

Overload Proteinuria. Overload proteinuria occurs when an increased load of small proteins filtered through the glomerulus exceed the tubular uptake capacity. Some examples of proteins causing overload proteinuria are (1) hemoglobin, (2) myoglobin, and (3) free Ig light chain paraproteins, when massive amounts of these proteins are released, respectively, by (1) red cell lysis, (2) muscle cell injury, and (3) multiple myeloma. Detection of light chains depends on electrophoretic and immunochemical testing. Hemoglobin or myoglobin confers a brown color to urine, and both yield positive reactions in the dipstick test for blood, which relies on the peroxidase activity of heme in hemoglobin or myoglobin. Muscle injury is identified by symptoms of muscle injury and high activities or concentrations of muscle markers such as creatine kinase and myoglobin in serum.

Postrenal Proteinuria. Postrenal proteinuria arises from (1) injury, (2) inflammation, or (3) malignancy of the lower urinary tract. Microscopic examination of urine may reveal inflammatory and malignant cells and bacteria; formed elements called casts that arise in kidney tubules help to distinguish whether a process is occurring in the kidneys or in the lower urinary tract.

Laboratory Considerations

Qualitative detection of excess protein in urine is most commonly achieved using dipstick tests, which are more sensitive to albumin than to most other plasma proteins. T erefore, dipsticks are excellent screening tests for major glomerular injury, but they are less useful for detecting tubular proteinuria or overload proteinuria from Ig light chains. Immunoassays for urine albumin detect glomerular injury at an earlier stage than assays for urine total protein or urine dipsticks.

Proteins in Cerebrospinal Fluid

CSF is the extracellular fluid around the brain and spinal column. CSF usually has total protein concentrations about 100-fold lower than those of plasma and a different protein composition. CSF for laboratory testing usually is obtained by a physician performing a spinal tap in the lumbar region.

Biochemistry and Function

CSF is secreted by the choroid plexuses, along the walls of the ventricles of the brain, and is reabsorbed into the blood through the arachnoid villi. CSF turnover normally is rapid, exchanging totally about four times per day. More than 80% of CSF protein originates from plasma by ultrafiltration and pinocytosis; the remainder is derived from intrathecal synthesis.

The protein concentration of CSF is lowest in ventricular fluid and is slightly higher along the spinal cord, where specimens usually are collected. Because CSF is mainly an ultrafiltrate of plasma, relatively small plasma proteins, such as (1) prealbumin, (2) albumin, and (3) transferrin, typically predominate. No protein with a size larger than that of IgG is present in sufficient amounts to be visible in electrophoretic patterns. The β_2-transferrin band represents carbohydrate-deficient transferrin (CDT).

Clinical Significance

Analysis of CSF proteins is performed mainly to determine whether permeability of the blood–brain barrier or intrathecal synthesis of immunoglobulins is increased.

Increased Permeability. Increased permeability of the blood–brain barrier may result from (1) a brain tumor, (2) intracerebral hemorrhage, (3) traumatic injury, or (4) inflammation associated with meningitis, encephalitis, or poliomyelitis. Among inflammatory processes, the greatest elevations in CSF total protein are seen in bacterial meningitis. Premature and full-term neonates have greater permeability and, as a result, considerably higher concentrations of total CSF protein (up to 130 mg/dL) when compared with healthy adults. Premature infants have CSF protein of up to 400 mg/dL.

Intrathecal Synthesis. Demonstration of increased intrathecal synthesis of immunoglobulins aids in the diagnosis of demyelinating diseases of the central nervous system (CNS). In multiple sclerosis, synthesis of immunoglobulins in the CNS is increased; the CSF concentration of immunoglobulins is increased, and the immunoglobulins have an oligoclonal pattern that is suggestive of multiple sclerosis.

Laboratory Considerations

Similar methods often are used to measure urine and CSF proteins. Common methods for measuring CSF protein include (1) pyrogallol red dye-binding assays, (2) benzethonium chloride turbidity assays, and (3) biuret assays. The reference interval for CSF total protein collected by lumbar puncture is 15 to 48 mg/dL. Elderly adults have slightly higher values—up to 60 mg/dL. The presence of blood in the CSF indicates contamination during collection or bleeding within the CNS.

The reference interval for albumin in lumbar CSF is 18 to 25 mg/dL. In normal CSF, individual IgA, IgD, and IgM values are less than 0.2 mg/dL. The reference interval for CSF IgG in adults is 0.8 to 4.2 mg/dL. Calculating the ratio of CSF albumin to serum albumin provides a measure of permeability of the blood–brain barrier; a ratio <9 indicates an intact barrier (where CSF albumin is measured in mg/dL and serum albumin is measured in g/dL). Calculations based on CSF IgG and albumin and on serum IgG and albumin provide estimates of rates of IgG synthesis in the CNS. Increased IgG synthesis, together with the finding of oligoclonal bands of Ig upon immunofixation electrophoresis or isoelectric focusing, supports the presence of an inflammatory process in the CNS such as multiple sclerosis. Because of the relatively low protein concentration of CSF, it must be concentrated before electrophoretic analysis, or high-sensitivity staining techniques must be used. Relatively high-resolution agarose zone gel electrophoresis or isoelectric focusing is required to achieve optimal detection of oligoclonal bands of Ig.

CSF is enriched in a number of proteins released by neural and glial cells. Active investigation is continuing to explore specific immunoassays of a number of CSF proteins as potential markers for traumatic or ischemic injury or for disease processes such as Alzheimer disease. The relatively large amounts of β_2-transferrin or prostaglandin D synthase (also known as β-trace) in CSF are sometimes used as a marker to determine whether clear fluid from the nasal or ear passages represent leakage of CSF.

Proteins in Amniotic Fluid

Amniotic fluid is analyzed for α-fetoprotein (AFP) and other analytes in antenatal screening for fetal defects (refer to Chapter 44 on disorders of pregnancy).

Proteins in Saliva and Oral Fluid

Saliva represents the fluid secreted by several salivary glands and has a very different protein composition than plasma, with amylase and small peptides representing the major components. Protein composition depends on the site and method of sampling saliva. Saliva is tested for secretory IgA in evaluation of possible immunological deficiency and for BMG in Sjögren syndrome. Oral fluid or crevicular fluid represents fluids released from the oral epithelium combined with saliva. Oral fluid is of interest because of the higher concentrations of immunoglobulins that allow it to be used as a test specimen for antibodies to infectious diseases such as HIV. Saliva is lacking in many of the hormone-binding proteins present in plasma; concentrations of hormones such as cortisol are much lower and are related to the concentrations of free hormone in plasma.

Proteins in Feces

Assay of feces for AAT is used sometimes in the diagnosis of gastrointestinal protein loss. Unlike most other plasma proteins, it is resistant to breakdown by proteolytic enzymes in the gut. Fecal AAT preferably is determined as clearance on a timed collection to determine an excretion rate corrected for the activity of serum AAT. For inflammatory bowel disease, it is useful to have markers of inflammation, as well as of increased permeability to plasma proteins. Fecal content of products secreted by white cells, such as lactoferrin and calprotectin, has been used as a measure of disease activity in inflammatory bowel disease.

Proteins in Peritoneal and Pleural Fluid

Pathological accumulations of fluid in the peritoneal (abdominal) and pleural (lung) cavities or elsewhere vary greatly in protein content. For example, they may be (1) transudates that represent ultrafiltrates with low protein concentrations relative to plasma and scant amounts of large proteins, or (2) exudates with relatively high protein concentrations resulting from increased vascular permeability related to tissue injury and inflammation. The distinction of transudates from exudates

assists in diagnosing the cause of fluid accumulation. The major cause of pleural transudates is congestive heart failure. Pleural exudates occur with infection, pleuritis, pulmonary embolism, and cancer. The following criteria have been commonly applied to identify exudates in pleural fluid: (1) pleural fluid protein/serum protein >0.5, (2) pleural LDH/serum LDH >0.6, and (3) pleural fluid LDH >200 IU/L. Pleural fluid may be turbid because of the presence of numerous white cells, fibrin particles, or chylomicrons. Chylous effusion (containing chylomicrons) results from lymphatic obstruction related to cancer, surgery, trauma, or other causes. Lymphatics serve as the major route for chylomicrons from the intestine to the blood circulation via the thoracic duct. Entry of chylomicrons into the pleural space in cases of lymphatic obstruction, therefore, is related to dietary fat intake, and fasting lowers the fat content of chylous effusions. Chylomicrons in fluids may be identified by separation of an upper creamy layer upon standing or by triglyceride analysis.

For peritoneal fluid, determination of the serum-to-fluid albumin gradient is useful in distinguishing transudates from exudates (which often are related to infection or cancer). Usually, transudates have a serum albumin-to-fluid albumin gradient >1.1 g/dL. Exudates have a smaller gradient because of a breakdown in the vascular barrier.

Review Questions

1. A nonspecific response to inflammation that includes elevation of certain plasma proteins and decrease of others due to cytokine production is referred to as a(n):
   a. cytokine response.
   b. acute-phase response.
   c. reduction reaction.
   d. allergic reaction.
2. An ampholyte is a(n):
   a. protein that contains one or more prosthetic groups.
   b. organic compound that contains both amino and carboxyl functional groups.
   c. ionized molecule with balanced negative and positive charges.
   d. relatively short chain of amino acids.
3. The pH at which a molecule such as a protein has a net charge of zero is referred to as the:
   a. isoelectric point.
   b. dissociation constant.
   c. isoelectric focus point.
   d. solubility point.
4. A paraprotein is:
   a. immunoglobulin heavy chains.
   b. a sidechain of a protein.
   c. a prosthetic group.
   d. a monoclonal immunoglobulin.
5. In the biuret reaction for protein quantification:
   a. an increase in buffer pH causes protein to bind to a blue dye.
   b. copper ions complex with peptide bonds in proteins.
   c. a change in the refractive index of light is measured.
   d. protein is precipitated by the addition of an acid solution.
6. As a separation technique, serum protein electrophoresis depends on:
   a. the number of peptide bonds present in a protein molecule.
   b. the tertiary structure of the protein.
   c. the ratio of the protein's charge to hydrodynamic size.
   d. the affinity of the protein for the support medium.
7. Analyzing protein in cerebrospinal fluid is done to:
   a. asssess the permeability of the blood–brain barrier.
   b. determine the permeability of the glomerular membrane.
   c. determine the presence of fetal defects.
   d. diagnose gastrointestinal protein loss.
8. The plasma protein that serves to transport a large number of compounds including bilirubin, calcium, drugs and free fatty acids is:
   a. prealbumin.
   b. immunoglobulin G.
   c. haptoglobin.
   d. albumin.
9. Most proteins are synthesized:
   a. in the kidney juxtaglomerular cells.
   b. by the hepatic parenchymal cells.
   c. in the gastrointestinal tract.
   d. in cellular mitochondria.
10. A malignant neoplasm of a clone of plasma cells that diffuses throughout the bone marrow and that is diagnosed in part by identification of a paraprotein in blood or urine is referred to as:
    a. multiple myeloma.
    b. Bence-Jones protein.
    c. hypogammaglobulinemia.
    d. Wilson disease.

CHAPTER

19 Serum Enzymes

Mauro Panteghini, M.D., and Renze Bais, Ph.D., F.F.Sc. (R.C.P.A.)

Objectives

1. Define the following and give an example of each type:
   - Hydrolase
   - Lyase
   - Oxidoreductase
   - Phosphotranferase
   - Transferase
2. List the factors that affect enzyme activity and appearance in blood.
3. For each of the following enzymes, state and describe the biochemistry, physiological actions (if known), tissue distribution, clinical significance, method of laboratory analysis, and possible analytical interferences:
   - 5′-Nucleotidase
   - Alanine aminotransferase
   - Aldolase
   - Alkaline phosphatase
   - Amylase
   - Aspartate aminotransferase
   - Creatine kinase
   - γ-Glutamyltransferase
   - Lactate dehydrogenase
   - Lipase
   - Serum cholinesterase
   - Tartrate-resistant acid phosphatase
4. List the isoenzymes, the clinical significance of the isoenzymes (if any), and methods of laboratory analysis used to assess the isoenzymes of each of the following:
   - Alkaline phosphatase
   - Amylase
   - Creatine kinase
   - Lactate dehydrogenase
   - Tartrate-resistant acid phosphatase
5. Describe two serum enzymes that are related to future cardiovascular (CV) events, including tissue distribution, rationale for association with adverse CV events, and methods of laboratory analysis.
6. Assess and solve case studies involving serum enzymes and isoenzymes and the laboratory analysis of these.

Key Words and Definitions

Acid phosphatase All phosphatases with optimal activity below pH 7.0 that catalyze the cleavage of orthophosphate from orthophosphoric monoesters; most of the activity in serum is of a tartrate-resistant type.

Acute pancreatitis A sudden inflammation of the pancreas that is usually accompanied with severe upper abdominal pain.

Aldolase A lyase that catalyzes cleavage of fructose-1,6-disphosphate into dihydroxyacetone-phosphate and glyceraldehyde 3-phosphate in the glycolytic breakdown of glucose to lactate.

Alkaline phosphatase A hydrolase that catalyzes the alkaline hydrolysis of a large variety of naturally occurring and synthetic substrates.

α-Amylase An enzyme that catalyzes the hydrolysis of 1,4-alpha-glycosidic linkages in starch, glycogen, and related polysaccharides and oligosaccharides.

Aminotransferases A subclass of enzymes of the transferase class that catalyze the transfer of an amino group from a donor (generally an amino acid) to an acceptor (generally a 2-koxo acid). Most of these enzymes are pyridoxyl phosphate proteins. Alanine and aspartate aminotransferase are examples that are of significant clinical utility.

Apoenzyme The protein component of an enzyme.

Cholinesterase An enzyme of the hydrolase class that catalyzes the cleavage of the acyl group from various esters of choline, including acetylcholine, and some related compounds.

Cholecystitis A painful inflammation of the gallbladder.

Coenzyme An organic nonprotein molecule that binds with the protein molecule (apoenzyme) to form the active enzyme (holoenzyme).

Creatine kinase A dimeric transferase enzyme that catalyzes the reversible phosphorylation of creatine by ATP. CK has four forms: CK-MM, CK-MB, CK-BB, and mitochondrial CK.

γ-Glutamyltransferase A transferase enzyme that reversibly catalyzes the transfer of a glutamyl group from a glutamyl-peptide and an amino acid to a peptide and a glutamyl-amino acid.

Holoenzyme Active enzyme formed by combination of a coenzyme and an apoenzyme.

Isoenzyme A molecular form that originates at the level of the genes that encode the structures of the enzyme proteins in question.

Isoform An enzyme molecular form that has been post-translationally modified.

Lactate dehydrogenase An oxidoreductase enzyme that reversibly catalyzes the reduction of pyruvate to (L)-lactate, using NADH (reduced form of nicotinamide adenine dinucleotide) as an electron donor.

Key Words and Definitions—cont'd

Lipase A hydrolase that hydrolyzes glycerol esters of long-chain fatty acid.

Lipoprotein-associated phospholipase A_2 An enzyme member of the phospholipase A_2 superfamily that cleaves oxidized phosphatidylcholine components of lipoprotein particles.

Myeloperoxidase An enzyme that catalyzes the conversion of chloride anion and hydrogen peroxide to hypochlorite, a metal chlorinating oxidant with a potent microbicidal activity.

5′-Nucleotidase A phosphatase that acts only on nucleoside-5′-phosphates, such as adenosine-5′-phosphate (AMP), releasing inorganic phosphate.

Paget disease A chronic disorder that results in enlarged and deformed bones (also known as osteitis deformans, osteodystrophia deformans).

Prosthetic group A tightly-bound, non-peptide structure required for the activity of an enzyme.

Regan isoenzyme Isoenzyme of alkaline phosphatase that has been observed in the plasma of patients with malignant tumors.

The basic principles of Enzyme and Rate Analyses are discussed in Chapter 14. Individual enzymes of diagnostic utility are discussed in this chapter. To better clarify their clinical application, the individual enzymes are discussed relative to the organ in which they are clinically most important. However, overlap may occur for this classification, as the same enzyme may be used for investigating disease in different organs.

Basic Concepts

Injury to tissue releases cellular substances such as enzymes that are used as plasma markers of tissue damage. For a substance to serve as a biochemical marker of damage to a specific organ or tissue, it must arise predominantly from the organ or tissue of interest. Some enzymes are found predominantly in specialized tissue (e.g., **lipase** in the pancreas); others, more widely distributed, have tissue-specific **isoenzymes** or **isoforms** (e.g., the pancreatic isoenzyme of **α-amylase**) that are evaluated to enhance tissue and organ specificity.

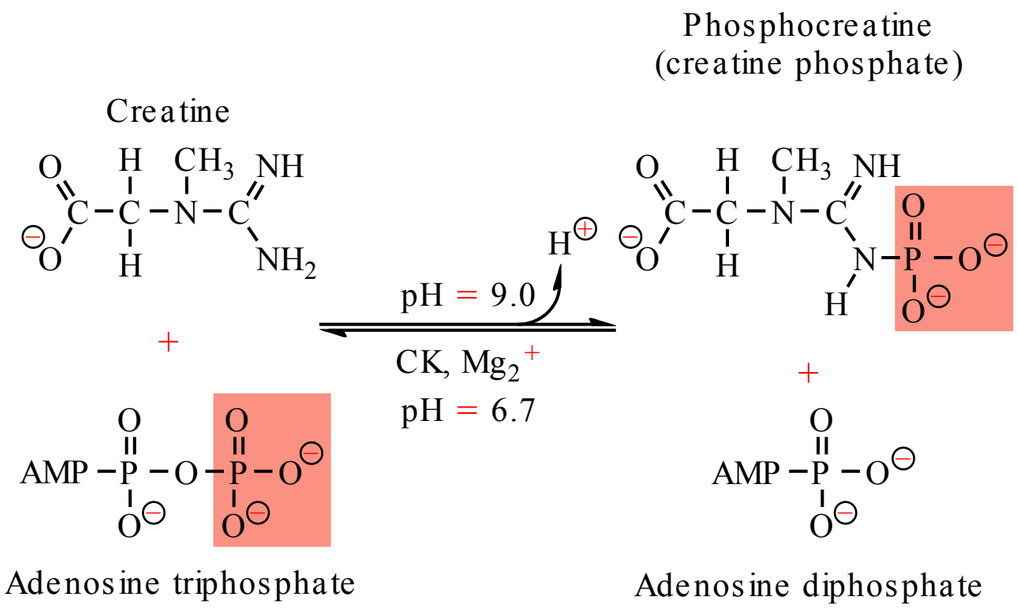
In general, clinical laboratorians are principally concerned with changes in activity in the serum or plasma of enzymes that are predominantly intracellular and physiologically present in the blood at low activity concentrations only. Changes in the serum activities of these enzymes are used to infer the location and nature of pathological changes in tissues of the body. Therefore, an understanding of the factors that affect the rate of release of enzymes from their cells of origin and the rate at which they are cleared from the circulation is necessary to interpret correctly changes in activity that occur with disease.

Knowledge of the intracellular locations of enzymes assists in determining the nature and severity of a pathological process. For instance, a mild, reversible viral inflammation of the liver, such as a mild attack of viral hepatitis, is likely to increase only the permeability of the cell membrane, thereby allowing cytoplasmic enzymes to leak out into the blood. However, a severe attack causing cell necrosis also disrupts the mitochondrial membrane, and both cytoplasmic and mitochondrial enzymes are detected in the blood. The timing of the enzyme's diagnostic window is another important aspect to be considered when these markers are used to evaluate acute injury. The diagnostic window for an injury marker is defined as the interval of time after an episode of injury during which plasma concentrations of the marker are increased, thereby demonstrating the occurrence of injury.

The main enzymes of established clinical value, together with their tissues of origin and their major clinical applications, are listed in Table 19-1.

Muscle Enzymes

Enzymes in this category include **creatine kinase** and **aldolase**.



Creatine Kinase

Creatine kinase (CK) (EC 2.7.3.2; adenosine triphosphate: creatine N-phosphotransferase) is a dimeric enzyme (82 kDa)

TABLE 19-1 Distribution and Application of Clinically Important Enzymes

Enzyme	Principal Sources of Enzyme in Blood	Principal Clinical Applications
Alanine aminotransferase	Liver	Hepatic parenchymal disease
Alkaline phosphatase	Liver, bone, intestinal mucosa, placenta	Hepatobiliary disease, bone disease
Amylase	Salivary glands, pancreas	Pancreatic disease (pancreatic isoenzyme)
Aspartate aminotransferase	Heart, liver, skeletal muscle, erythrocytes	Hepatic parenchymal disease
Creatine kinase	Skeletal muscle, heart	Muscle disease
γ-Glutamyltransferase	Liver, pancreas, kidney	Hepatobiliary disease
Lactate dehydrogenase	Heart, erythrocytes, lymph nodes, skeletal muscle, liver	Hemolytic and megaloblastic anemias, leukemia and lymphoma, oncology
Lipase	Pancreas	Pancreatic disease

that catalyzes the reversible phosphorylation of creatine (Cr) by adenosine triphosphate (ATP).

Physiologically, when muscle contracts, ATP is converted to adenosine diphosphate (ADP), and CK catalyzes the rephosphorylation of ADP to ATP using creatine phosphate (CrP) as the phosphorylation reservoir. Optimal pH values for the forward (Cr + ATP →ADP + CrP) and reverse (CrP + ADP →ATP + Cr) reactions are 9.0 and 6.7, respectively. Mg^{2+} is an obligate activating ion that forms complexes with ATP and ADP. The optimal concentration range for Mg^{2+} is narrow, and excess Mg^{2+} is inhibitory. Other inhibitors of CK activity include (1) Mn^{2+}, (2) Ca^{2+}, (3) Zn^{2+}, (4) Cu^{2+}, (5) iodoacetate, and (6) other sulfhydryl-binding reagents. The enzyme in serum is relatively unstable, and activity is lost as a result of sulfhydryl group oxidation at the active site of the enzyme. It is possible to partially restore activity by incubating the enzyme preparation with sulfhydryl compounds, such as (1) N-acetylcysteine, (2) dithiothreitol (Cleland reagent), and (3) glutathione.

Biochemistry

CK activity is greatest in striated muscle and heart tissue, which contain some 2500 and 550 U/g of protein, respectively. Other tissues, such as (1) brain, (2) gastrointestinal tract, and (3) urinary bladder, contain significantly less activity, and the liver and erythrocytes are essentially devoid of activity (Table 19-2).

CK is a dimer that is composed of two subunits, each with a molecular weight of about 40,000 Da. These subunits (B and M) are the products of loci on chromosomes 14 and 19, respectively. Because the active form of the enzyme is a dimer, only three different pairs of subunits can exist: BB (or CK-1), MB (or CK-2), and MM (or CK-3). The distribution of these isoenzymes in the various tissues of humans is shown in Table 19-2. All three of these isoenzyme species are found in the cytosol of the cell or are associated with myofibrillar structures. However, there exists a fourth form that differs from the others both immunologically and by electrophoretic mobility. This isoenzyme (CK-Mt) is located between the inner and outer membranes of mitochondria, and it constitutes, in the heart for example, up to 15% of total CK activity. The gene for CK-Mt is located on chromosome 15.

CK activity may also be found in macromolecular form—the so-called macro-CK. Macro-CK is found, often transiently, in the sera of up to 6% of hospitalized patients, but only a minor proportion of these have increased CK activities in serum. It exists in two forms: types 1 and 2. Type 1 is a complex of CK, typically CK-BB, and an immunoglobulin, often IgG. It is not of pathological significance, but it can be the cause of elevated CK results, causing diagnostic confusion and leading to unnecessary further investigation. Prevalence has been estimated as between 0.8% and 2.3%. Macro-CK type 2 is oligomeric CK-Mt, with a reported prevalence of between 0.5% and 2.6%. It is found predominantly in adults who are severely ill with malignancy or liver disease and in children who have notable tissue distress. The appearance of this isoenzyme in serum is usually associated with a poor prognosis. Macro-CK can interfere with the assay of CK-MB by some immunoinhibition methods.

TABLE 19-2 Approximate Concentrations of Tissue Creatine Kinase Activity (Expressed as Multiples of CK Activity Concentrations in Serum) and Cytoplasmic Isoenzyme Composition

		Isoenzymes, %		
Tissue	Relative CK Activity	CK-BB	CK-MB	CK-MM
Skeletal muscle (type I, slow twitch, or red fibers)	50,000	<1	3	97
Skeletal muscle (type II, fast twitch, or white fibers)	50,000	<1	1	99
Heart	10,000	<1	22	78
Brain	5,000	100	0	0
Smooth muscle				
Gastrointestinal tract	5,000	96	1	3
Urinary bladder	4,000	92	6	2

Both M- and B-subunits have a C-terminal lysine residue, but only the former is hydrolyzed by the action of carboxypeptidases present in blood. Carboxypeptidases B (EC 3.4.17.2) and N (arginine carboxypeptidase; EC 3.4.17.3) sequentially hydrolyze the lysine residues from CK-MM to produce two CK-MM isoforms: CK-MM_2 (one lysine residue removed) and CK-MM_1 (both lysine residues removed). Loss of the positively charged lysine produces a more negatively charged CK molecule with greater anodic mobility at electrophoresis. Because CK-MB has only one M-subunit, the dimer coded by the M and B genes is named CK-MB_2, and the lysine-hydrolyzed dimer is named CK-MB_1.

Clinical Significance

Serum CK is increased in nearly all patients when (1) injury, (2) inflammation, or (3) necrosis of skeletal or heart muscle occurs.

Elevation of serum CK activity may be the only sign of subclinical neuromuscular disorders. Serum CK activity is greatly elevated in all types of muscular dystrophy. In progressive muscular dystrophy (particularly Duchenne sex-linked muscular dystrophy), enzyme activity in serum is highest in infancy and childhood and may be increased long before the disease is clinically apparent. Serum CK activity characteristically falls

as patients get older and as the mass of functioning muscle diminishes with progression of the disease. About 50% to 80% of asymptomatic female carriers of Duchenne dystrophy show a threefold to sixfold increase in CK activity. High values of CK are noted in (1) viral myositis, (2) polymyositis, and (3) similar muscle diseases. However, in neurogenic muscle diseases, such as (1) myasthenia gravis, (2) multiple sclerosis, (3) poliomyelitis, and (4) Parkinsonism, serum enzyme activity is not increased.

In acute rhabdomyolysis due to crush injury, with severe muscle destruction, serum CK activities exceeding 200 times the upper reference limit (URL) may be found. If the CK remains below 5000 U/L (about 30 times the URL) during the first 3 days after the insult, the probability of developing acute renal failure appears to be low. Serum CK is also increased by other direct trauma to muscle, including intramuscular injection and surgical intervention. Finally, a number of drugs when given at pharmacologic doses increase serum CK activities. T e drugs principally responsible are (1) statins, (2) fibrates, (3) antiretrovirals, and (4) angiotensin II receptor antagonists.

Changes in serum CK and its MB isoenzyme after acute myocardial infarction have been used for diagnosis for many years. However, it is now more advantageous to use more cardiac-specific nonenzymatic markers, such as cardiac troponin I or T.

During normal childbirth, a sixfold elevation in maternal total serum CK activity occurs. Surgical intervention during labor further increases the activity of CK in serum.

Methods for Determination of Creatine Kinase Activity

Currently, all commercial assays for total CK are based on the reverse reaction, which proceeds about six times faster than the forward reaction.

CK catalyzes the conversion of CrP to Cr with concomitant phosphorylation of ADP to ATP. T e ATP produced is measured by hexokinase (HK)/glucose-6-phosphate dehydrogenase (G6PD) coupled reactions that ultimately convert $NADP^+$ (nicotinamide adenine dinucleotide phosphate) to NADPH (reduced form of NADP), which is monitored spectrophotometrically at 340 nm. T e assay is optimized by adding (1) N-acetylcysteine to activate CK, (2) EDTA to bind Ca^{2+} and increase the stability of the reaction mixture, and (3) adenosine pentaphosphate (Ap_5A) in addition to AMP to inhibit adenylate kinase (AK). A reference procedure based on this reaction principle and on optimization was developed by the International Federation of Clinical Chemistry and Laboratory Medicine (IFCC) for the measurement of CK at 37 °C.[4]

Specimens for CK analysis include heparinized serum and heparinized plasma. Anticoagulants other than heparin should not be used in collection tubes because they inhibit CK activity. CK activity in serum is relatively unstable and is rapidly lost during storage. Average stabilities are less than 8 hours at room temperature, 48 hours at 4 °C, and 1 month at −20 °C. T erefore the serum specimen should be chilled to 4 °C if the serum is not analyzed immediately and should be stored at −80 °C if analysis is delayed for longer than 30 days. A moderate degree of hemolysis (<1 g/L hemoglobin) is tolerated because erythrocytes contain no CK activity. However, severely hemolyzed specimens are unsatisfactory because enzymes and intermediates (AK, ATP, and G6P/glucose-6-phosphate) liberated from the erythrocytes may affect the lag phase and side reactions occurring in the assay system.

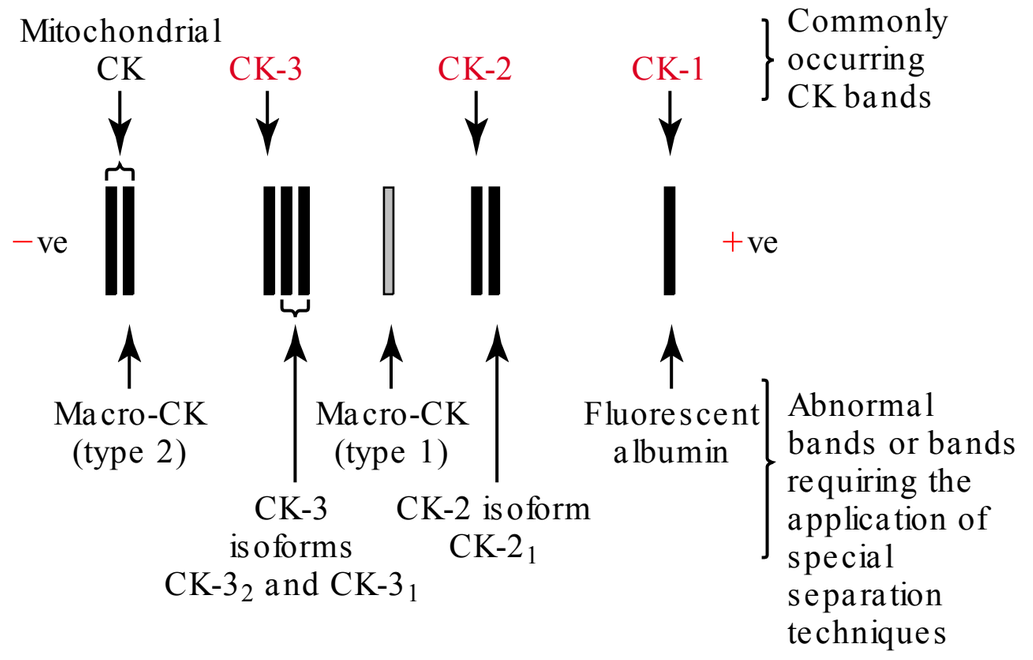


Figure 19-1 A diagrammatic representation of the electrophoretic pattern of CK isoenzymes (some of which are seen in blood only in disease) and some of the reported anomalous forms.

Serum CK activity is subject to a number of physiological variations. It is influenced by (1) sex, (2) age, (3) race, (4) muscle mass, and (5) physical exercise. Men have higher values than women, and blacks have higher values than nonblacks. In white subjects, the reference interval was found to be 46 to 171 U/L for males and 34 to 145 U/L for females, when measured with an assay traceable to the IFCC 37 °C reference procedure.[4] Newborns generally have higher CK activity resulting from skeletal muscle trauma during birth.

Methods for Separation and Quantification of Creatine Kinase Isoenzymes

Electrophoretic methods are useful for separation of all CK isoenzymes. T e isoenzyme bands are visualized by incubating the support (e.g., agarose, cellulose acetate) with a concentrated CK assay mixture using the reverse reaction. NADPH formed in this reaction is then detected by observing the bluish-white fluorescence after excitation by long-wave (360 nm) ultraviolet light. NADPH may be quantified by fluorescent densitometry, which is capable of detecting bands of 2 to 5 U/L. T e mobility of CK isoenzymes at pH 8.6 toward the anode is BB > MB > MM, with the MM remaining cathodic to the point of application. T e discriminating power of electrophoresis also allows the detection of abnormal bands (Figure 19-1).

Immunochemical methods are applicable to the direct measurement of CK-MB. Immunoinhibition techniques measuring the catalytic activity of the B subunit of CK dimer were first introduced. T ese methods were limited in their use in that interference from CK-BB, macro-CKs, or CK-Mt led to low specificity. Furthermore, because the CK-B subunit accounts for one-half of CK-MB activity, the change in absorbance should be doubled to obtain CK-MB activity. T is

resulted in a significant decrease in the analytical sensitivity of the method.

The recommended approach is to measure concentrations of the CK-MB protein ("mass") by using immunoassays with monoclonal antibodies. Measurements use the "sandwich" technique, in which one antibody specifically recognizes only the MB dimer. The sandwich technique ensures that only CK-MB is estimated because neither CK-MM nor CK-BB reacts with both antibodies. Mass assays are very sensitive, with a lower limit of detection for CK-MB usually less than 1 μg/L. Other advantages include (1) sample stability; (2) noninterference with hemolysis, (3) anticoagulants, (4) other catalytic activity inhibitors, (5) full automation; and (6) fast turnaround time.

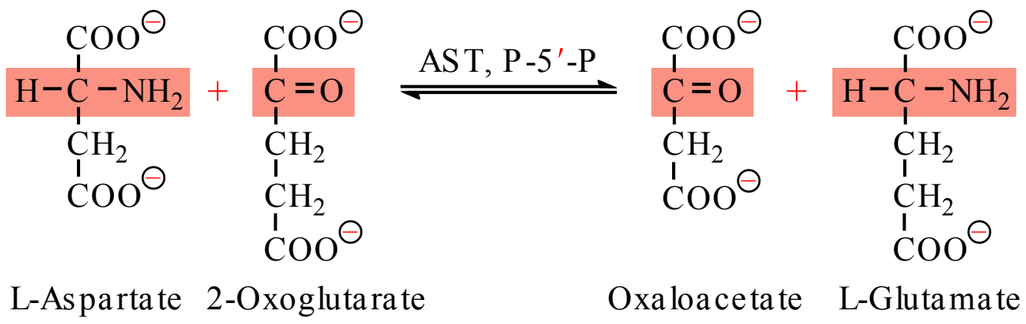
CK activity in the serum of healthy people is due almost exclusively to CK-MM activity (although small amounts of CK-MB may be present) and is the result of physiological turnover of muscle tissue. With CM-MB mass assays, the URL for males is 5.0 μg/L, with values for females being less than male values.

Aldolase

Aldolase (ALD) (EC 4.1.2.13; d-fructose-1,6-bisdiphosphate d-glyceraldehyde-3-phosphate-lyase) catalyzes the splitting of d-fructose-1,6-diphosphate to d-glyceraldehyde-3-phosphate (GLAP) and dihydroxyacetone-phosphate (DAP)—an important reaction in the glycolytic breakdown of glucose to lactate.

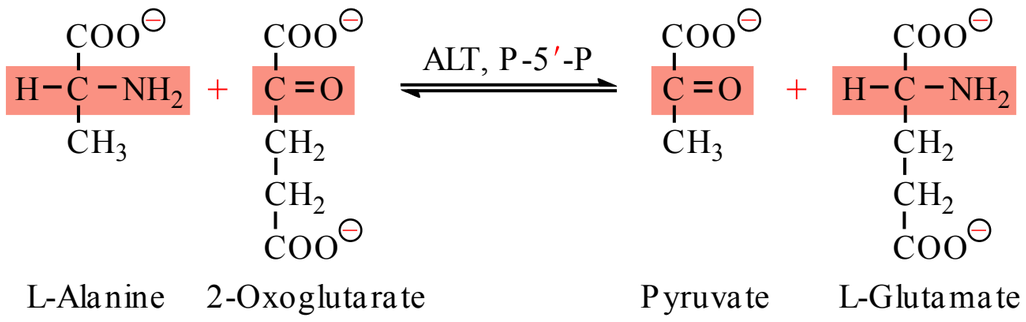
Serum ALD determinations have been of some clinical interest in diseases of skeletal muscle. Some researchers believe that increased ALD activity in combination with the CK/AST ratio is useful in distinguishing neuromuscular atrophies from myopathies. In general, however, measurement of ALD activity in the serum of subjects with suspected muscle disease does not add information to that available more readily from measurement of other enzymes, especially CK.

Liver Enzymes



Enzymes in this category include (1) alanine aminotransferase (2) aspartate aminotransferases, (3) **γ-glutamyltransferase**, (4) **alkaline phosphatase**, and (5) **5′-nucleotidase**.

Clinically, the most common alterations in liver enzyme activities are (1) hepatocellular damage (elevated aminotransaminase activities) and (2) cholestasis (elevated alkaline phosphatase, 5′-nucleotidase, and γ-glutamyltransferase activities).



Aminotransferases

The **aminotransferases** constitute a group of enzymes that catalyze the interconversion of amino acids to 2-oxo-acids by transfer of amino groups. **Aspartate aminotransferase (AST)** (EC 2.6.1.1; l-aspartate: 2-oxoglutarate aminotransferase) and **alanine aminotransferase (ALT)** (EC 2.6.1.2; l-alanine: 2-oxoglutarate aminotransferase) are examples of aminotransferases that are of clinical interest.

The 2-oxoglutarate/l-glutamate couple serves as one amino group acceptor and donor pair in all amino-transfer reactions; the specificity of the individual enzymes derives from the particular amino acid that serves as the other donor of an amino group. Thus AST catalyzes the following reaction:

ALT catalyzes the analogous reaction:

The reactions are reversible, but the equilibria of the AST and ALT reactions favor formation of aspartate and alanine, respectively.

Pyridoxal-5′-phosphate (P-5′-P) and its amino analogue, pyridoxamine-5′-phosphate, function as **coenzymes** in aminotransfer reactions. The P-5′-P is bound to the **apoenzyme** and serves as a true **prosthetic group**. P-5′-P bound to the apoenzyme accepts the amino group from the first substrate—aspartate or alanine—to form enzyme-bound pyridoxamine-5′-phosphate and the first reaction product, oxaloacetate or pyruvate, respectively. The coenzyme in amino form then transfers its amino group to the second substrate, 2-oxoglutarate, to form the second product, glutamate. P-5′-P is thus regenerated.

Both coenzyme-deficient apoenzymes and **holoenzymes** may be present in serum. Therefore, addition of P-5′-P under conditions that allow recombination with the enzymes usually produces an increase in aminotransferase activity. In accordance with the principle that all factors affecting the rate of reaction must be optimized and controlled, the addition of P-5′-P in aminotransferase methods ensures that all enzymatic activity is measured.

Biochemistry

Aminotransaminases are widely distributed throughout the body. AST is found primarily in the (1) heart, (2) liver, (3) skeletal muscle, and (4) kidney, whereas ALT is found primarily in the liver and kidney, with lesser amounts in heart and skeletal muscle (Table 19-3). ALT is exclusively cytoplasmic; however, both mitochondrial and cytoplasmic forms of AST are found in cells. These are genetically distinct isoenzymes with a dimeric structure composed of two identical polypeptide subunits of about 400 amino acid residues.

Clinical Significance

Liver disease is the most important cause of increased aminotransaminase activity in serum. In most types of liver disease, ALT activity is higher than that of AST. Exceptions may

TABLE 19-3 Aminotransferase Activities in Human Tissues, Relative to Serum as Unity

	AST	ALT
Heart	7800	450
Liver	7100	2850
Skeletal muscle	5000	300
Kidneys	4500	1200
Pancreas	1400	130
Spleen	700	80
Lungs	500	45
Erythrocytes	15	7
Serum	1	1

From King J. Practical clinical enzymology. London: D. Van Nostrand Co. Ltd., 1965.

be seen, however, in (1) alcoholic hepatitis, (2) hepatic cirrhosis, and (3) liver neoplasia. In viral hepatitis and other forms of liver disease associated with acute hepatic necrosis, serum AST and ALT activities are elevated even before the clinical signs and symptoms of disease (such as jaundice) appear. Activities for both enzymes may reach values as high as 100 times the URL, although 10-fold to 40-fold elevations are most frequently encountered. The most efficient aminotransferase threshold for diagnosing acute liver injury lies at seven times the URL (clinical sensitivity and specificity >95%). Peak values of aminotransaminase activity occur between the 7th and 12th days; activities then gradually decrease, reaching physiological concentrations by the 3rd to 5th week if recovery is uneventful. Peak activities bear no relationship to prognosis and may fall with worsening of the patient's condition.

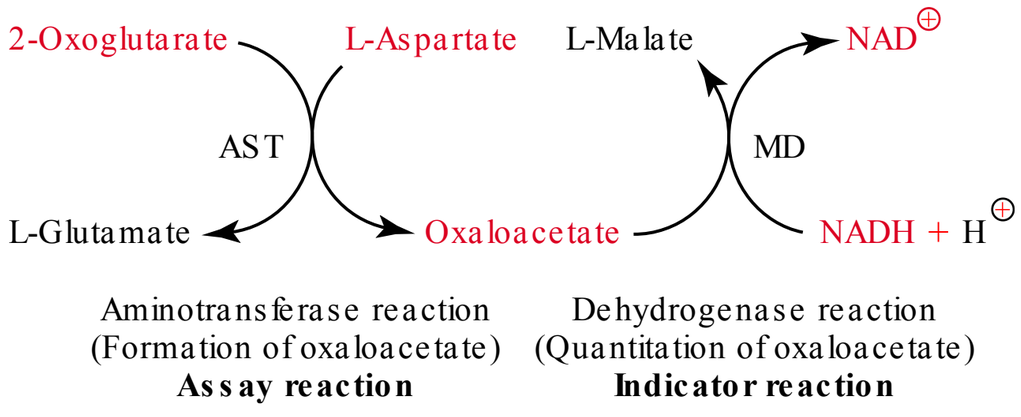
Persistence of increased ALT activity for longer than 6 months after an episode of acute hepatitis is used to diagnose chronic hepatitis. Most patients with chronic hepatitis have maximum ALT activities less than seven times the URL. The activity of ALT may be persistently normal in 15% to 50% of patients with chronic hepatitis C, but the likelihood of continuously normal ALT activity decreases with an increasing number of measurements. In patients with acute hepatitis C, the activity of ALT should be measured periodically over the next 1 to 2 years to determine if it becomes and stays normal. The clinical situation in toxic hepatitis is different from that in infectious hepatitis. In acetaminophen-induced hepatic injury, the peak of aminotransaminase activity is more than 85 times the URL in 90% of cases—a value rarely seen with acute viral hepatitis.

The activities of aminotransferases are also elevated in nonalcoholic fatty liver disease (NAFLD). This disease includes a spectrum of liver pathology, from simple steatosis to nonalcoholic steatohepatitis (NASH), in which inflammatory changes and focal necrosis may progress to (1) liver fibrosis, (2) cirrhosis, and (3) hepatic failure (see Chapter 37). NAFLD is now considered to be an additional feature of the "metabolic syndrome" with elevation of serum aminotransferase activities associated with (1) higher body mass index, (2) increased waist circumference, (3) elevated serum triglycerides, (4) elevated fasting insulin and (5) lower HDL cholesterol—all characteristic features of this syndrome.

Aminotransferase activities observed in cirrhosis vary with the status of the cirrhotic process and vary from the URL to four to five times higher, with an AST/ALT ratio (AAR) greater than 1. This appears to be attributable to a reduction in ALT production in a damaged liver, associated with reduced clearance of AST in advancing liver fibrosis. An AAR ≥1 has ≈90% positive predictive value for diagnosing the presence of advanced fibrosis in patients with chronic liver disease. Furthermore, the extent of elevation in the AAR has been known to reflect the grade of fibrosis in these patients.

Twofold to fivefold elevations of the activities of both enzymes occur in patients with primary or metastatic carcinoma of the liver, with the activity of AST usually higher than ALT activity, but their values are often within the reference interval in the early stages of malignant infiltration of the liver. Slight or moderate elevations in AST and ALT activities have been observed after administration of various medications, such as (1) nonsteroidal anti-inflammatory drugs, (2) antibiotics, (3) antiepileptic drugs, and (4) statins. Over-the-counter medications and herbal preparations are also implicated. In patients with (1) increased aminotransaminase activities, (2) negative viral markers, and (3) a negative history for drugs or alcohol ingestion. The diagnostic evaluation should include investigation of less common causes of chronic hepatic injury such as (1) hemochromatosis, (2) Wilson disease, (3) autoimmune hepatitis, (4) primary biliary cirrhosis, (5) sclerosing cholangitis, (6) celiac disease, and (7) α_1-antitrypsin deficiency.

Although serum activities of both AST and ALT become elevated whenever disease processes affect liver cell integrity, ALT is the more liver-specific enzyme. Serum elevations of ALT activity are rarely observed in conditions other than parenchymal liver disease. Thus the incremental benefit of determination of AST, in addition to ALT, may be limited.



After acute myocardial infarction, increased AST activity appears in serum (see Table 19-3). AST activity also is increased in progressive muscular dystrophy and dermatomyositis, although it is usually normal in other types of muscle disease, especially in those of neurogenic origin. Slight to moderate AST elevations are noted in hemolytic disease.

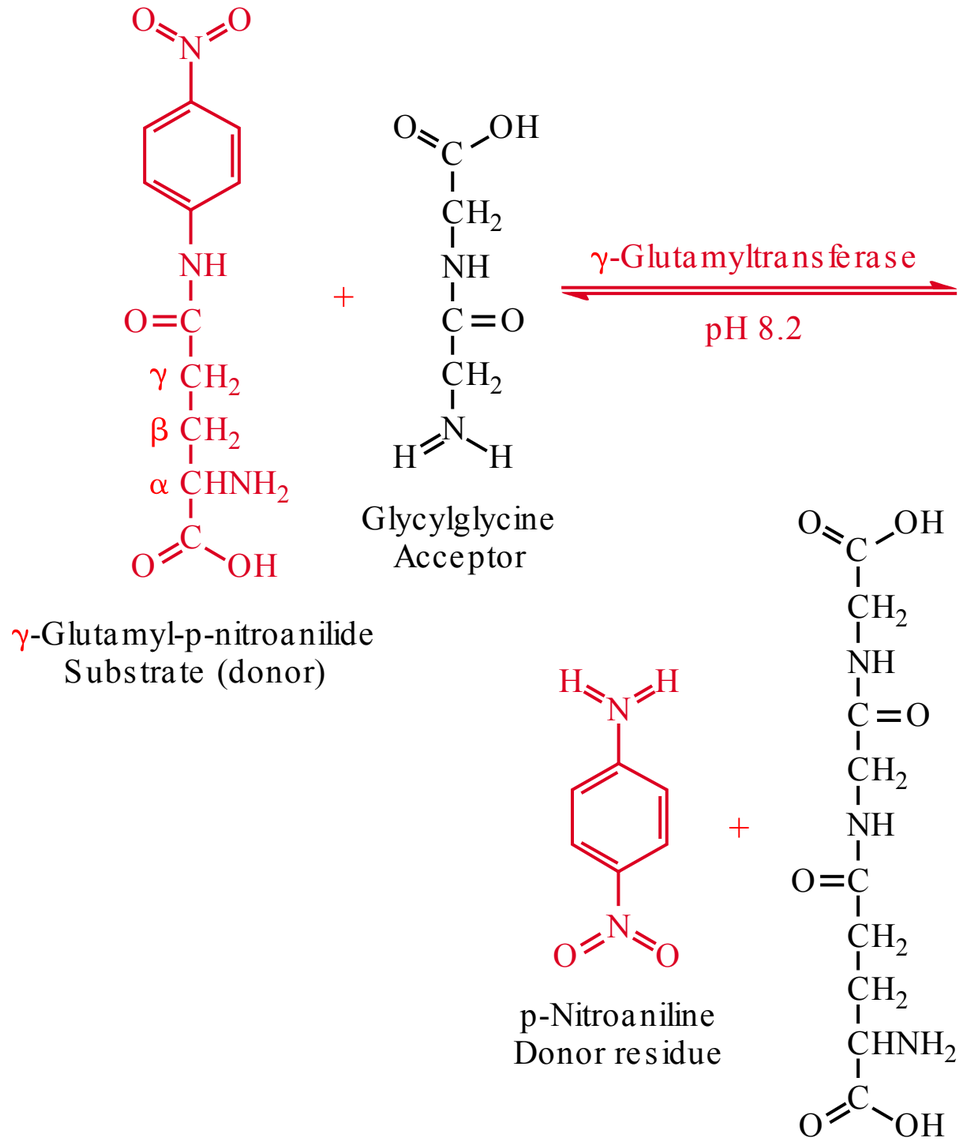
Several studies have described AST activities linked to immunoglobulins, or macro-AST. Typical findings include a persistent increase in serum AST activity in an asymptomatic patient, with absence of any demonstrable pathology in organs rich in AST. Increased AST activity reflects decreased clearance of the abnormal complex from plasma. Macro-AST has no known clinical relevance. However, identification is important to avoid unnecessary diagnostic procedures in these patients. The demonstration of macro-AST in serum is obtained by differential precipitation with polyethylene glycol (PEG) 6000 (see "Amylase" section later in this chapter).

Methods of Analysis

Continuous-monitoring methods are commonly used to measure aminotransaminase activity by coupling aminotransaminase reactions to specific dehydrogenase reactions. The oxo-acids formed in the aminotransaminase reaction are measured indirectly by enzymatic reduction to corresponding

hydroxy acids, and the accompanying change in NADH concentration is monitored spectrophotometrically. T us oxaloacetate, formed in the AST reaction, is reduced to malate in the presence of malate dehydrogenase (MD).

Pyruvate formed in the ALT reaction is reduced to lactate by **lactate dehydrogenase** (LD). T e substrate, NADH, and an auxiliary enzyme, MD or LD, are present in suf cient quantities so that the reaction rate is limited only by the amounts of AST and ALT, respectively. As the reactions proceed, NADH is oxidized to NAD^+ (nicotinamide adenine dinucleotide). T e disappearance of NADH is followed by measurement of the decrease in absorbance at 340 nm. T e change in absorbance per minute (ΔA/min) is proportional to the micromoles of NADH oxidized and in turn to micromoles of substrate transformed per minute. A preliminary incubation period is necessary to ensure that NADH-dependent reduction of endogenous oxo-acids in the sample is completed before 2-oxoglutarate is added to start the aminotransaminase reaction. As has been mentioned, supplementation with P-5′-P ensures that all aminotransaminase activity of the sample is measured.



Primary IFCC reference procedures are available for the measurement of catalytic activity concentrations of AST and ALT at 37 °C.[13,14] To assure accuracy and comparability between laboratories, the manufacturer's product calibrator values and measurement results obtained with commercial systems in daily routine practice should be traceable to these reference measurement procedures.[4]

AST activity in serum is stable for up to 48 hours at 4 °C. Specimens need to be stored frozen if they are to be kept longer. ALT activity should be assayed on the day of sample collection because activity is lost at room temperature, at 4 °C, and at −25 °C. ALT stability is better maintained at −70 °C. Hemolyzed specimens should not be used, especially when AST is measured, because of the large amount of this enzyme present in red cells.

When assays traceable to the IFCC reference procedures are used, the AST URL for adults is 35 U/L, with no significant sex-related differences.[1] Conversely, a difference in ALT activities has been noted between adult males and females. Corresponding ALT URLs are 60 U/L and 42 U/L, respectively.[1] ALT does not reveal an age dependency during childhood, whereas serum AST activity in neonates and in children younger than 3 years old is twice that in adults.

γ-Glutamyltransferase

Peptidases catalyze the hydrolytic cleavage of peptides to form amino acids or smaller peptides. T ey constitute a broad group of enzymes of varied specificity, and some individual enzymes act as amino acid transferases and catalyze the transfer of amino acids from one peptide to another amino acid or peptide. γ-Glutamyltransferase (GGT) (EC 2.3.2.2; γ-glutamyl-peptide: amino acid γ-glutamyltransferase) catalyzes the transfer of the γ-glutamyl group from peptides and compounds to an acceptor. Substrates for GGT include (1) the γ-glutamyl acceptor, (2) some amino acid or peptide, or (3) even water, in which case simple hydrolysis takes place. T e enzyme acts only on peptides or peptide-like compounds that contain a terminal glutamate residue joined to the remainder of the compound through the terminal (-γ-) carboxyl. Glycylglycine is five times more effective as an acceptor than is glycine or the tripeptide (gly-gly-gly). An example of a reaction catalyzed by the GGT is shown here:

Biochemistry

GGT is present (in decreasing order of abundance) in (1) proximal renal tubule, (2) liver, (3) pancreas, and (4) intestine. T e enzyme is present in cytoplasm (microsomes), but the larger fraction is located in the cell membrane and may transport amino acids and peptides into the cell across the cell membrane in the form of γ-glutamyl peptides. GGT is critical for the maintenance of adequate intracellular levels of reduced glutathione, a major antioxidant agent.

Clinical Significance

Even though renal tissue has the highest concentration of GGT, the enzyme present in serum appears to originate primarily from the hepatobiliary system. T us, the activity of GGT is considered a sensitive indicator of the presence of

hepatobiliary disease, but its usefulness is limited by lack of specificity. Similar to alkaline phosphatase, GGT activity is highest in cases of intrahepatic or post-hepatic biliary obstruction, reaching activities some 5 to 30 times the URL. High elevations of GGT activity are also observed in patients with primary or metastatic liver neoplasm. Moderate elevations occur in infectious hepatitis. Small increases in GGT activity are observed in more than 50% of patients with NAFLD, and similar but transient increases are noted in cases of drug intoxication. In acute and chronic pancreatitis and in some pancreatic malignancies (especially if associated with hepatobiliary obstruction), enzyme activity may be 5 to 15 times the URL.

Elevated activities of GGT also are found in the sera of patients with alcoholic hepatitis and in most sera from people who are heavy drinkers. Increased activities of the enzyme are also found in the serum of patients receiving anticonvulsant drugs such as phenytoin and phenobarbital. Such an increase in GGT activity in serum may reflect induction of new enzyme activity by the action of alcohol and drugs and/or their toxic effects on microsomal structures in liver cells.

Epidemiological studies have shown that serum GGT activity possesses an independent prognostic value for cardiovascular morbidity and mortality.

Methods of Analysis

Early GGT assays used l-γ-glutamyl-p-nitroanilide (GGPNA) as the substrate, with glycylglycine serving as the γ-glutamyl residue acceptor. The p-nitroaniline produced in the reaction is determined by its yellow color, which is measured at 405 nm. However, GGPNA has limited solubility in the reaction mixture. Therefore, with GGPNA, it is difficult to obtain saturating concentrations of substrate. Derivatives of GGPNA, in which various groups have been introduced into the benzene ring, have been used to increase solubility in water. The most useful of these substrates is l-γ-glutamyl-3-carboxy-4-nitroanilide, which is readily soluble in water and is split by GGT at a rate comparable with that observed with GGPNA. In the IFCC reference measurement procedure for GGT, l-γ-glutamyl-3-carboxy-4-nitroanilide serves as the substrate, with glycylglycine serving as an acceptor. Buffering is provided by glycylglycine itself. The temperature of the reaction is 37 °C, and the wavelength of measurement of the reaction product, 5-amino-2-nitrobenzoate, is 410 nm.

GGT activity is stable for at least 1 month at 4 °C and for 1 year at −20 °C. Nonhemolyzed serum is the preferred specimen, but EDTA plasma has also been used. Heparin may produce turbidity in the reaction mixture; citrate, oxalate, and fluoride depress GGT activity by 10% to 15%.

In adults, the URL for GGT activity in serum is 40 U/L for females and 70 U/L for males when measured with an assay traceable to the IFCC reference procedure.[1] Reference limits are approximately twofold higher in people of African ancestry. In normal full-term neonates, GGT activity at birth is approximately six to seven times the adult reference interval. The activity then declines, reaching adult values by the age of 5 to 7 months.

Alkaline Phosphatase

Alkaline phosphatase (ALP) [EC 3.1.3.1; orthophosphoric-monoester phosphohydrolase (alkaline optimum)] catalyzes the alkaline hydrolysis of a large variety of naturally occurring and synthetic substrates. Divalent ions, such as (1) Mg^{2+}, (2) Co^{2+}, and (3) Mn^{2+}, are activators of the enzyme, and Zn^{2+} is a constituent metal ion. Inhibitors of ALP activity include (1) phosphate, (2) borate, (3) oxalate, and (4) cyanide ions. Buffers for ALP assay are classified as (1) inert (carbonate and barbital), (2) inhibiting (glycine and propylamine), or (3) activating (2-amino-2-methyl-1-propanol [AMP], tris(hydroxymethyl) aminomethane [TRIS], and diethanolamine [DEA]).

Biochemistry

ALP activity is present in most organs of the body and is located in the (1) mucosa of the small intestine, (2) proximal convoluted tubules of the kidney, (3) bone (osteoblasts), (4) liver, and (5) placenta. Although the exact metabolic function of the enzyme is not yet understood, it appears that ALP is associated with lipid transport in the intestine and with the calcification process in bone.

ALP exists in multiple forms, some of which are true isoenzymes, encoded at separate genetic loci (Figure 19-2). Bone, liver, and kidney ALP forms share a common primary structure coded for by the same genetic locus, but they differ in carbohydrate content.

The ALP activity present in the sera of healthy adults originates mainly in the liver, with most of the rest coming from the skeleton. The respective contributions of these two forms to the total activity are age dependent. Minimal amounts of intestinal ALP may also be present, particularly in the sera of individuals of blood group B or O. Because intestinal ALP activity in serum may increase after a meal, ALP should be measured preferentially in fasting sera.

Clinical Significance

Clinically, serum ALP measurements are of particular value in the investigation of hepatobiliary disease and bone disease associated with increased osteoblastic activity.

Hepatobiliary Disease

The response of the liver to any form of biliary tree obstruction induces the synthesis of ALP by hepatocytes. Some of the newly formed enzyme enters the circulation to increase enzyme activity in serum. Elevation tends to be threefold greater in extrahepatic obstruction (e.g., by stone, by cancer of the head of the pancreas) than in intrahepatic obstruction and is greater the more complete the obstruction. Serum enzyme activities may reach 10 to 12 times the URL and usually return to normal on surgical removal of the obstruction. A similar increase is seen in patients with advanced primary liver cancer or widespread secondary hepatic metastases. Liver diseases that principally affect parenchymal cells, such as infectious hepatitis, typically show only moderately (less than threefold) increased or even normal serum ALP activities. Increases may also be seen as a consequence of a reaction to drug therapy. Intestinal ALP isoenzyme, an asialoglycoprotein normally

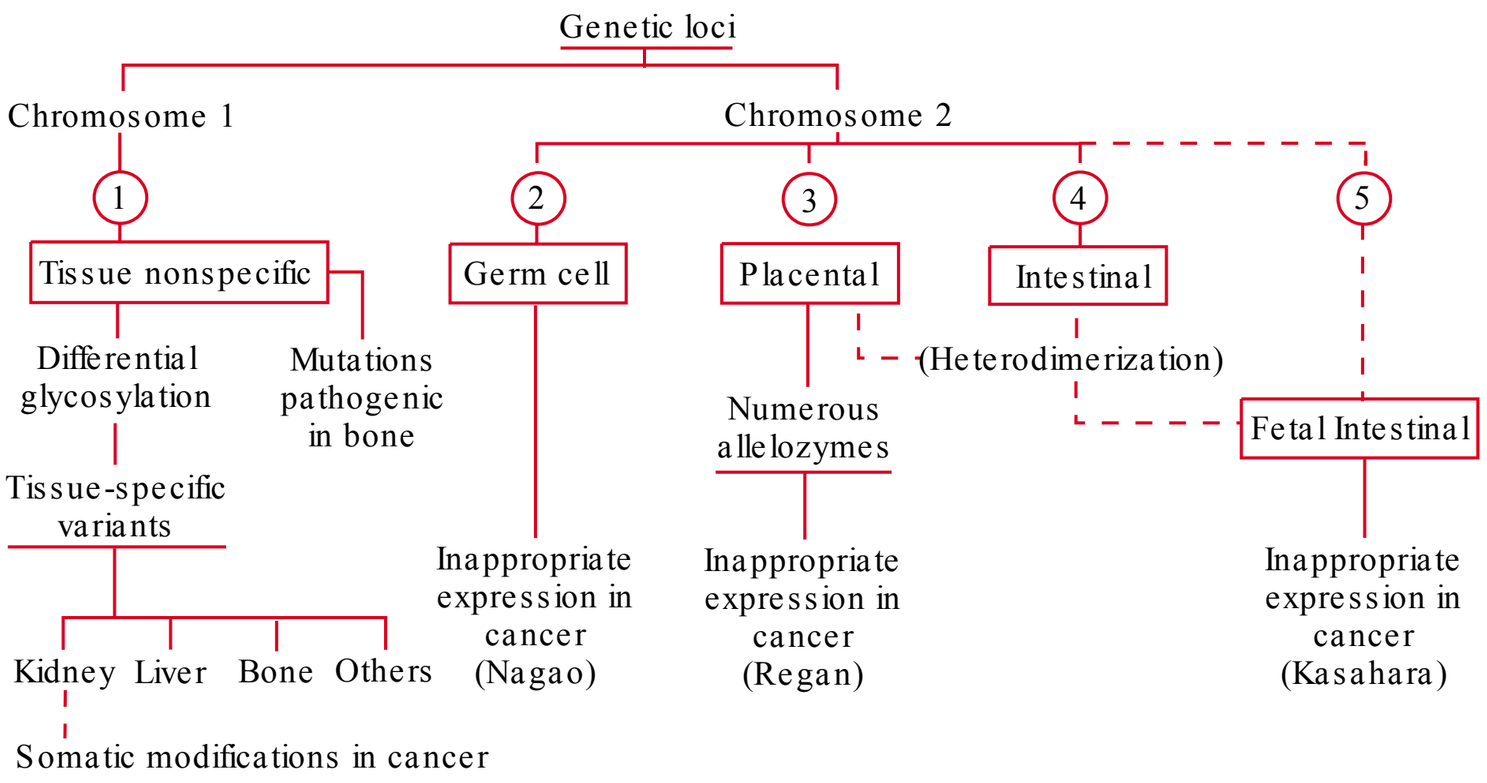


Figure 19-2 Identities, chromosomal assignments, and main physiological and pathological expression of genes encoding human alkaline phosphatases. The gene names (and gene symbols) are alkaline phosphatase, liver/bone/kidney (ALPL); alkaline phosphatase, intestinal (ALPI); alkaline phosphatase, placental (ALPP); and alkaline phosphatase, placental-like 2 (ALPPL2). Broken lines show two alternative proposed origins of the fetal intestinal alkaline phosphatase; the sequence of a cDNA is reportedly identical to that of adult intestinal alkaline phosphatase. All isoenzymes and isoforms are glycoproteins, thus imposing a further level of microheterogeneity. Different processes of cleavage or preservation of the membrane-anchoring domain can generate additional isoforms. (Modifed *f*rom Moss DW. Perspectives in alkaline phosphatase research. Clin Chem 1992;38:2486-92.)

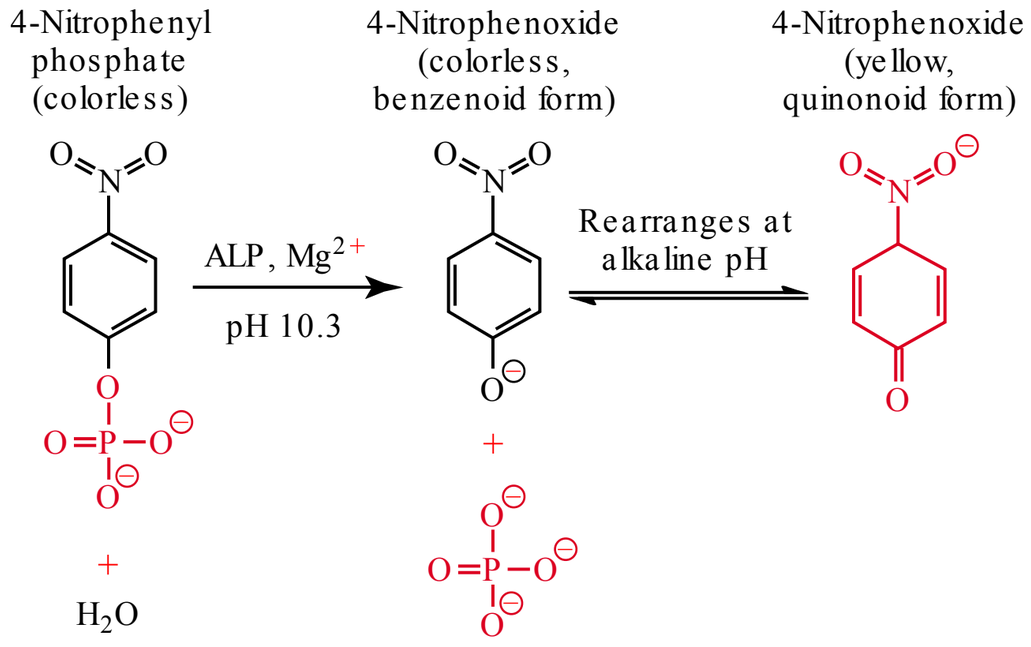
cleared by the hepatic asialoglycoprotein receptors, is often elevated in patients with liver cirrhosis.

Bone Disease

Bone ALP is produced by the osteoblast and has been demonstrated in matrix vesicles deposited as "buds" derived from the cell's membrane. T e enzyme therefore is an excellent indicator of global bone formation activity. Genetic inability to produce tissue-nonspecific ALP, including bone isoform, a rare inherited disorder known as hypophosphatasia, results in severe bone disease and impaired bone growth.

Among the bone diseases, the highest concentrations of bone ALP are encountered in **Paget disease** (osteitis deformans) as a result of the action of osteoblastic cells as they try to rebuild bone that is being resorbed by uncontrolled activity of osteoclasts (see Chapter 39). Activities from 10 to 25 times the URL are not unusual with the increase reflecting the extent of disease. In vitamin D deficiency (osteomalacia and rickets), concentrations two to four times the URL may be observed. Primary hyperparathyroidism and secondary hyperparathyroidism are associated with slight to moderate elevations of bone ALP in serum, with the existence and degree of elevation reflecting the presence and extent of skeletal involvement. Very high enzyme concentrations are present in patients with osteogenic bone cancer. Bone ALP is slightly increased in osteoporosis, but osteoporotic individuals are not clearly distinguished from age-matched controls. Transient elevations of ALP may be found during healing of bone fractures. Physiological bone growth increases bone ALP in serum, and this accounts for the fact that in the sera of growing children, the enzyme concentration is 1.5 to 7 times that in healthy adult serum; the maximum is reached earlier in girls than in boys.

Other Conditions That Increase ALP



An increase in ALP activity of up to two to three times the URL is observed in women in the third trimester of pregnancy, and the additional enzyme is of placental origin. Reports have described a benign familial elevation in serum ALP activity due to increased concentrations of intestinal ALP. Transient, benign increases in serum ALP activity may be observed in infants and children, with changes often more than 10 times the URL. Increases in both liver and bone forms are seen. T ese changes seem to reflect a reduction in the removal of ALP from blood caused by transient modifications of enzyme glycosylation.

ALP forms essentially identical to the normal placental or germ cell isoenzymes appear in the sera of some patients with malignant disease. T ese carcinoplacental isoenzymes (e.g., **Regan isoenzyme**) result from derepression of the placental or placental-like 2 ALP genes. T e presence of these isoenzymes is readily detected in serum by their stability at 65 °C. Tumors have also been found to produce ALPs that appear to be post-translationally modified forms of nonplacental isoenzymes.

Methods of Analysis for Total ALP Activity and Isoenzyme Content

T e most popular of the chromogenic substrates for ALP is 4-nitrophenyl phosphate (usually abbreviated 4-NPP, or PNPP from the older name, p-nitrophenyl phosphate). T is

ester is colorless, but the final product is yellow at the pH of the reaction:

The enzyme reaction is continuously monitored by observing the rate of formation of the 4-nitrophenoxide ions at 405 nm. This reaction forms the basis of current methods of ALP assay. The liberated phosphate group is transferred to water, and the rate of phosphatase action is enhanced if certain amino alcohols are used as phosphate-accepting buffers. Among these activators are compounds such as (1) AMP, (2) DEA, (3) TRIS, and (4) N-methyl-d-glucamine (MEG). The IFCC-recommended procedure uses 4-NPP as the substrate and AMP as the phosphate-acceptor buffer.[15]

Serum or heparinized plasma, free of hemolysis, should be used. Complexing anticoagulants—such as citrate and EDTA—must be avoided because they bind cations, such as Mg^{2+} and Zn^{2+}, which are necessary cofactors for ALP activity measurement. Freshly collected serum samples should be kept at room temperature and assayed as soon as possible but preferably within 4 hours after collection. In sera stored at a refrigerated temperature, ALP activity increases slowly (2% per day); this is thought to be due to the reincorporation of the cations required for full activity. Frozen specimens should be thawed and kept at room temperature for 18 to 24 hours before measurement to achieve full enzyme reactivation.

ALP activities in serum vary with age. Children show higher ALP activity than healthy adults as a result of leakage of bone ALP from osteoblasts during bone growth. When assays that are traceable to the IFCC reference procedure were used, the ALP reference intervals (central 95th percentiles) for adult males and adult premenopausal females were 43 to 115 U/L and 33 to 98 U/L, respectively.[15]

Assays for ALP isoenzymes are needed when (1) the source of an elevated ALP activity in serum is not obvious and should be clarified; (2) the main clinical question is concerned with detecting the presence of liver or bone involvement; and (3) it is important to ascertain any modifications in the activity of osteoblasts to monitor disease activity and the effects of appropriate therapies in the case of bone disorders. Criteria that have been used to differentiate the isoenzymes and other multiple forms of ALP include (1) electrophoretic mobility; (2) stability to denaturation by heat or chemicals; (3) response to the presence of selected inhibitors; (4) affinity for specific lectins; and (5) immunochemical characteristics.

After electrophoresis, ALP zones are visualized by incubating the gel in a solution of buffered substrate. The liver ALP typically moves most rapidly toward the anode. Bone ALP, which typically gives a more diffuse zone than the liver form, has slightly reduced anodal mobility, although the two zones usually overlap to some extent. Intestinal ALP migrates more slowly than the bone enzyme, whereas the placental isoenzyme commonly appears as a discrete band overlying the diffuse bone fraction. An additional band, which is frequently present in the serum of patients with various hepatic diseases, contains a high-molecular-weight form of ALP but is strongly negatively charged. Therefore, it moves slowly into or may even fail to enter polyacrylamide gel, but it migrates more anodally than the main liver zone on nonsieving media, such as cellulose acetate. This is form corresponds to the main liver form attached to the membrane moiety. Complexes between ALP and immunoglobulins, or macro-ALP, occur occasionally in serum, giving rise to abnormally migrating bands in the γ-globulin zone; however, they do not provide specific diagnostic information in the present state of knowledge.

In general, electrophoretic separation of bone and liver ALP forms is difficult because of structural similarity. To improve their separation, serum is pretreated for 15 minutes at 37 °C with neuraminidase to remove part of the terminal sialic acid residues. As the sialic acid residues of bone ALP are more readily attacked than those of liver ALP, the electrophoretic mobility of the bone form is reduced to a greater extent than that of liver ALP. The improved separation allows quantitative estimates to be made by densitometric scanning. Measurement of GGT, which is increased in liver disease but not in bone disease, may be a useful rapid alternative tool to distinguish between the two diseases as the explanation for increased serum ALP.

Overnight incubation of the serum sample with neuraminidase is used to confirm the presence of intestinal ALP. This treatment reduces the anodal mobility of all ALP isoenzymes except that of intestinal origin, which is neuraminidase resistant because terminal sialic acid residues are not present in the molecule.

Immunoassays for direct determination of bone ALP, which measure enzyme activity or mass concentration, are commercially available. Cross-reactivity with the liver isoform varies by 6% to 20%. Despite lack of complete specificity, immunoassays of bone ALP may offer some advantages in monitoring bone disease and the effects of appropriate therapies once the diagnosis of bone involvement has been established.

5′-Nucleotidase

5′-Nucleotidase (NTP) (EC 3.1.3.5; 5′-ribonucleotide phosphohydrolase) is a phosphatase that acts only on nucleoside-5′-phosphates, such as adenosine-5′-phosphate (AMP) and adenylic acid, releasing inorganic phosphate.

NTP is a glycoprotein that is widely distributed throughout the tissues of the body and is principally localized in the cytoplasmic membrane of the cells in which it occurs. Despite

its ubiquitous distribution, serum NTP activities appear to reflect hepatobiliary disease with considerable specificity. NTP is increased in those hepatobiliary diseases characterized by interference with the secretion of bile. T is may be due to extrahepatic causes (a stone or a tumor occluding the bile duct), or it may arise from intrahepatic conditions, such as cholestasis caused by malignant infiltration of the liver or biliary cirrhosis. When parenchymal cell damage is predominant, as in infectious hepatitis, serum NTP activity is only moderately elevated.

T e assay of NTP activity has been considered of value as an addition to measurement of nonspecific total ALP in patients with suspected hepatobiliary disease, and abnormal NTP activity is routinely interpreted as evidence of hepatic origin of increased ALP activity in serum. However, approximately half of individuals in whom liver ALP activity is increased in serum may simultaneously show a normal NTP activity. Alternatively, increased NTP activity in the serum of patients with normal liver ALP activity is very often associated with the presence of liver disease. T us the frequent dissociation of the two enzyme activities supports the usefulness of determining both (liver) ALP and NTP to enhance diagnostic ef ciency in diseases of the liver.[7]

In a commercially available assay, serum NTP catalyzes the hydrolysis of inosine-5′-phosphate (IMP) to yield inosine, which is then converted to hypoxanthine by purine-nucleoside phosphorylase (EC 2.4.2.1). Hypoxanthine is oxidized to urate with xanthine oxidase (EC 1.2.3.2). Two moles of hydrogen peroxide are produced for each mole of hypoxanthine liberated and converted to uric acid. T e formation rate of hydrogen peroxide is monitored by a spectrophotometer at 510 nm by the oxidation of a chromogenic system. T e effect of ALPs on IMP is inhibited by β-glycerophosphate.

NTP activity in serum or plasma heparin is stable for at least 4 days at 4 °C and 4 months at −20 °C. T e reference interval for NTP activity at 37 °C ranges from 3 to 9 U/L, with no sex-related differences.

Pancreatic Enzymes

T e most commonly used serum biomarkers for investigation of pancreatic disease, and more specifically **acute pancreatitis**, are the digestive enzymes—(P-type) amylase and lipase. Pancreatic function and pathology are discussed in Chapter 38.

Amylase

Alpha-amylase (AMY) (EC 3.2.1.1; 1,4-α-d glucan glucanohydrolase) catalyzes the hydrolysis of 1,4-α-glucosidic linkages in polysaccharides. Both straight-chain (linear) polyglucans (amylose) and branched polyglucans (amylopectin and glycogen) are hydrolyzed but at different rates. T e enzyme does not attack the α-1,6-linkages at the branch points. AMYs are calcium metalloenzymes, with the calcium essential for functional integrity. However, full activity is displayed only in the presence of various anions, with chloride and bromide being the most effective activators. AMY in human serum has a moderately sharp pH optimum at 6.9 to 7.0.

Biochemistry

Amylases that occur normally in human plasma are small molecules with molecular weights varying from 54 to 62 kDa. T e enzyme is small enough to pass through the glomeruli of the kidneys, and AMY is the only plasma enzyme physiologically found in urine. It is present in a number of organs and tissues. T e greatest concentration is present in the salivary glands, which secrete a potent AMY (S-type) to initiate hydrolysis of starches while food is still in the mouth and esophagus. In the pancreas, the enzyme (P-type) is synthesized by acinar cells and then is secreted into the intestinal tract by way of the pancreatic duct system. AMY activity is also found in extracts from (1) ovaries, (2) fallopian tubes, (3) lungs, and (4) adipose tissue. Some tumors of lung and ovary may also contain considerable AMY activity (usually S-type). Ascitic and pleural fluids may contain AMY as a result of the presence of a tumor or pancreatitis.

T e enzyme present in normal serum and urine is predominantly of pancreatic (P-AMY) and salivary gland (S-AMY) origin. T ese isoenzymes are products of two closely linked loci on chromosome 1. AMY isoenzymes also undergo post-translational modification of (1) deamidation, (2) glycosylation, and (3) deglycosylation to form various isoforms, which have been separated in both serum and urine using isoelectric focusing or electrophoresis.

Clinical Signif cance

Total blood AMY activity is physiologically low and constant and is greatly increased in acute pancreatitis and salivary gland inflammation. In **acute pancreatitis**, a rise in serum AMY activity occurs within 5 to 8 hours of symptom onset. Activities typically return to normal by the third or fourth day. A fourfold to sixfold elevation in AMY activity above the URL is usual, with maximal concentrations attained in 12 to 72 hours. T e magnitude of the AMY elevation is not related to the severity of pancreatic involvement; however, the greater the rise, the greater the probability of acute pancreatitis. T e clinical specificity of total AMY for the diagnosis of acute pancreatitis is, however, low because increased values are also found in a number of acute intra-abdominal disorders and in several extrapancreatic conditions (Table 19-4).

Lack of specificity of total AMY measurement has resulted in the direct measurement of P-AMY instead of total enzyme activity for the differential diagnosis of patients with acute abdominal pain. When a decision limit of an activity equal to threefold the URL was applied, the clinical specificity of P-AMY for the diagnosis of acute pancreatitis was greater than 90%.[11] Sensitivity in late detection of this condition is also notably improved with P-AMY. P-AMY values remain elevated in 80% of patients with uncomplicated pancreatitis 1 week after onset, when only 30% still show increased total AMY activity.

Biliary tract diseases, such as **cholecystitis**, cause up to fourfold elevation in serum P-AMY activity as a result of primary or secondary pancreatic involvement. Other intra-abdominal events also lead to a significant increase in serum P-AMY activity. In renal insuf ciency, serum AMY activity

is increased in proportion to the extent of renal impairment (usually, no more than five times the URL). Hyperamylasemia (with an S-type isoenzyme mobility) may also occur in neoplastic diseases with elevations as high as 50 times the URL.

In 1% of the population, macroamylases are present in sera and may cause hyperamylasemia; these are complexes between ordinary AMY (usually S-type) and immunoglobulin (IgG or IgA). These macroamylases are not filtered through the glomeruli of the kidneys because of their large size (greater than 200 kDa) and are thus retained in the plasma, where their presence may increase AMY activity some twofold to eightfold above the URL. No clinical symptoms are associated with this disorder.

Methods of Analysis for Total and Pancreatic Amylase Activity

When hydrolyzed by AMY, small oligosaccharide substrates have been found to yield better defined products than do starches. Use of defined substrates in the AMY assay has improved the reaction stoichiometry and has led to more controlled and consistent hydrolysis conditions. Substrates used include (1) maltotetraose, (2) maltopentaose, and (3) 4-nitrophenyl (4-NP)-glycoside substrates prepared by bonding 4-NP to the reducing end of a defined oligosaccharide. If the oligosaccharide is maltoheptaose (G7), the substrate is then 4-NP-G7. AMY splits this substrate to produce free oligosaccharides (G5, G4, and G3) and 4-NP-G2, 4-NP-G3, and 4-NP-G4. Combined hydrolysis by AMY in the specimen and by the reagent α-glucosidase (EC 3.2.1.20; maltase) results in free NP production, which is detected by its absorbance at 405 nm.

$$5\ \text{ethylidene-4-NP-G}_7 + 5\ \text{H}_2\text{O} \xrightarrow{\alpha\text{-amylase}} 2\ \text{ethylidene-G}_5 + 2\ \text{4-NP-G}_2 + 2\ \text{ethylidene-G}_4 + 2\ \text{4-NP-G}_3 + \text{ethylidene-G}_3 + \text{4-NP-G}_4$$

$$2\ \text{4-NP-G}_2 + 2\ \text{4-NP-G}_3 + 10\ \text{H}_2\text{O} \xrightarrow{\alpha\text{-glucosidase}} 4\ \text{4-NP} + 10\ \text{G}$$

Historically, problems arose with use of the 4-NP-glycoside assay with regard to the poor stability of the reconstituted assay mixture, because of slow hydrolysis of the 4-NP-glycoside by α-glucosidase. This effect has been reduced by covalently linking a "blocking" group such as 4,6-ethylidene group the nonreducing end of the molecule. Such a substrate is known as an ethylidene-protected substrate (EPS). These substrates have shown a more advantageous hydrolysis pattern, thus increasing liberation of 4-NP. A novel-type α-glucosidase is also available (recombinant enzyme AGH-211) that completely hydrolyzes nitrophenylated substrates. As a result, cleavage of one α-glucosidic linkage by AMY results in the release of one molecule of 4-NP. The IFCC has optimized this method at 37 °C, recommending it as a reference measurement procedure for AMY.[12] The serum reference interval for the IFCC recommended method is 31 to 107 U/L.

With the exception of heparin, all common anticoagulants inhibit AMY activity because they chelate Ca^{2+}. Therefore, AMY assays should be performed only on serum or heparinized plasma. AMY is quite stable, and activity is fully retained during storage for 4 days at room temperature, for 2 weeks at −4 °C, for 1 year at −25 °C, and for 5 years at −75 °C.

Only methods based on selective S-AMY inhibition by monoclonal antibodies have shown sufficient (1) precision, (2) reliability, (3) practicability, and (4) analytical speed to be clinically useful for P-AMY determination. A double monoclonal antibody assay is commercially available that uses the synergistic action of two immunoinhibitory monoclonal antibodies to S-AMY. After S-AMY activity is inhibited by the addition of antibodies, uninhibited P-AMY activity is measured using EPS-4-NP-G7 as a substrate.[11] False-positive P-AMY results have been reported in subjects with macroamylasemia, in whom immunoglobulin complexed to AMY forms diminishes or voids the ability of monoclonal antibodies included in the test to efficiently inhibit S-AMY. Upon electrophoresis, macro-AMY usually forms a broad migrating band, different from the homogeneous bands that are produced by AMY isoenzymes present in serum. If electrophoretic separation is not available, precipitation of the macrocomplex by a PEG 6000 solution (240 g/L) represents an alternative. Residual AMY activity of less than 30% in the supernatant is indicative of macroamylasemia (Figure 19-3).

In healthy adults, P-AMY represents approximately 40% to 50% of total AMY activity in serum. When the immunoinhibition method is used at 37 °C, the reference interval for P-AMY activity in sera from adults was 13 to 53 U/L.[5]

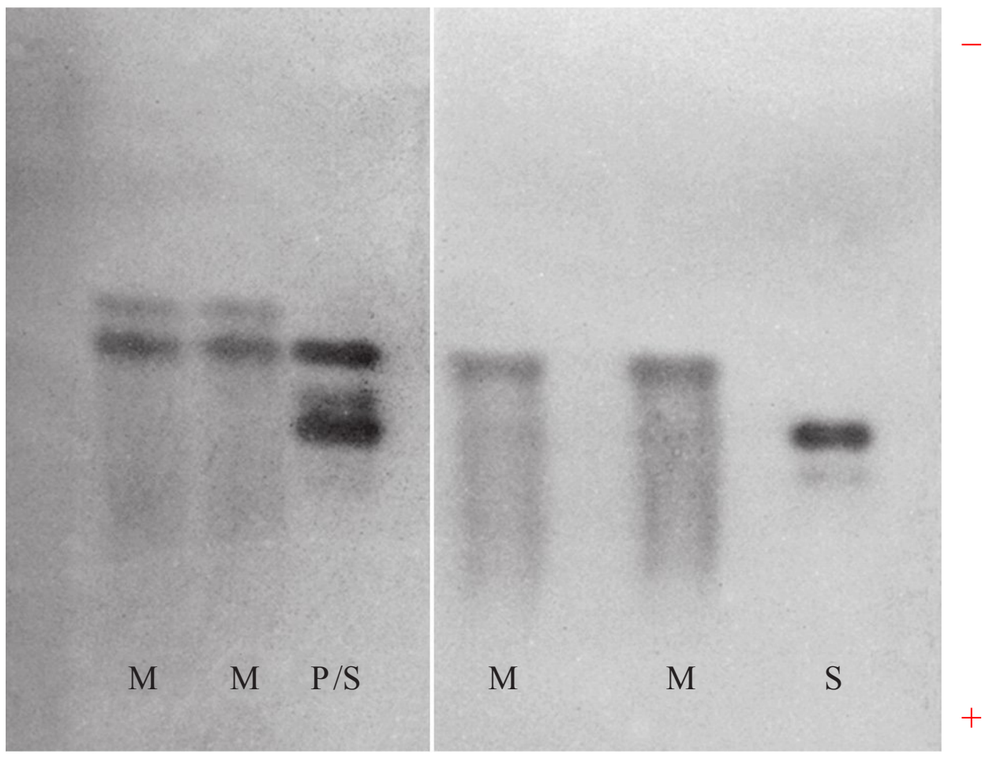

Figure 19-3 Demonstration of macroamylasemia by polyethylene glycol (PEG) 6000 solution. P-AMY, Pancreatic amylase.

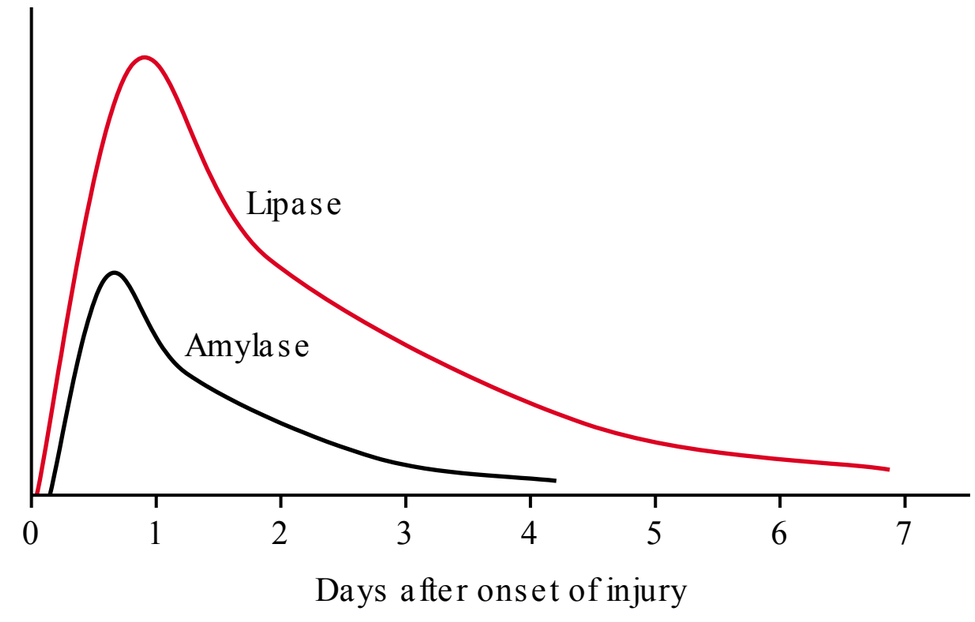

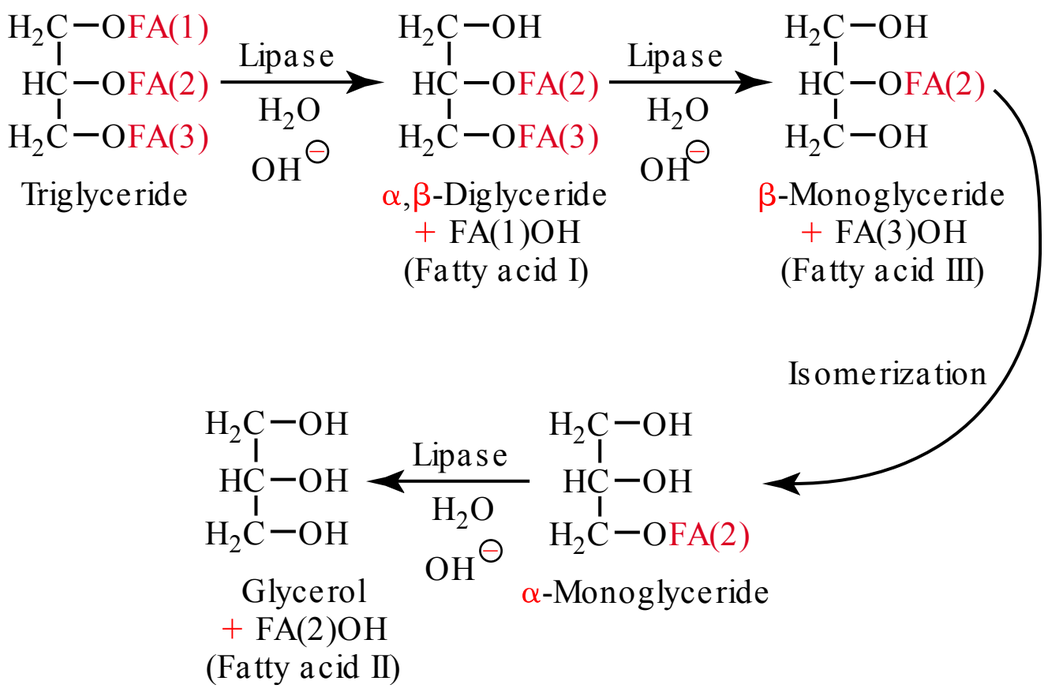

Figure 19-4 Time-dependent changes in serum amylase and lipase after acute pancreatitis.

Lipase

Human pancreatic **lipase** (LPS) (EC 3.1.1.3; triacylglycerol acylhydrolase) is a single-chain glycoprotein with a molecular weight of 48 kDa. The LPS gene resides on chromosome 10. For full catalytic activity and greatest specificity, the presence of bile salts and a cofactor called colipase, which is a small protein secreted by the pancreas, is required.

Biochemistry

Lipases hydrolyze glycerol esters of long-chain fatty acids.

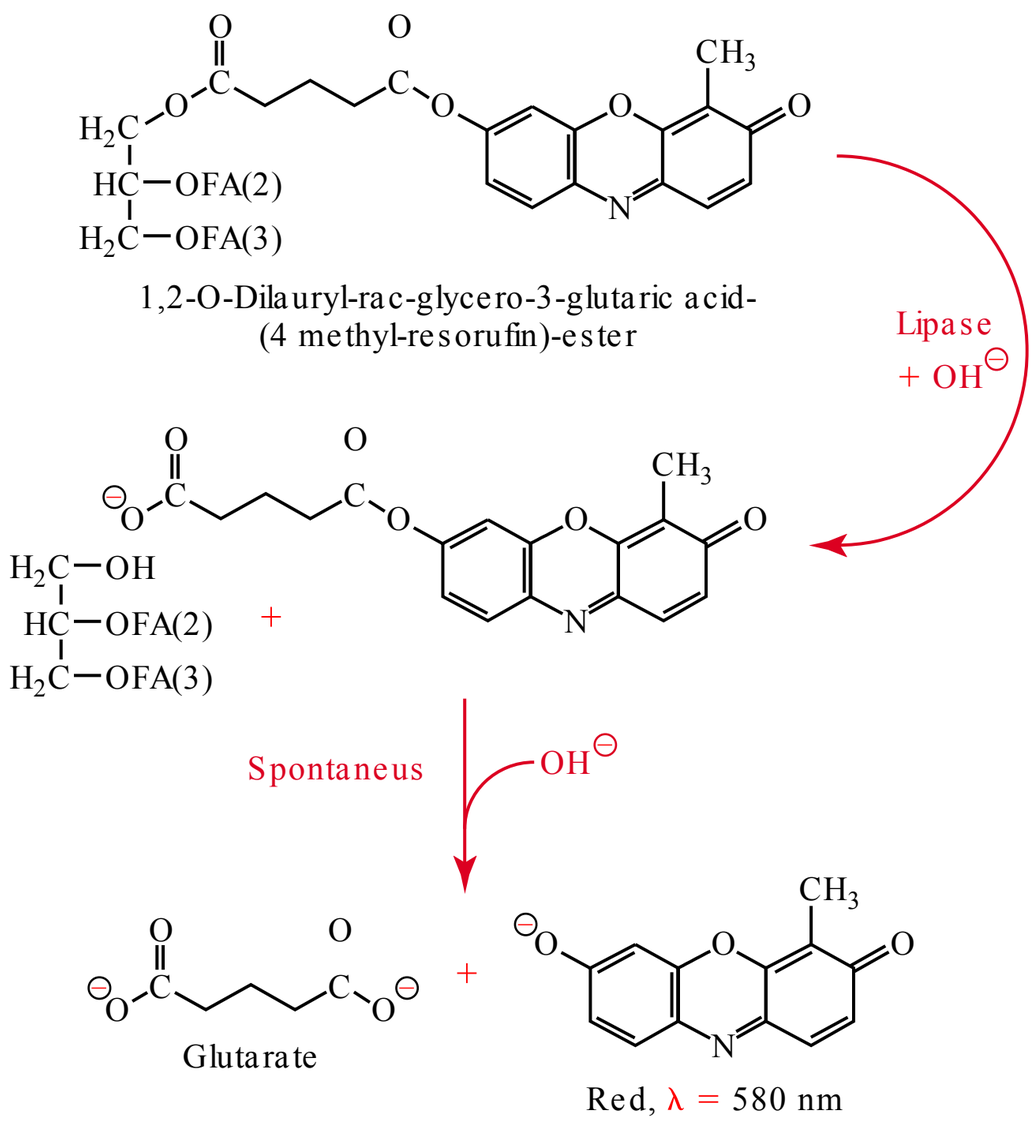
Only ester bonds at carbons 1 and 3 (α-positions) are attacked, and products of the reaction include 2 moles of fatty acids and 1 mole of 2-acylglycerol (β-monoglyceride) per mole of substrate. The latter is resistant to hydrolysis, but it spontaneously isomerizes to the α-form (3-acylglycerol), which allows the third fatty acid to be split off but at a much slower rate.

LPS acts only when the substrate is present in an emulsified form at the interface between water and substrate. The rate of LPS action depends on the surface area of the dispersed substrate. Bile acids ensure that the surface of the dispersed substrate remains free of other proteins, including lipolytic enzymes, by lining the surface of the insoluble substrate and the aqueous medium.

Most LPS activity found in serum derives from the pancreas, but some is secreted by gastric and intestinal mucosa. The concentration of LPS in the pancreas is about 5000-fold greater than in other tissues, and the concentration gradient between pancreas and serum is ≈20,000-fold. LPS is a small enough molecule to be filtered through the glomerulus, but it is totally reabsorbed by the renal tubules and thus is not physiologically detected in urine.

Clinical Significance

LPS measurement of serum is used to diagnose acute pancreatitis. The clinical sensitivity is 80% to 100% depending on the selected diagnostic cutoff, and the clinical specificity is 80% to 100% depending on the mix of the patient population studied. After an attack of acute pancreatitis, serum LPS activity increases within 4 to 8 hours, peaks at about 24 hours, and decreases within 7 to 14 days. Elevations between 2 and 50 times the URL have been reported.



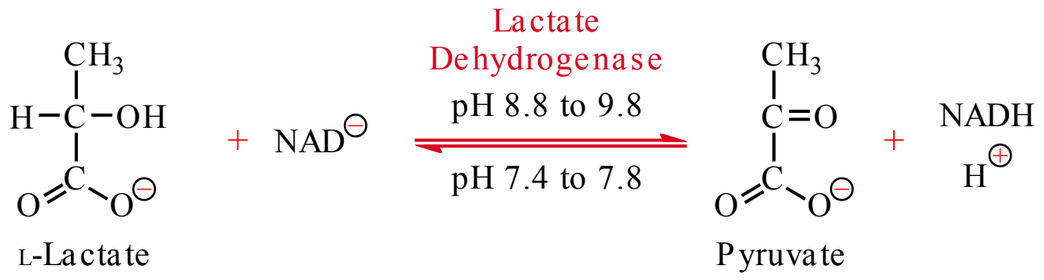
Acute pancreatitis is sometimes difficult to diagnose because it must be differentiated from other acute intra-abdominal disorders with similar clinical findings, such as (1) perforated gastric or duodenal ulcer, (2) intestinal obstruction, or (3) mesenteric vascular obstruction. In differential diagnosis, elevation of serum LPS activity to greater than 3 times the URL, in the absence of renal failure, is a more specific diagnostic finding than increases in serum AMY activity.[2] Furthermore, LPS concentrations remain elevated longer than those of AMY, which is another advantage over AMY measurement in patients with delayed presentation (Figure 19-4). Therefore, it is recommended that LPS should replace AMY as the initial diagnostic test for acute pancreatitis in the emergency department; obtaining both serum activities for both AMY and LPS is not warranted.

In patients with a reduced glomerular filtration rate, serum LPS activity is increased. Thus care should be exercised in interpretation of elevated serum LPS values in the presence of renal insufficiency.

Methods of Analysis

Many LPS methods have been described and have used both triglyceride and nontriglyceride substrates and (1) titrimetric, (2) turbidimetric, (3) spectrophotometric, (4) fluorometric, and (5) immunologic techniques. In general, long-chain triglyceride (and some diglyceride) substrates have demonstrated correlation of results with the clinical state that is superior to that seen with methods using other substrates.[9]

Numerous substrates and complex auxiliary and indicator systems have been used in spectrophotometric methods. Particularly, synthetic 1,2-O-dilauryl-rac-glycero-3-glutaric acid-(4-methyl-resorufin)-ester consisting of two glycerol ether bonds and one ester bond has been proposed, and assays based on its use are currently gaining widespread use. LPS hydrolyzes the ester bond in an alkaline medium to an unstable dicarbonic acid ester that spontaneously hydrolyzes to yield glutaric acid and methylresorufin; this is a bluish-purple chromophore with peak absorption at 580 nm.



Te rate of methylresorufin formation is directly proportional to the LPS activity of the sample. Te URL is 38 U/L at 37 °C, and no sex- or age-related differences have been noted.[10]

LPS activity in serum is stable at room temperature for 1 week; sera may be stored for 3 weeks in the refrigerator and for several years if frozen.

Other Clinically Important Enzymes

Lactate Dehydrogenase

Lactate dehydrogenase (LD) (EC 1.1.1.27; I-lactate: NAD^+ oxidoreductase) catalyzes the oxidation of l-lactate to pyruvate with the mediation of NAD^+ as a hydrogen acceptor.

As indicated, the reaction is reversible, and the reaction equilibrium strongly favors the reduction of pyruvate to lactate (P →L)—the "reverse reaction." Te optimal pH varies with the predominant isoenzymes in the sample and depends on the temperature and on substrate and buffer concentrations. Both pyruvate and lactate in excess inhibit LD activity, although the effect of pyruvate is greater. Substrate inhibition decreases with increases in pH. EDTA inhibits the enzyme, perhaps by binding Zn^{2+}.

Biochemistry

LD has a molecular weight of 134 kDa and is composed of four peptide chains of two types: M (or A) and H (or B), each under separate genetic control. Te structures of LD-M and LD-H are determined by loci on human chromosomes 11 and 12, respectively. Te subunit compositions of the five isoenzymes are listed in Box 19-1 in order of their decreasing anodal mobility in an alkaline medium.

A different, sixth LD isoenzyme, LD-X (also called LD_C), composed of four X (or C) subunits, is present in postpubertal human testes. A seventh LD, called LD-6, has been identified in the sera of severely ill patients.

LD activity is present in many cells of the body and is invariably found only in the cytoplasm of the cell. Different tissues show different isoenzyme composition. In the (1) heart, (2) kidneys, and (3) erythrocytes, the electrophoretically faster moving isoenzymes LD-1 and LD-2 predominate, whereas in liver and skeletal muscle, the more cathodal LD-4 and LD-5 isoenzymes predominate. However, skeletal muscle damage may result in anodic LD patterns. Isoenzymes of intermediate mobility account for LD activity from many sources such as (1) spleen, (2) lungs, (3) lymph nodes, (4) leukocytes, and (5) platelets.

Clinical Significance

Because of its wide tissue distribution, serum elevations in the activities of LD are seen in a variety of clinical conditions, including (1) myocardial infarction, (2) hepatitis, (3) hemolysis, and (4) disorders of the lung and muscle. Serum LD

BOX 19-1 Subunit Compositions of the Five Isoenzymes of LD in Order of Their Decreasing Anodal Mobility in an Alkaline Medium

LD-1 (HHHH; H_4)
LD-2 (HHHM; H_3M)
LD-3 (HHMM; H_2M_2)
LD-4 (HMMM; HM_3)
LD-5 (MMMM; M_4)

measurement is relevant, however, only in hematology and oncology.[3]

Hemolytic anemias significantly increase LD concentrations in serum. Marked elevations of LD activity—up to 50 times the URL—are observed in the megaloblastic anemias, usually resulting from deficiency of folate or vitamin B_{12}. T ese elevations rapidly return to normal after appropriate treatment. For monitoring purposes, LD is relevant in predicting disease activity in leukemia, as well as the survival rate (probability of survival) and duration in Hodgkin's disease and non-Hodgkin's lymphoma.

Patients with malignant disease often show increased LD activity in serum; up to 70% of patients with liver metastases and 20% to 60% of patients with other nonhepatic metastases (e.g., in lymph nodes) have elevated LD activity. Notably elevated activities of LD-1 are observed in germ cell tumors (≈60% of cases) such as seminoma of the testis and dysgerminoma of the ovary. T e percentage of patients with increased amounts of LD depends on the stage of disease. LD appears to be a useful predictor of outcome in patients with (1) testicular tumor, (2) melanoma, and (3) small cell lung cancer.

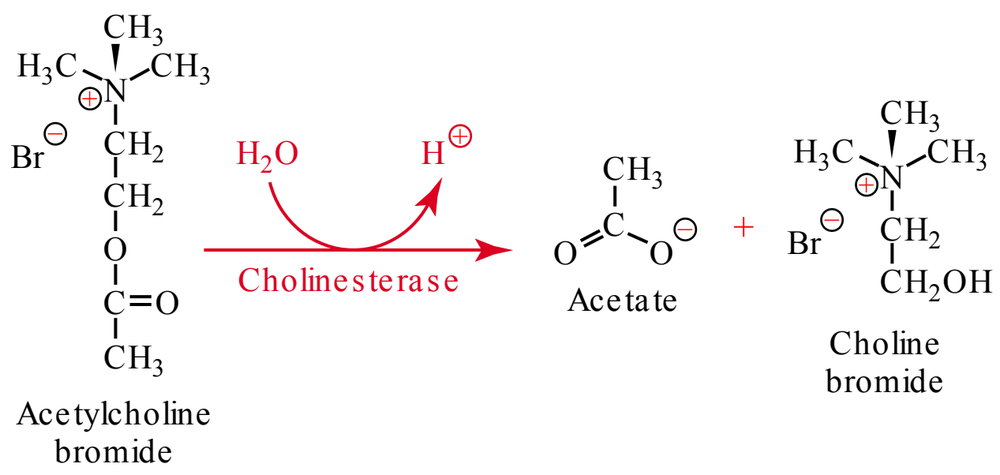
Elevations in LD activity are observed in liver disease, but their clinical use in a liver profile appears limited and would not appear to add significantly to the use of the measurement of aminotransferase activities for this purpose.

Macro-LD, usually due to the formation of an autoantibody/enzyme complex that leads to a persistent increase in the amount of circulating enzyme, has been estimated to occur in <1 in 10,000 individuals. Documentation of a macro-LD by the presence of an abnormally migrating band at electrophoresis should be established in suspected individuals to avoid additional follow-up investigation or unnecessary treatment.

Methods of Analysis for Total Lactate Dehydrogenase Activity and Isoenzyme Content

Routine methods for quantitation of total LD activity use kinetic spectrophotometry to measure the interconversion of the coenzyme NAD^+ and NADH at 340 nm. Procedures employing the L→P reaction are recommended, as less dependence on NAD^+ and lactate concentrations and less contamination of NAD^+ with inhibiting products are observed compared with NADH. An L→P reference method has been developed by the IFCC as a reference procedure for LD at 37 °C.[16,17]

Serum is the preferred specimen for measuring LD activity. Plasma samples may be contaminated with platelets, which contain high concentrations of LD. Serum should be separated from the clot as soon as possible after the specimen has been obtained. Hemolyzed serum must not be used because erythrocytes contain 4000 times more LD activity than does serum. T e different isoenzymes vary in their sensitivity to cold, and LD-4 and LD-5 are especially labile. T us, serum specimens should be stored at room temperature, at which no loss of activity occurs for at least 3 days.



T e reference interval for LD activity in adult white subjects, as determined at 37 °C with a procedure traceable to the IFCC reference method, is 125 to 220 U/L.[4] LD reference limits are higher in children, and a gradual decrease is noted over the whole childhood period.

Electrophoretic separation is the only procedure commercially available to demonstrate LD isoenzymes.

Cholinesterase

Two related enzymes have the ability to hydrolyze acetylcholine. One is acetylcholinesterase (EC 3.1.1.7; acetylcholine acetylhydrolase), which is called true cholinesterase or choline esterase I. True **cholinesterase** is found in (1) erythrocytes, (2) the lungs and spleen, (3) nerve endings, and (4) the gray matter of the brain. It is responsible for the prompt hydrolysis of acetylcholine released at the nerve endings to mediate transmission of the neural impulse across the synapse. Degradation of acetylcholine is required for depolarization of the nerve and repolarization in the next conduction event. T e second cholinesterase is acylcholine acylhydrolase (EC 3.1.1.8; acylcholine acylhydrolase), also called pseudocholinesterase, serum cholinesterase (CHE), butyrylcholinesterase, or choline esterase II. It is found in (1) liver, (2) pancreas, (3) heart, (4) white matter of the brain, and (5) serum. Although its exact biological role is unknown, a physiological role for CHE in deactivation of octanoyl ghrelin, a hormone that stimulates feeding and promotes weight gain through its metabolic actions, has been proposed.

T e type of reaction catalyzed by both cholinesterases is shown:

Acetylcholine bromide

Choline bromide

Biochemistry

CHE in normal sera is separated by electrophoresis into 7 to 12 bands. T e forms of CHE differ in molecular size and appear to be aggregates of different numbers of the same basic unit. Of greater interest are the atypical (genetic) variants of the enzyme, characterized by diminished activity against acetylcholine and other substrates, which are found in the sera of a small fraction of apparently healthy people. T e gene controlling the synthesis of CHE exists in many allelic forms. Four of the most common forms are designated as E^u, E^a, E^f and E^s T ese four allelic genes are combined to form one normal and nine abnormal genotypes. T e normal, most common phenotype is designated as E^uE^u or UU (u for usual). T e gene E^a is referred to as the atypical gene; the sera of people homozygous for this gene (E^aE^a = AA) are only weakly active toward most substrates for CHE and demonstrate increased resistance to inhibition of enzyme activity by dibucaine. T e E^f gene (*f* for fluoride resistant) gives rise to

a weakly active enzyme but with increased resistance to fluoride inhibition. The E^s gene (s for silent) is associated with the absence of enzyme or the presence of a protein with minimal or no catalytic activity. The variant enzymes (allelozymes) are less effective catalysts than the usual form; the affinity of the enzymes for the substrates is reduced (K_m is increased), and the affinity for competitive inhibitors, such as dibucaine or fluoride, is similarly decreased. This gives rise to the characteristic dibucaine- or fluoride-resistant properties of the genetic variants that are exploited in their characterization. Homozygous forms, AA and FF, are found in 0.3% to 0.5% of the white population; their incidence among blacks is even lower.

Clinical Significance

Measurements of CHE activity in serum are used (1) as a test of liver function, (2) as an indicator of possible insecticide poisoning, and (3) for the detection of patients with atypical forms of the enzyme who are at risk for prolonged responses to certain muscle relaxants used in surgical procedures.

In the absence of genetic causes or known inhibitors, any decrease in CHE activity reflects impaired synthesis of the enzyme by the liver. Serial measurement of CHE has been promoted as an indication of prognosis in patients with liver disease and for monitoring of liver function after liver transplantation.

Among the organic phosphorous compounds that inhibit cholinesterase activity are many insecticides, such as (1) parathion, (2) sarin, and (3) tetraethyl pyrophosphate. Workers in agriculture and in organic chemical industries may be subject to poisoning by inhalation of these materials or by direct contact with them. Both cholinesterases are inhibited, but the activity of CHE falls more rapidly than does that of the erythrocyte enzyme. A decrease in the erythrocyte enzyme is used as a measure of chronic exposure.

Succinyldicholine (suxamethonium) and mivacurium, drugs used in surgery as muscle relaxants, are hydrolyzed by CHE, and their pharmacologic effect normally persists only long enough to meet the needs of the surgical procedure. In patients with low enzyme activities or in those with a weakly active variant, destruction of the drug will not occur rapidly enough, and the patient may enter a period of prolonged paralysis of the respiratory muscles (apnea) requiring mechanical ventilation until the drug effects gradually wear off. The degree of drug sensitivity varies with the phenotype of the patient. Total CHE activity is highest in individuals who are homozygous for the usual allele and is progressively lower in (1) those who are heterozygous for the usual and a variant allele, (2) those who are homozygous or heterozygous for variant alleles, and (3) those in whom two "silent" alleles are paired and no activity is detected. Measurements of total CHE activity and determination of "dibucaine number" and "fluoride number" are needed to fully characterize CHE variants. The latter values indicate the percentage inhibition of enzyme activity toward specified substrates in the presence of standard concentrations of dibucaine or fluoride. Mutation genotyping may confirm CHE gene abnormalities.

Methods of Analysis

Many contemporary methods use acylthiocholine esters as substrates. Also, the iodide salts of (1) acetylthiocholine, (2) propionylthiocholine, (3) butyrylthiocholine, (4) benzoylthiocholine, and (5) succinylthiocholine have all been used. These latter substrates are hydrolyzed at approximately the same rate as choline esters, and the thiocholine formed is measured by reaction with chromogenic disulfide agents, such as 5,5′-dithio-bis(2-nitrobenzoate) (DTNB) (Ellman's reagent). The reaction of the thiocholine product with colorless DTNB forms colored 5-mercapto-2-nitro-benzoic acid, which is measured spectrophotometrically at 410 nm. Measuring CHE activity using succinyldithiocholine is the method of choice to diagnose succinylcholine sensitivity, which is purely based on the enzyme activity recorded in serum. This method is also well suited for other clinical applications of the test.[6]

Based on differences in sensitivity to inhibition by the local anesthetic dibucaine, a simple test was developed to classify the type of CHE as (1) usual, (2) intermediate, or (3) atypical ("dibucaine number"). Particularly, the usual CHE is inhibited by 80%, but atypical CHE is inhibited by only 20%. Subjects heterozygous for the normal and the atypical gene show about 60% inhibition of CHE. Molecular biological methods are used to identify various CHE genetic defects.

Serum is the sample of choice. Enzyme activity in serum is stable for several weeks if the specimen is stored under refrigeration, and for several years if stored at −20 °C.

When the succinyldithiocholine/DTNB method is used at 37 °C, the reference interval for healthy adults with the usual CHE genotype is 33 to 76 U/L for women and 40 to 78 U/L for men, respectively. The median activity in individuals with a heterozygous genotype is 22 U/L (range, 5 to 35 U/L), and for atypical homozygotes 1.5 U/L (range, 1 to 4 U/L). A significant CHE decrease (≈30%) during pregnancy and early puerperium is explained by hemodilution.

Acid Phosphatase (Tartrate-Resistant 5b Isoform)

Under the name of **acid phosphatase** (ACP) (EC 3.1.3.2; orthophosphoric-monoester phosphohydrolase [acid optimum]), all phosphatases with optimal activity below a pH of 7.0 are categorized. ACP is present in lysosomes, which are organelles present in all cells with the possible exception of erythrocytes. Extralysosomal ACPs are also present in many cells. The greatest concentrations of ACP activity are seen in (1) prostate, (2) bone (osteoclasts), (3) spleen, (4) platelets, and (5) erythrocytes. The lysosomal and prostatic enzymes are strongly inhibited by dextrorotatory tartrate ions, whereas the erythrocyte and bone isoenzymes are not. Most of the physiologically low ACP activity of (unhemolyzed) serum is of a tartrate-resistant type (TR-ACP) and probably originates mainly in osteoclasts. Activities of this fraction are increased in growing children and pathologically in conditions of increased osteolysis and bone remodeling.

At least four ACP-determining genes have been identified and mapped. The erythrocyte ACP gene is located on chromosome 2; a further gene on chromosome 19 encodes the TR-ACP expressed in osteoclasts and other tissue macrophages,

such as alveolar macrophages and Kupffer cells (type 5 ACP). Isoenzyme 5 consists of two structurally related isoforms that differ in terms of their carbohydrate content: TR-ACP 5a, which derives mainly from macrophages and dendritic cells, and type 5b, a more specific marker of osteoclastic activity. Genes that encode the tartrate-inhibited lysosomal and prostatic ACPs, mapped to chromosomes 11 and 13, respectively, exhibit considerable homology.

TR-ACP is a potentially useful marker of conditions with a marked osteolytic component. Elevations in serum TR-ACP activity occur in (1) Paget's disease, (2) hyperparathyroidism with skeletal involvement, and (3) the presence of malignant invasion of the bones by cancers. T e activity of TR-ACP appears to show relatively small dynamic changes in comparison with other markers of bone resorption (e.g., those related to type I collagen metabolism). T is may be attributable to the fact that the enzyme is released into the sealed osteoclast microenvironment, rather than directly into the circulation. Unlike blood concentrations of other markers of bone resorption (e.g., C-telopeptide of type I collagen), activity of TR-ACP is not affected by renal dysfunction. T e only nonbone condition in which elevated activities of TR-ACP are found in serum is Gaucher's disease of the spleen, a lysosomal storage disorder. T e hairy cells of hairy cell leukemia (leukemic reticuloendotheliosis) also express the osteoclast-type ACP, providing a useful histological marker. However, in this condition, the isoenzyme does not enter the plasma in increased amounts.

Immunoassays for serum TR-ACP have been developed that preferentially detect isoform 5b. One method uses a monoclonal antibody to bind serum TR-ACP in a solid phase format. After the capture, osteoclastic enzyme (type 5b) is specifically determined by measuring its activity at optimal pH 6.1. Another assay uses two monoclonal antibodies generated against purified bone TR-ACP 5b. One of the antibodies captures active intact isoform, while the second eliminates interference of inactive 5b fragments in serum. After the immunoreaction, the activity of bound TR-ACP 5b is measured.

Serum should be immediately separated from erythrocytes and stabilized by the addition of 50 µL of acetic acid (5 mol/L) per milliliter of serum to lower the pH to below 6.5. Under these conditions, TR-ACP activity is maintained at room temperature for several hours, for up to a week if the serum is refrigerated, and for 4 months if stored at −20 °C. Hemolyzed serum specimens are contaminated with considerable amounts of the erythrocyte tartrate-resistant isoenzyme and should be rejected.

Enzymes as Cardiovascular Risk Markers

Several cells typical for atherosclerotic plaque secrete enzyme molecules that mirror plaque destabilization and rupture. T eir concentrations in the circulation have been shown to be associated with future cardiovascular (CV) events. Enzymes in this category include lipoprotein-associated phospholipase A_2 and myeloperoxidase.

Lipoprotein-Associated Phospholipase A_2

Lipoprotein-associated phospholipase A_2 (Lp-PLA_2) (EC 3.1.1.47; platelet-activating factor [PAF] acetylhydrolase), a 45.4 kDa monomeric protein, is a member of the phospholipase A_2 superfamily. It is produced mainly by (1) monocytes, (2) macrophages, (3) T lymphocytes, and (4) mast cells and has been found to be upregulated in atherosclerotic lesions, especially in complex plaque prone to rupture. Lp-PLA_2 displays proatherogenic properties by promoting modification of oxidized LDLs.

Several prospective epidemiologic studies have reported an association between increased plasma concentrations of Lp-PLA_2 and future coronary and cerebrovascular events. T e strength of association varies and is generally modest (hazard ratios <2). However, because some controversy persists as to its independence from LDL cholesterol, no clear recommendation on the clinical usefulness of Lp-PLA_2 can be given until definitive data document its incremental value above and beyond traditional CV risk factors. A manual ELISA method for Lp-PLA_2 mass concentration has received U.S. Food and Drug Administration (FDA) clearance for use as an aid in CV risk prediction. An immunoturbidimetric method that uses the same monoclonal antibodies has become commercially available, allowing the assay to be run on automated chemistry analyzers. It has been recommended that an Lp-PLA_2 concentration >200 µg/L be used as the threshold for higher risk of CV events.

EDTA plasma is the recommended sample for measuring Lp-PLA_2. Average stabilities are up to 4 hours at ambient temperature, 12 hours at 4 °C, and 6 months at −20 °C.

Myeloperoxidase

Myeloperoxidase (MPO) (EC 1.11.1.7; donor, hydrogen peroxide oxidoreductase) is a member of the heme peroxidase superfamily. It is a tetrameric hemoprotein (molecular weight 144 kDa) consisting of a pair of heavy (57 kDa) and light (15 kDa) chains. It is stored in azurophilic granules of polymorphonuclear neutrophils and monocytes-macrophages; when released (typically with inflammation), it catalyzes the conversion of chloride anion and hydrogen peroxide to hypochlorite (HOCl), a metal ion–independent chlorinating oxidant that possesses potent microbicidal activity. T us it has a role in host defense against pathogens.

It is surprising to note that MPO also may have a causative role in plaque destabilization through its ability to activate latent metalloproteinases (MMPs). Infiltrating macrophages and neutrophils participate in the transformation of stable coronary artery plaques to unstable lesions with a thin fibrous cap through secretion of MMPs and MPO, which degrade the collagen layer that protects atheromas from erosion or abrupt rupture. As a result, plaques that have been highly infiltrated with macrophages have a thin fibrous cap and are vulnerable to erosion or rupture, converting late-stage atherosclerosis into acute CV events.

Several epidemiologic studies indicate that MPO concentrations in plasma may be an important CV risk marker, especially in patients with unstable coronary artery disease. However, uncertainty continues regarding the additional benefits conferred by MPO beyond those of standard cardiac

biomarkers such as troponin.[8] Increased MPO is not likely to be specific for cardiac disease, as activation of neutrophils and macrophages can occur in any (1) infectious, (2) inflammatory, or (3) infiltrative disease process.

MPO mass assays based on sandwich ELISA methods have been developed and are commercially available. One has been approved by the FDA for use in conjunction with (1) clinical history, (2) electrocardiography, and (3) other cardiac biomarkers to evaluate patients presenting with chest pain at risk of major adverse cardiac events. T is assay has been licensed to three other companies and has been made suitable for automated platforms or point-of-care instruments.

MPO is reasonably stable, and EDTA is the preferred anticoagulant. MPO is continuously released from white blood cells in heparinized blood, and a spurious increase in MPO concentrations is noted when blood collection tubes are left standing at room temperature. Higher MPO concentrations also have been found in serum as the result of leakage of enzyme from leukocytes during coagulation.

An MPO concentration of 640 pmol/L, which was reported as the URL, is not influenced by sex or age.

Review Questions

1. T e enzyme that demonstrates highest serum activity in intrahepatic biliary obstruction and is also elevated in primary liver neoplasm is:
   a. alkaline phosphatase (ALP).
   b. creatine kinase (CK).
   c. amylase (AMY).
   d. γ-glutamyltransferase (GGT).
2. Activity of which of the following isoenzymes of CK is highest in the serum of healthy individuals?
   a. CK-MM
   b. CK-MB
   c. CK-BB
   d. CK-Mt
3. T e serum enzyme that demonstrates an increase in activity 4 to 8 hours after an attack of acute pancreatitis, peaks at 24 hours, and then returns to normal within a week is:
   a. AMY.
   b. lipase (LPS).
   c. ALP.
   d. serum cholinesterase (CHE).
4. Which of the following enzymes catalyzes the reaction of glutamate and pyruvate to form 2-oxoglutarate and an amino acid?
   a. ALP
   b. Aspartate aminotransferase (AST)
   c. Alanine aminotransferase (ALT)
   d. CK
5. In the laboratory measurement of ALP, a chromogenic assay forms the basis of almost all current methods used for ALP analysis. T e substrate in this assay is:
   a. acid phosphatase.
   b. 4-nitrophenyl phosphate.
   c. p-nitroaniline.
   d. succinyldithiocholine.
6. Measurement of decreased activity of which of the following enzymes is used to determine possible insecticide poisoning?
   a. CK
   b. ALP
   c. ALT
   d. CHE
7. Children have higher ALP activity than healthy adults because:
   a. ALP leaks from osteoblasts during normal bone growth.
   b. developing hepatocytes produce excess ALP during normal growth.
   c. striated muscle contains the greatest activity of ALP, and children are more energetic than adults with concomitant release of excess ALP from muscle.
   d. the presence of ALP in the pancreas is elevated during childhood.
8. T e isoenzyme of amylase that is synthesized by acinar cells of the pancreas and that remains elevated in most individuals for at least one week after the onset of pancreatitis is:
   a. S-AMY.
   b. macro-AMY.
   c. P-AMY.
   d. G-AMY.
9. Which of the following enzymes demonstrates an increase in activity with progressive Duchenne muscular dystrophy, followed by a decrease as muscle mass decreases?
   a. ALP
   b. ALT
   c. CHE
   d. CK
10. T e oxidoreductase that is increased significantly during megaloblastic anemia is:
    a. lactate dehydrogenase.
    b. CK.
    c. ALP.
    d. acid phosphatase.

CHAPTER 20

Tumor Markers and Cancer Genes

Lori J. Sokoll, Ph.D., F.A.C.B., Alex J. Rai, Ph.D., D.A.B.C.C., F.A.C.B., and Daniel W. Chan, Ph.D., D.A.B.C.C., F.A.C.B.

Objectives

1. Define the following terms:
   - Cancer
   - Carbohydrate-related marker
   - Carcinogen
   - Cathepsin
   - Ectopic syndrome
   - Metastasis
   - Microarray
   - Mucin
   - Oncofetal antigen
   - Oncogene
   - Proto-oncogene
   - Tumor marker
   - Tumor-suppressor gene
2. State the clinical utility of tumor marker assessment and list the properties of an ideal tumor marker; list the concerns associated with using tumor markers for cancer assessment.
3. For each of the following, state the purpose, the need for evaluation, and the way in which each is determined with regard to tumor marker analysis:
   - Marker distribution
   - Predictive value
   - Reference interval
   - Role in disease management
4. For each of the following classes of tumor markers, list examples and state the clinical applications, the specificity, and the analytical methodology used to assess each example:
   - Blood group antigens
   - Carbohydrate marker
   - Circulating tumor cells
   - Enzymes
   - Genetic markers
   - Hormones
   - Oncofetal antigens
   - Proteins
   - Receptors
5. Compare oncogenes, proto-oncogenes, and tumor-suppressor genes in terms of normal function of these genes (if any), what cellular changes occur when the gene is altered, what diseases occur when the gene is altered, and how these genes are assessed in the clinical laboratory.
6. Evaluate and assess case studies related to tumor markers and tumor marker analysis.

Key Words and Definitions

Adenocarcinoma A carcinoma derived from glandular tissue.

Apha fetoprotein (AFP) A plasma protein produced by the fetal liver, yolk sac, and gastrointestinal tract; serum levels decline markedly by the age of one year but are again elevated in many hepatocellular carcinomas and teratocarcinomas and embryonal cell carcinomas.

Benign prostatic hyperplasia (BPH) A noncancerous enlargement of the prostate gland.

Blood group antigen Antigen containing a major carbohydrate component usually found on the surface of cells or secreted by cells.

Cancer A relative autonomous growth of tissue.

Cancer staging The process by which cancer is divided into groups of early and late disease; useful for prognosis and for guiding therapy.

Carbohydrate markers Carbohydrate-related tumor markers may be (1) antigens on the tumor cell surface or (2) secreted by the tumor cells.

Carcinoembryonic antigen (CEA) A glycoprotein secreted into the glycocalyx coating the luminal surface of gastrointestinal epithelia.

Carcinogen Any cancer-producing substance.

Carcinoma A malignant new growth made up of epithelial cells tending to infiltrate the surrounding tissues and give rise to metastases.

Chronic myelocytic leukemia (CML) Chronic leukemia characterized by granular leukocytes.

Cytokeratin One of the two types of keratin normally found in human tissue, constituting a group of proteins; these are normally found in keratin filaments.

Digital rectal examination (DRE) A technique used for the for early detection of prostate cancer. It is performed by inserting a gloved, lubricated finger into the rectum and feeling for abnormalities.

Ectopic syndrome Production of a hormone by nonendocrine cancerous tissue that normally does not produce the hormone (e.g., ACTH production by small-cell lung carcinoma).

Fluorescence in situ hybridization (FISH) An in situ hybridization technique in which DNA probes are labeled with fuorescent tags and hybridized to DNA to identify and localize specific sequences.

Key Words and Definitions—cont'd

Genetic Information Nondiscrimination Act of 2008 (GINA) Legislation enacted by the Congress of the United States that prohibits the use of genetic information in health insurance and employment.

Gleason Score A grading system used to help evaluate the prognosis of men with prostate cancer.

Glioma A malignant tumor of the glial tissue of the nervous system.

Immunoglobulin superfamily (IgSF) A large group of cell surface and soluble proteins that are involved in the recognition, binding, or adhesion processes of cells.

Lymphoma Any neoplastic disorder of the lymphoid tissue.

Medullary thyroid cancer (MTC) A slow-growing tumor associated with multiple endocrine neoplasia (MEN) syndromes.

Mesothelioma A tumor derived from mesothelial tissue (peritoneum, pleura, pericardium); both benign and malignant varieties exist. Malignant varieties are often the result of excessive exposure to asbestos.

Metastasis The spread of cancer from one part of the body to another.

Microarray-based genotyping A molecular technique used to simultaneously screen hundreds to thousands of genetic markers per individual.

Mucin A high-molecular-weight glycoprotein complex.

Multiple endocrine neoplasia (MEN) syndromes Three disorders affecting the thyroid and other hormonal (endocrine) glands.

Oncofetal antigen Protein produced during fetal life that decreases to low or undetectable levels after birth; reappears in some forms of cancer as the result of reactivation of genes in transformed malignant cells.

Oncogene A mutated normal cellular gene (proto-oncogene) that causes the malignant transformation of normal cells when activated.

Partin tables A statistical model developed by Alan W. Partin, M.D., Ph.D. at the Johns Hopkins University School of Medicine that show the probability that the cancer is confined to the prostate and likely to be cured with surgery.

Philadelphia chromosome An abnormality of chromosome 22 present in marrow cells of most patients with chronic granulocytic leukemia. It is generally a reciprocal translocation between chromosomes 9 and 22 that results in expression of a fusion gene (called BCR-ABL) that acts as an oncogene.

Prognosis A prediction of the future course and outcome of a patient's disease based on currently known indicators (e.g., age, sex, tumor stage, tumor marker level).

Receiver operating characteristic (ROC) curve A plot of sensitivity versus 1 minus specificity, or the true-positive rate versus the false-positive rate; it allows one to pinpoint the decision cut point at which optimal sensitivity and specificity can be achieved.

Survivin A protein that neutralizes caspase activity and thus inhibits apoptosis, expressed during the G_2/M phase of the cell cycle in many tumors but not in most normal differentiated adult tissues.

Tumor marker A substance produced by a tumor found in blood, body fluids, or tissue that may be used to predict the presence and size of the tumor and monitor its response to therapy.

Tumor-suppressor gene A gene involved in the regulation of cellular growth; loss of a tumor-suppressor gene has the potential to allow autonomous growth.

A **tumor marker** is a substance produced by a tumor or by the host in response to a tumor, which is used (1) to differentiate a tumor from normal tissue, or (2) to detect the presence of a tumor based on measurements in the blood or secretions.[3,12] Such substances are found in cells, tissues, or body fluids and are measured qualitatively or quantitatively by chemical, immunological, or molecular biological methods.

Morphologically, cancer tissue has been recognized by pathologists as resembling fetal tissue more than normal adult differentiated tissue. Tumors are graded according to their degree of differentiation as (1) well differentiated, (2) poorly differentiated, or (3) anaplastic (without form). Tumor markers are the biochemical or immunological counterparts of the differentiation state of the tumor. In general, some tumor markers represent re-expression of substances produced normally by embryogenically closely related tissue (Table 20-1).

Some tumor markers are associated with one type of cancer; others are seen in several cancer types. Many of the

TABLE 20-1 Expression of Oncodevelopmental Tumor Markers

Production of Tumor Markers by Various Tissues

Marker	Normal Producing	Embryogenically Closely Related	Distantly Related	Unrelated
CEA	Colon	Stomach, liver, pancreas	Lung, breast	Lymphoma
AFP	Liver, yolk sac	Colon, stomach, pancreas	Lung	
CG	Placenta	Germinal tumors	Liver	Epidermal lung
Serotonin	Enteroendocrine	Adrenal carcinoid	Oat cell, lung	Epidermal lung

AFP, α-Fetoprotein; CEA, carcinoembryonic antigen; CG, human chorionic gonadotropin.

Modified from Sell S. Cancer markers. In: Moossa AR Schempff SC, Robson MC, eds. Comprehensive textbook of oncology, 2nd edition, volume 1. Baltimore: Williams & Wilkins, 1991:225-38.

better-known markers are also seen in noncancerous conditions. Consequently, these tumor markers are not diagnostic for cancer. However, it is thought that the concentration of tumor markers in blood reflects tumor activity and volume.

Clinically, an ideal tumor marker should be both specific for a given type of cancer and sensitive enough to detect small tumors for early diagnosis or during screening.[12] Unfortunately, few markers are specific for a single individual tumor (tumor-specific markers); most are found with different tumors of the same tissue type (tumor-associated markers). Tumor markers are present in greater quantities in cancer tissue or in blood from cancer patients than in benign tumors or in blood from healthy subjects. In practice, current tumor markers are most useful for evaluating the progression of disease after initial therapy and for monitoring subsequent treatment modalities.

This chapter begins with general discussions on (1) cancer, (2) clinical applications of tumor markers, (3) how the utility of tumor markers is evaluated, (4) clinical guidelines for the use of tumor markers,[1,10-13] and (5) how tumor markers are measured. Several clinically relevant tumor markers from each of these general categories are then discussed in detail: (1) enzymes, (2) hormones, (3) oncofetal antigens, (4) **carbohydrate markers**, (5) **blood group antigens**, (6) proteins, (7) receptors, and (8) genes and molecular tests.

Cancer

In 2013, the estimated number of new cancer cases (excluding skin cancer) was 1.66 million. Prostate cancer was the leader among men, and breast cancer was the leader in women, followed by cancer of the lung, colon-rectum, and bladder (men) or uterine corpus (women). After peak death rates from all cancers were reached in 1990 for men and 1991 for women, death rates decreased by 22.9% in men and by 15.3% in women from 1990/1991 to 2008. Death rate reductions in men from lung, prostate, and colorectal cancers accounted for 78% of the decrease, and in women breast and colorectal cancers accounted for 56% of the decrease. These trends support the conclusion that early detection and more effective treatment combined with prevention (e.g., decreasing smoking, improving diet) will reduce the mortality rate of cancer in the future.[6] The American Cancer Society (ACS) estimates that in 2013, 174,100 cancer deaths are expected to be caused by tobacco use, and one-third of cancer deaths will likely be related to (1) excess weight, (2) physical inactivity, and (3) poor nutrition.[2]

A simple definition of **cancer** is "a relatively autonomous growth of tissue." Other more detailed definitions exist and are continually being refined and new ones proposed. For example, the National Cancer Institute (http://www.cancer.gov/; accessed September 9, 2013) defines cancer as "a term used for diseases in which abnormal cells divide without control and are able to invade other tissues. Cancer cells can spread to other parts of the body through the blood and lymph systems." Common to all of the definitions is the concept of autonomous and abnormal cell growth. An understanding of the cause of this autonomous and abnormal growth would clearly facilitate the search for a cure.

Also of importance in the search for a cure to cancer is the determination of which **carcinogen** (any cancer producing agent) is responsible for any given cancer. For example, a carcinogen may be (1) physical (e.g., radiation), (2) chemical (e.g., a polycyclic hydrocarbon), or (3) biological (e.g., a virus). Exposure to such an agent may cause cancer by producing direct genotoxic effects on deoxyribonucleic acid (DNA) (e.g., as with radiation) or by increasing cell proliferation (e.g., by a hormone), or cancer may be caused in both ways (e.g., through the use of tobacco).

Advances in molecular genetics have resulted in a better understanding of the genesis of human cancer. The proliferation of normal cells is thought to be regulated by growth-promoting oncogenes and counterbalanced by growth-constraining **tumor-suppressor genes**. The development of cancer appears to involve the activation or the altered expression of oncogenes, or the loss or inactivation of a tumor-suppressor gene.

Early detection of cancer offers the best chance for cure, as the tumor is still small enough to be completely removed surgically. Unfortunately, most cancers do not produce symptoms until the tumors are too large to be removed surgically, or until cancerous cells have already spread to other tissue (metastasized).

Although other modes of therapy, such as administration of chemical toxins or irradiation, are effective in destroying most tumor cells, they usually are not curative. The few residual viable tumor cells are able to (1) proliferate, (2) develop resistance to further therapy, and (3) eventually cause death.

Clinical Applications

Potential uses of tumor markers are summarized in Table 20-2. In general, tumor markers may be used (1) for diagnosis, **prognosis**, and prediction; (2) for monitoring the effects of therapy; and (3) as targets for localization and therapy. Ideally, a tumor marker should be produced by tumor cells and should be detectable in body fluids. It should not be present in healthy people or in benign conditions. Therefore, it could be used in screening for the presence of cancer in asymptomatic individuals in the general population. Most tumor markers, however, are present in (1) normal, (2) benign, and (3) cancerous tissues and lack specificity. However, if the incidence of cancer is high among certain populations, screening could be feasible. An example is the use of **α-fetoprotein (AFP)** in screening for hepatocellular **carcinoma** in China and Alaska. Prostate-specific antigen (PSA) has been used in conjunction with **digital rectal examination (DRE)** for early detection of prostate cancer. Because of elevation of serum PSA in **benign prostatic hyperplasia (BPH),** approaches such as PSA velocity and percent free PSA have been used to increase specificity of PSA and improve the detection of prostate cancer.

The clinical staging of cancer **cancer staging** is aided by quantification of the concentration of marker that is considered a reflection of the tumor burden. Marker concentration at the time of diagnosis may be used as a prognostic indicator of disease progression and patient survival. After successful initial treatment,

TABLE 20-2 Current Applications of Tumor Markers and Their Limitations

Application	Current Usefulness	Comments
Screening for cancer	Limited	1. For screening, you must have a marker that is elevated at early disease stages, when the disease is localized and potentially curable. Most circulating cancer markers (with the exception of PSA) are elevated notably only in the late stages of disease. Thus diagnostic sensitivity is usually low for early-stage disease. 2. With the exception of PSA, most cancer markers are not specific for a particular tissue, and elevations may be due to diseases of other tissue, including benign and inflammatory diseases. Thus diagnostic specificity may be low, leading to many false positives. In screening, there is a necessity for a definitive diagnostic method that will separate true positives from false positives. If this procedure is invasive (e.g., surgery) and/or expensive, patients will not accept it. 3. Screening, even if effective for early cancer diagnosis, must demonstrate benefit to the screened population in terms of survival or other clinical end points.
Diagnosing cancer	Limited	Same as above. Low diagnostic sensitivity and specificity. However, for selected subgroups of high-risk patients for whom the chance of cancer is high (high prevalence), tumor marker analysis may not aid the clinician in ordering more elaborate testing (e.g., imaging techniques, laparoscopic investigations).
Evaluating cancer prognosis	Limited	Most cancer markers have prognostic value, but their accuracy is not good enough to warrant specific therapeutic interventions. For example, higher preoperative concentrations of PSA are associated with capsular penetration, high Gleason score, positive surgical margins, and positive lymph node status, but the decision to treat with which of two different modalities (e.g., radical prostatectomy vs. nonsurgical approaches) cannot be made on the basis of tumor marker data alone. Same applies to many other cancers.
Predicting therapeutic response	Important	Despite the importance of using biomarkers in predicting response to specific therapies, very few known markers have such predictive power. These include the steroid hormone receptors for predicting response to antiestrogens and HERr-2/neu amplification for predicting response to Herceptin in breast cancer patients. More predictive markers are needed to individualize therapy and maximize clinical response.
Performing tumor staging	Limited	Same as for prognosis. The data are not good enough for accurate staging unless the value reflects tumor volume.
Detecting tumor recurrence or remission	Controversial	Despite the importance of using biomarkers to detect cancer relapse, current markers are limited by the following: 1. Lead time is short (weeks to a few months) and does not significantly affect outcome, even if therapy is instituted earlier. 2. Therapies for treating recurrent disease are not effective at present. 3. In certain groups of patients, biomarkers are not produced and do not detect relapses. 4. Sometimes biomarkers provide misleading information (e.g., clinical relapses occur without biomarker elevation, or biomarker is elevated nonspecifically, without progressive disease, leading to overtreatment or discontinuation of a current and successful treatment protocol).
Localizing tumor and directing radiotherapeutic agents	Limited	Only a few biomarkers are available for this application, and success is limited at present.
Monitoring the effectiveness of cancer therapy	Important	For patients with advanced disease who are treated with various modalities, it is important to know whether therapy works. In this regard, biomarkers usually provide information that is (1) readily interpretable, (2) more economical, (3) more sensitive, and (4) safer than radiological or invasive procedures. For certain cancers, this may facilitate increased enrollment of patients into therapeutic clinical trials.

Modified from Diamandis EP. Tumor markers: past, present, and future. In: Diamandis EP, Fritsche HA, Lilja H, et al, eds. Tumor markers: physiology, pathobiology, technology, and clinical application. Washington, DC: AACC Press, 2002:5.

such as surgery, the marker concentration should decrease. If the half-life after treatment is longer than the expected half-life, treatment has not been successful in removing the tumor. However, the magnitude of reduction may reflect the degree of success of treatment or the extent of disease involvement.

Targeted therapy in oncology is becoming more effective and is considered by many to be the therapeutic choice of the future. Tumor markers capable of guiding targeted therapy will improve therapeutic efficacy and will generate less toxicity. Examples in breast cancer are the estrogen and progesterone receptors for the selection of hormonal therapy, HER-2, and for the selection of breast cancer patients for trastuzumab (Herceptin) therapy; and Oncotype DX (Genomic Health, Inc., Redwood City, Calif; http://www.genomichealth.com/; accessed on September 9, 2013) for the identification of patients who most likely will benefit from adjuvant tamoxifen or chemotherapy.

Most tumor marker concentrations correlate with effectiveness of treatment and responses to therapy. In breast cancer, the concentration of markers, such as CA 15-3 or CA 27.29, changes with treatment and with the clinical outcome of the patient. Concentrations usually (1) increase with progressive disease, (2) decrease with remission, and (3) do not change significantly with stable disease. In reality, tumor marker kinetics in the monitoring of cancer may be more complicated. Marker concentrations in response to treatment may show an initial delay before demonstrating the expected pattern of change.

In addition, antibodies to tumor markers labeled with a radioactive tag are used to localize the tumor masses (radioimmunoscintigraphy) or to provide direction for labeled antibodies to attack the tumor site. Examples include the use of radiolabeled antibodies to **carcinoembryonic antigen (CEA)** to localize colon tumors and the application of labeled antibodies against ferritin to target hepatocellular carcinoma. T is approach is also used for treatment by allowing the antibody to bind to the tumor marker epitopes and kill the tumor cell with the dose of radioactivity.

Evaluating Clinical Utility

To evaluate the clinical usefulness of a tumor marker, it is necessary to (1) establish reference intervals, (2) calculate predictive values, (3) evaluate the distribution of marker concentrations, and (4) determine its role in disease management.

Reference Intervals

Reference intervals are obtained from a healthy population, preferably by using individuals of the same age and sex as those with the cancer of interest (see Chapter 5). In practice, reference intervals determined using healthy subjects are applicable to analytes with physiologically well-defined concentrations. However, for testing with relatively specific applications, such as the use of tumor markers in the diagnosis and management of cancer, a decision cut point may be more appropriate than the upper limit of the reference population. In most cases, using patients with benign disease as the nondisease group is more appropriate than using a healthy population. T e decision cut point is determined using a predictive value model.

Predictive Value Models

T e predictive value model includes the clinical sensitivity and specificity and the predictive value of a test (see Chapter 3). A useful approach to evaluating multiple tests for the same analyte or multiple markers for the same type of cancer is the **receiver operating characteristic (ROC)** curve. An example is shown in Figure 20-1.

Distribution of Markers

T e distribution of tumor marker concentrations is usually shown as the percentage of patients with elevated concentrations as determined by using various cutoffs in (1) healthy, (2) benign, and (3) cancerous groups. When available, international staging criteria should be used to classify cancer patients. Diagnosis should be based on pathological findings.

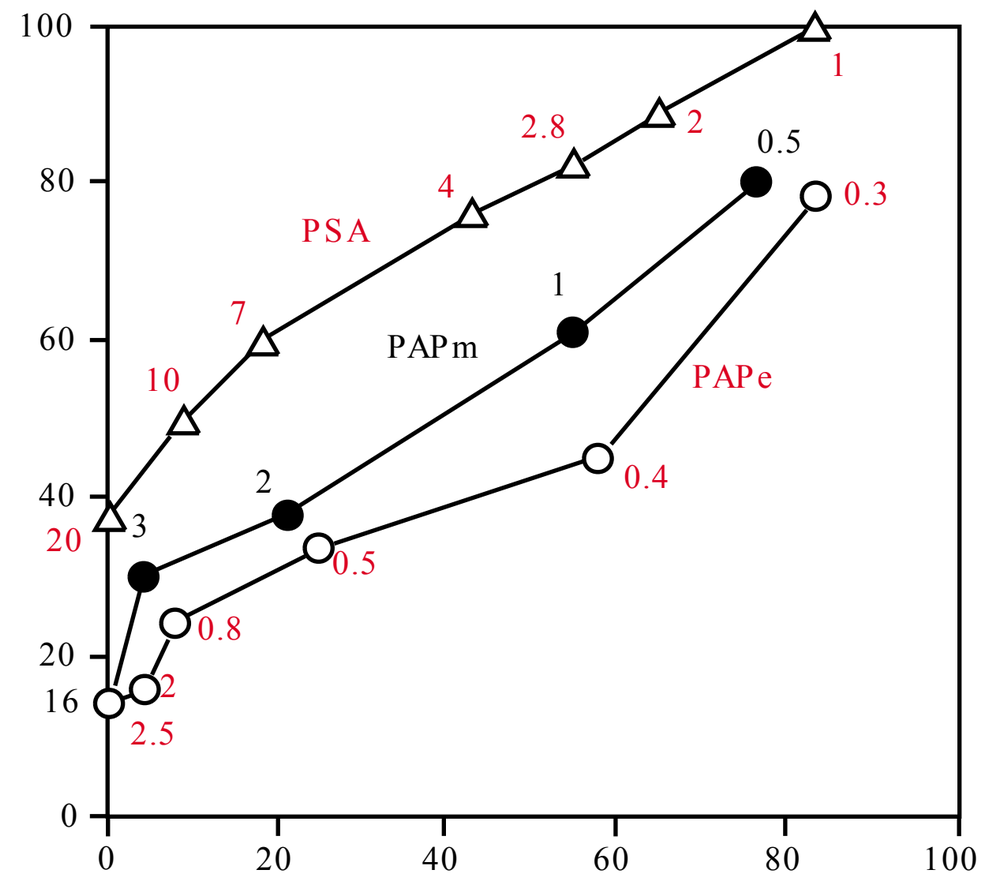

Figure 20-1 Receiver operating characteristic (ROC) curves for prostate-specifc antigen (PSA), prostatic acid phosphatase by monoclonal immunoassay (PAPm), and enzymatic prostatic acid phosphatase (PAPe). Data for all 128 patients with prostatic disease are plotted, along with several quantitative decision cut points (as indicated in the fgure) for each assay. Units are µg/L for PAPm and PSA, and U/L for PAPe. (From Rock RC, Chan DW, Bruzek DJ, et al. Evaluation of a monoclonal immunoradiometric assay for prostate-specifc antigen. Clin Chem 1987;33:2257-61.)

In breast cancer, for example, normal women are used as the healthy population for comparison. Nonmalignant or benign groups are selected to include people with the most likely causes of marker elevation, including (1) benign liver disease, (2) breast disease, and (3) pregnancy. Non–breast metastatic cancer groups are selected to show the specificity of the marker by using (1) endometrial, (2) colon, (3) lung, (4) prostate, and (5) ovarian carcinoma, and (6) other patients.

Disease Management

Most tumor markers are used to monitor treatment and progression of cancer. Markers may be used to (1) determine the success of initial treatment (e.g., surgery, radiation), (2) detect the recurrence of cancer, and (3) monitor the effectiveness of the treatment modality.

When the effectiveness of cancer therapy is monitored, marker concentration should (1) increase with progression of cancer, (2) decrease with regression of cancer, and (3) remain constant in the presence of stable disease. With recurrence of cancer after successful initial treatment, the marker concentration may not fall within the expected time according to its half-life. It may fall to a steady concentration that is higher than normal, or it may fall within the reference interval of healthy individuals. A subsequent rise in the marker concentration suggests cancer recurrence.[1]

If therapy is given, changes in marker concentrations should reflect the clinical progression of the disease. “Progressive disease is defined by an increase in the marker concentration of

at least 25%. Sampling should be repeated within 2 to 4 weeks for additional evidence. The sampling interval during therapy may depend on the type of tumor and should be related to clinical follow-up."

A decrease in marker concentration of at least 50% is indicative of partial remission, "with the concept that tumor load is related to the changes in serum tumor marker concentrations."

Clinical Guidelines

The diagnosis and staging of cancer involve a number of tools, including (1) physical examination, (2) imaging, and (3) laboratory studies. Application of these tools has resulted in several tumor markers that are used for (1) screening, (2) diagnosis, (3) staging, (4) prognosis, and (5) directing treatment modalities. However, not all tumor markers are appropriate for all uses, and not all cancers have established tumor markers. Therefore, each type of cancer and each tumor marker must be properly evaluated for use, and clinicians must be educated regarding proper use of tumor markers to conserve resources.

Several national and international groups have released guidelines on the selection and clinical use of tumor markers. These groups include the National Academy of Clinical Biochemistry (NACB), the European Group on Tumor Markers (EGTM), the American Cancer Society (ACS), the American Society for Clinical Oncology (ASCO), and others. Table 20-3 summarizes the recommendations of several of these groups and their websites.

Analytical Methods

Tumor markers are measured by a variety of analytical techniques, including enzyme assay (see Chapters 14 and 19); immunoassay (see Chapter 15); receptor assay and instrumental techniques such as chromatography (see Chapter 12); electrophoresis (see Chapter 11); mass spectrometry interfaced with liquid or gas chromatography (see Chapter 13); and microarrays.

Enzymes

Enzymes were one of the first groups of tumor markers identified. Their elevated activities were used to indicate the presence of cancer. Their measurement is relatively easy using spectrophotometric determination of enzymatic activities. With the introduction of radioimmunoassay (RIA) in the late 1950s, the mass of an enzyme could be measured as a protein antigen instead of its catalytic activity.

With few exceptions, an increase in the activity or mass of an enzyme or isoenzyme is not specific nor sensitive enough to be used to identify the type of cancer or the specific organs involved. Therefore, enzymes are most suitable as nonspecific tumor markers. Elevated enzymes may signal the presence of malignancy. Isoenzymes and multiple forms of enzymes may provide additional organ specificity.

Enzymes discussed in this chapter include (1) alkaline phosphatase, (2) lactate dehydrogenase, (3) neuron-specific enolase, (4) prostatic acid phosphatase, (5) prostate-specific antigen, (6) the urokinase-plasminogen activator system, and (7) cathepsins.

Alkaline Phosphatase

(1) Liver, (2) bone, and (3) placenta are primary sources of alkaline phosphatase (ALP). The ALP in the sera of normal adults is derived primarily from the liver or biliary tract. Elevated ALP is seen in primary or secondary liver cancer. Quantification may be helpful in evaluating metastatic cancer with bone or liver involvement. Greatest elevations are seen in patients with osteoblastic lesions, such as those with prostatic cancer with bone metastases. Minimal elevations are seen in patients with osteolytic lesions, such as those with breast cancer with bone metastases.

In liver metastases, serum ALP shows a better correlation with the extent of liver involvement than do the results of other liver function tests. To determine the origin of elevated ALP, tests of other liver enzymes may be performed. Elevations in 5′-nucleotidase or γ-glutamyltransferase suggest that the elevated ALP is of liver origin. Determination of ALP isoenzymes may provide additional specificity. Other malignancies, such as (1) leukemia, (2) sarcoma, and (3) **lymphoma** complicated with hepatic infiltration, may also elevate alkaline phosphatase.

Placental alkaline phosphatase (PALP) is synthesized by the trophoblast and is elevated in the sera of pregnant women. PALP was first identified as the Regan isoenzyme in 1968 by Fishman and colleagues and was recognized as one of the first oncodevelopmental markers, along with α-fetoprotein and CEA. It is elevated in a variety of malignancies, including (1) ovarian, (2) lung, (3) trophoblastic, and (4) gastrointestinal cancers; as well as in (5) seminoma and (6) Hodgkin's disease.

Lactate Dehydrogenase

Lactate dehydrogenase (LD) is an enzyme in the glycolytic pathway that is released as the result of cell damage. Elevation of LD in malignancy is rather nonspecific. It has been demonstrated in a variety of cancers, including (1) liver cancer, (2) non-Hodgkin's lymphoma, (3) acute leukemia, (4) nonseminomatous germ cell testicular cancer, (5) seminoma, and (6) neuroblastoma; as well as in (7) other carcinomas, such as breast, colon, stomach, and lung cancer. Serum LD has been shown to correlate with tumor mass in solid tumors and provides a prognostic indicator for disease progression. Its value in monitoring of therapy, however, is limited. Serum markers are rarely considered for tumor staging; however, LD concentrations are used in the staging of testicular cancers and melanoma.

Neuron-Specific Enolase

Neuron-specific enolase (NSE) is the γ-subunit of the glycolytic enzyme phosphopyruvate hydrolase, which exists as a homodimer (γγ) and a heterodimer (αγ). The enzyme is found in neuronal tissue and in cells of the diffuse neuroendocrine system. NSE therefore is associated with tumors of neuroendocrine origin. NSE is released into the blood as a result

TABLE 20-3 Summary of Key Guideline Recommendations*

Cancer Type	NACB	ASCO	ACS	EGTM
Breast	• ER and PR and HER-2 in all cancers for predicting response to therapy • CA 15-3/CA 27.29 and CEA for monitoring advanced disease • Tissue UPA/PAI-1 by ELISA for prognosis in node-negative breast cancer • Oncotype DX for predicting recurrence in node-negative, ER-positive breast cancer patients receiving adjuvant tamoxifen	• Routine use of CA 15-3, CA 27.29, or CEA alone not recommended • Increasing CA 15-3, CA 27.29, and CEA may be used to suggest treatment failure • ER and PR determined for primary lesions. Steroid hormone receptors to be used to select patients for endocrine therapy • HER-2 overexpression or amplification in tissue may be used to select patients for Herceptin (trastuzumab) therapy • Tissue UPA/PAI-1 by ELISA for prognosis in node-negative breast cancer • Oncotype DX for predicting recurrence/treatment response to tamoxifen in node-negative, ER-positive breast cancer	None	• Steroid receptors in tissue predicting response to hormone therapy • CEA and one MUC1 gene–related protein in serum for prognosis, follow-up, and monitoring of therapy • HER-2/neu in tissue for predicting response to Herceptin (trastuzumab) in patients with advanced disease
Ovarian	CA 125 as an aid in diagnosis and for monitoring therapy, detecting recurrence, and determining prognosis	None	None	• CA 125 as an aid in diagnosis and prognosis, and in follow-up and monitoring of treatment • Risk of malignancy Index as an aid in diagnosis
Prostate	• PSA for early detection (with DRE), prognosis, and monitoring • % fPSA for PSA between 4 and 10 µg/L and negative DRE	None	PSA (DRE optional) screening and detection	• PSA for detection in symptomatic men • PSA in follow-up and monitoring of therapy
Germ cell	• AFP, CG, LD for diagnosis/case finding, staging/prognosis, recurrence, and monitoring of therapy in testicular tumors • AFP for differential diagnosis of NSGCT	None	None	• AFP, CG, LD, and PLAP† for case finding, staging, prognosis, follow-up, and monitoring of therapy • PLAP† for case finding
Colon	CEA for prognosis, postoperative surveillance, and monitoring of advanced disease	CEA for prognosis, detection of recurrence, and monitoring of therapy	None	CEA for prognosis and monitoring of therapy
Lung	CEA and CYFRA 21-1 in NSCLC and NSE and ProGRP in SCLC for differential diagnosis, postoperative surveillance, monitoring of therapy in advanced disease, and detection of recurrence; CYFRA 21-1 in NSCLC for prognosis	None	None	• NSE in SCLC, CYFRA 21-1, and SCC in NSCLC for differential diagnosis • CEA, CYFRA 21-1 in NSCLC, and NSE in SCLC for prognosis and for follow-up and monitoring of therapy

*"None" indicates that the relevant group has not yet considered this type of cancer.
†Placental alkaline phosphatase (PLAP) is used to monitor seminomas in nonsmokers only.
ACS, American Cancer Society; ASCO, American Society of Clinical Oncology; EGTM, European Group on Tumor Markers; fPSA, free PSA; NACB, National Academy of Clinical Biochemistry; NSGCT, nonseminomatous germ cell tumors; tPSA, total PSA.

of cell lysis as opposed to secretion. NSE is also released into CSF with neuronal injury. NSE is found in tumors associated with neuroendocrine origin, including (1) small cell lung cancer (SCLC), (2) neuroblastoma, (3) pheochromocytoma, (4) carcinoid, (5) medullary carcinoma of the thyroid, (6) melanoma, and (7) pancreatic endocrine tumor.

Serum NSE concentrations have been measured by immunoassay. When a cutoff of 12.5 μg/mL is used, NSE has a clinical sensitivity of 80% in patients with SCLC and a clinical specificity of 80% to 90%. The NSE concentration appears to correlate with stage and provides a useful prognosis for disease progression. The value of NSE in detecting disease relapse has not been proved. Although the findings are mixed, NSE appears to be useful in monitoring chemotherapy and correlates with disease state. Immunostaining of tissue for NSE may provide the differential diagnosis between SCLC and other histological carcinoma types.

More than 90% of children with advanced neuroblastoma have been reported to have elevated serum concentrations of NSE. High concentrations of NSE are associated with poor prognosis, and concentrations seem to correlate with stage of disease.

Prostatic Acid Phosphatase

Prostatic acid phosphatase (PAP) used clinically has been replaced by PSA, as it not as sensitive as PSA for the detection of early cancer. Also, it is less likely to be elevated in BPH than is PSA. However, as an individual marker, PAP may be useful for disease management in the rare patient whose tumor does not secrete PSA, and it may prove useful when combined with other markers for improving prostate cancer detection or predicting recurrence after radical prostatectomy. The method of choice for the use of PAP is measurement of its enzymatic activity, although at present its mass is more commonly measured by immunoassay.

Prostate-Specific Antigen

Prostate-specific antigen (PSA) is a protein that is produced by the prostate gland. Functionally, PSA is a serine protease of the kallikrein family and has been widely used to screen men for prostate cancer. It is also used to monitor for recurrence after initial treatment and response to therapy.

Biochemistry

PSA is a single-chain glycoprotein that is 7% carbohydrate. It consists of 237 amino acid residues and four carbohydrate sidechains and has an MW of 28,430 Da. The complete gene encoding PSA, KLK3, has been sequenced and located on chromosome 19. It is produced exclusively by epithelial cells of the acini and ducts of the prostate gland. PSA is secreted into the lumina of the prostatic duct. In seminal fluid, PSA cleaves seminal vesicle–specific proteins into several low-molecular-weight proteins as part of the process of liquefaction of the seminal coagulum. Therefore, PSA possesses chymotrypsin-like and trypsin-like activity. The PSA promoter contains three androgen response elements and is activated by (1) androgens, (2) progestins, and (3) glucocorticoids.

Molecular Forms of Prostate-Specific Antigen

Most PSA is complexed with two protease inhibitors (1) α_1-antichymotrypsin (ACT) (MW, 100,000 Da) and (2) α_2-macroglobulin (AMG); a minor component is free PSA (MW, 28,430 Da). Most immunoassays measure both free and ACT-complexed PSA but not PSA-AMG, which is sterically inhibited. In human seminal fluid, approximately 60% to 70% of PSA is enzymatically active, and the remainder is inactive. Inactive forms of free PSA are composed of three distinct molecular forms: (1) BPSA, (2) pPSA, and (3) iPSA. BPSA is a degraded form of free PSA that contains two internal peptide bond cleavages at Lys 145 and Lys 183. In tissue, BPSA is relatively localized in the transition zone of the prostate and contributes to free PSA in BPH serum.

Physiological Properties

The metabolic clearance rate of PSA follows a two-compartment model, with initial half-lives of 1.2 and 0.75 hours for free PSA and total PSA and subsequent half-lives of 22 and 33 hours. Because of this relatively long half-life, at least 2 to 3 weeks may be necessary for the serum PSA to return to baseline concentrations after certain procedures, including (1) transrectal biopsy, (2) transurethral resection of the prostate, and (3) radical prostatectomy. Benign prostatic conditions, such as BPH and prostatitis, will also elevate PSA concentrations. Although the DRE typically causes no clinically important effects on serum PSA concentrations in most patients, in some it may lead to a twofold elevation. Inhibitors of 5α-reductase, such as finasteride, for the treatment of BPH cause a decrease in PSA concentrations of approximately 50%; therefore, results should be adjusted. Significant physiological variation in serum PSA concentrations (up to 30%) has been noted.

Clinical Applications

The measurement of PSA is used to detect and monitor treatment of prostate cancer.

Screening and Early Detection of Prostate Cancer

By itself, PSA testing is limited in the screening or detection of early prostate cancer. PSA is specific for prostatic tissue but not for prostatic cancer. Thus serum PSA is increased not only by prostate cancer but also by BPH and other conditions that affect the prostate. BPH is a common disease in men 50 years of age and older and studies have shown that PSA concentrations in patients with BPH are similar yet statistically different from those associated with early prostatic cancer. Unfortunately, the overlap of PSA concentrations between these two groups is so extensive, particularly between 4 and 10 μg/L, that selecting an optimum cutoff of PSA for the recommendation of a prostate biopsy is almost impossible. Results from the Prostate Cancer Prevention Trial showed the presence of prostate cancer over all ranges of PSA. The clinical sensitivity of PSA is 78% at the typically used cutoff of 4.0 μg/L. With lowering of the cutoff to 2.8 μg/L, sensitivity increases to 92%, whereas specificity decreases from 33% to 23%. Raising the cutoff to 8 μg/L improves the specificity to

90%. Cutoffs lower than 4 μg/L have been suggested by some, for example, the National Comprehensive Cancer Network (NCCN/ http://www.nccn.org/; accessed September 9, 2013)

In practice, the clinical utility of using serum PSA together with DRE is considered by many to be more accurate and sensitive than digital examination alone. However, DRE testing is considered optional according to recent guidelines promulgated by ACS.[9] Of note, the use of PSA measurements is now controversial with the recent recommendation against screening by the U.S. Preventive Services Task Force. T e ACS emphasizes informed choice based on the use of decision-making tools and screening discussions between patients and physicians at age 50 for men at average risk with a 10-year life expectancy, and at earlier ages for men at high risk. Men at high risk include (1) black men and (2) men with a strong family history of prostate cancer. To improve the usefulness of PSA testing in detecting early prostate cancer (clinical sensitivity) and/or to spare unnecessary biopsies (clinical specificity), several approaches have been suggested.[11] One approach involves the use of age-adjusted reference intervals as follows: 0 to 2.5 μg/L for men aged 40 to 49 years, 0 to 3.5 μg/L for those 50 to 59 years, 0 to 4.5 μg/L for men 60 to 69 years, and 0 to 6.5 μg/L for those 70 to 79 years. With lowering of the upper limit of the reference interval, cancer will be detected more frequently in younger men, for whom potential cure by radical prostatectomy is most beneficial, although this may also allow improved detection of insignificant tumors. Increasing the upper limit for older men takes into account increases in PSA with aging due to BPH. However, 25% of men with a PSA between 2 and 4 μg/L may have cancer, similar to the 4 to 10 μg/L range; thus use of age-specific ranges may result in missed, clinically significant tumors in older men.

Another approach is to use PSA density (division of PSA concentration by prostatic volume as determined by transrectal ultrasonography) to account for increased PSA from larger prostates, as in men with BPH. Patients with PSA between 4 and 10 μg/L, a negative DRE result, and elevated PSA density (typical cutoff, 0.15) are at increased risk for prostate cancer. T e third approach is to use PSA velocity (the rate of PSA increase as a function of time). It is recommended that velocity be calculated on the basis of at least three PSA results determined over at least 18 months. Increases in PSA in (1) health, (2) BPH, and (3) prostatic cancer appear to be different, with the highest rate (>0.75 μg/L/y) observed in patients with prostate cancer. Specificity is improved to 90% for BPH, and sensitivity is 72% for prostate cancer. T e PSA velocity cutoff of 0.75 μg/L/y is recommended for men with a total PSA concentration of 4 to 10 μg/L; lower cutoffs of 0.35 to 0.4 μg/L/y are suggested when PSA concentrations are <4 μg/L.

An additional approach involves the use of molecular forms of PSA and free PSA. Percent free PSA, that is (free PSA/total PSA) × 100, has been used to improve the clinical sensitivity and specificity of detecting prostate cancer, particularly for patients in the diagnostic "gray" zone of PSA between 4 and 10 μg/L or between 2 and 20 μg/L.[8] Men with cancer have less circulating free PSA (≈10% to 30%) and more PSA bound to protease inhibitors (≈70% to 90%) compared with men without cancer. Percent free PSA results are interpreted by using a single cutoff or a continuum of values to determine the relative risk of prostate cancer in individual men. In biopsied men with a total PSA between 4 and 10 μg/L and a DRE nonsuspicious for cancer, sensitivity for cancer detection is 95% when a percent free PSA cutoff of ≤25% is used. If this same cutoff (>25%) is used, 20% of biopsied men with benign disease could be spared from biopsy. Percent free PSA may have particular usefulness in evaluating men who had a previous negative biopsy. A prostate health index that incorporates total, free, and [−2]proPSA has shown further improvement for prostate cancer detection in the 2 to 10 ng/mL PSA interval. Complexed PSA (cPSA) has also shown improved specificity over total PSA for prostate cancer detection in specific PSA subranges in a multicenter clinical trial.

Staging of Prostate Cancer

Concentrations of PSA has been found to correlate with clinical stages of prostate cancer PSA has also been found to correlate with (1) pathological stages of tumor extension and metastases, (2) cancer volume, and (3) cancer grade (Gleason score). Approximately 80% of men with PSA concentrations <4 μg/L at diagnosis have organ-confined disease; this decreases to 70% and 50% for PSA concentrations of 4 to 10 μg/L and >10 μg/L, respectively. Because significant overlap is seen in PSA concentrations among stages, PSA cannot be used to determine the pathological stage in a given individual. T erefore, PSA by itself should not be used to decide whether a patient has prostate cancer confined to the organ and therefore is a likely candidate for radical prostatectomy or other treatment, or for active surveillance. T e concentration of PSA serves as a guide and is more useful in evaluating the presence of metastases. Patients with PSA concentrations less than 20 μg/L rarely have bone metastases. PSA contributes to the prediction of prostate cancer pathological stage as part of a nomogram (the **Partin tables**) that also includes clinical stage and biopsy **Gleason score**. Multivariate logistic regression is used to estimate (1) the probability of organ-confined disease, (2) extraprostatic extension, (3) seminal vesicle involvement, or (4) lymph node involvement.

Monitoring Treatment

T e greatest clinical use of PSA involves monitoring of definitive treatment for prostate cancer. Such treatment includes (1) radical prostatectomy, (2) radiation therapy, and (3) antiandrogen therapy.

PSA is produced almost exclusively by prostatic tissue; thus after radical prostatectomy, the PSA concentration should fall to below the detection limit of the assay. T is may require 2 to 3 weeks owing to the half-life of PSA. If the half-life is longer than usual, residual tumor may be present, although detectable PSA may also reflect benign prostatic tissue. Biochemical recurrence has been defined as two postprostatectomy PSA concentrations ≥0.2 μg/L. A cutoff of 0.4 μg/L is also used. Increasing PSA after radical prostatectomy is a strong indication of disease recurrence. T e time between PSA concentration elevation and clinical evidence of recurrence

(metastases) averages 8 years. PSA doubling time is also useful in assessing risk of progression to **metastasis**, with a low likelihood if the doubling time is greater than 10 to 15 months.

Unlike with surgery, normal prostatic tissue remains with external beam radiation treatment; therefore, PSA concentrations fall but do not become undetectable. The recent American Society for Therapeutic Radiology and Oncology (ASTRO) Phoenix guidelines (http://www.acr.org/; accessed September 9, 2013) define biochemical failure after radiotherapy, which also includes interstitial prostate brachytherapy, as a PSA rise of 2.0 µg/L or greater over the nadir.

Hormone therapy includes (1) bilateral orchiectomy, (2) treatment with luteinizing hormone–releasing hormone agonists, and (3) antiandrogen therapy. PSA testing is useful for predicting prognosis and monitoring treatment response to this type of therapy in patients with metastatic prostate cancer. The concentration of PSA is inversely proportional to the survival time and (1) increases with cancer progression, (2) decreases in remission, and (3) remains unchanged in stable disease. Androgen deprivation therapy may have a direct effect on PSA concentration that is independent of the antitumor effect. Production of PSA may be seen under the influence of androgenic hormones such as dihydrotestosterone. Thus PSA concentrations in patients who receive antiandrogen therapy may have a different meaning than they do in patients receiving other types of therapies.

Analytical Methods

Sandwich immunoassays using labels such as (1) enzymes, (2) fluorescence, or (3) chemiluminescence are used to measure PSA. Most of these assays are automated on commercially available immunoassay systems. Different assays and even the same assay with different lots of reagent, however, may produce different results. Such differences are due to (1) changes in assay calibration, (2) production lot variation, (3) assay reaction time, (4) reagent matrices, (5) assay limit of detection, and (6) imprecision. Antibodies may react with different PSA epitopes; therefore, some antibodies react dissimilarly with various molecular forms of PSA. Currently, most PSA assays are standardized to the Hybritech (Beckman Coulter, Inc., Brea, Calif; https://www.beckmancoulter.com/; accessed on September 9, 2013) PSA method or to standards introduced by the World Health Organization in 1999. The two international preparations consist of 100% free PSA (code 96/668) and 90% PSA/ACT complex, with 10% free PSA (code 96/670). Because of differences in the molar absorptivities used, PSA results from Hybritech standardized assays are approximately 20% higher than those obtained with WHO standardized assays.

One of the most valuable applications of PSA is the detection of residual or recurrent disease following radical prostatectomy. Traditionally, 0.1 µg/L has been used as the lower limit of detection, which was based on assay analytical characteristics as well as clinical need. Ultrasensitive PSA assays can be defined as those with a functional sensitivity (20% CV) of 0.01 µg/L or lower. One PSA assay has been labeled as a third-generation assay, and many automated assays now achieve limits of detection close to 0.001 µg/L. Although cancer recurrence may be detected earlier, the effect on clinical management is unclear, and no assay has a specific FDA claim for earlier detection of recurrence.

Free PSA is not typically used as a single measurement but is expressed as a ratio or percentage of total PSA. Because of assay differences among manufacturers, total and free PSA should be measured in the same specimen using assays from the same diagnostics company. %fPSA is approved by the FDA as an aid in distinguishing prostate cancer from benign prostatic conditions in men aged 50 and older with a total PSA between 4 and 10 µg/L with a nonsuspicious DRE. The complexed PSA (cPSA) assay (Siemens Healthcare Diagnostics, Deerfield, Ill) measures PSA-ACT and other minor PSA complexes by rendering free PSA nonreactive with a free PSA-specific antibody. The two FDA intended uses are the same as for total PSA: (1) as an aid in the detection of prostate cancer in men aged 50 years or older in conjunction with DRE, and (2) for serial measurements to aid in the management of prostate cancer patients. A cPSA concentration of 3.2 µg/L is equivalent to a PSA cutoff of 4.0 µg/L, and a PSA threshold of 2.5 µg/L corresponds to a cPSA concentration of 2.2 µg/L.

The Urokinase-Plasminogen Activator System

The urokinase-plasminogen activator system consists of three main components: (1) the enzyme urokinase-plasminogen activator (uPA; a 53 kDa serine protease), (2) the uPA membrane-bound receptor (uPAR), and (3) the uPA inhibitors, PAI-1 and PAI-2.

The urokinase-plasminogen activator is produced as a single inactive polypeptide, which is activated by cleavage between lysine 158 and isoleucine 159. The cleavage is catalyzed by a number of proteases, including (1) cathepsin B, (2) cathepsin L, and (3) hK2. The active form of uPA consists of an A chain, which interacts with its cell surface receptor, uPAR, and a catalytically active B chain. The most thoroughly characterized activity of uPA is the conversion of plasminogen to active plasmin, which degrades extracellular matrix (ECM) components and activates matrix metalloproteinases (MMPs). These further degrade the ECM and activate and release specific growth factors (fibroblast growth factor [FGF]-2 and transforming growth factor [TGF]-β]. The activity of uPA is controlled in vivo by two inhibitor molecules: PAI-1 and PAI-2. These not only act to inhibit uPA but also have a number of other functions, including (1) angiogenesis, (2) cell adhesion and migration, and (3) inhibition of apoptosis.

Historically, uPA was the first protease implicated in metastasis evaluated for prognostic value in humans. For example, breast cancer patients with high activity of uPA in their primary tumors have a poorer disease-free pattern than those patients with low uPA activity. The prognostic impact of uPA appears to be independent of other traditionally used markers, such as (1) axillary node status, (2) tumor size, (3) tumor grade, and (4) estrogen receptor (ER) status. In most studies, uPA is a more potent predictor of overall survival than tumor size, tumor grade, or ER status, and is equally powerful as nodal status. ASCO has recommended uPA/PAI, measured

by ELISA on 300 mg of breast cancer tissue, to determine prognosis in newly diagnosed node-negative patients; concentrations of both markers may aid in determining the benefit of chemotherapeutic treatment.

uPA has been used as a prognostic marker in breast cancer and has demonstrated utility in colorectal cancer. Preliminary studies have implicated uPA as a prognostic marker in (1) ovarian, (2) renal, (3) hepatocellular, (4) pancreatic, (5) urinary, (6) bladder, (7) lung (adenocarcinoma), and (8) cervical cancers, as well as (9) **gliomas**. High concentrations of uPA also correlate with aggressive disease in both gastric and esophageal cancers. Thus uPA may be useful as a general prognostic marker in cancer.

The original assay developed for uPA measured its catalytic activity. This assay has been replaced by enzyme-linked immunosorbent assay (ELISA), and several research and commercially available kits have been developed for detection of uPA and PAI-1 in tumor tissue. Generally, increased concentrations of uPA, PAI-1, or both indicate poor prognosis. A uPA concentration below 3 ng/mg total tissue and a PAI-1 below 14 ng/mg total tissue have a notably better prognosis.

Cathepsins

Cathepsins are lysosomal protease enzymes; cathepsins (1) B, (2) D, and (3) L have been investigated for their role in tumor development and progression.

Similar to other proteases, cathepsins are synthesized as high-molecular-weight precursors that require processing for activation. For example, cathepsin B (CB) is a thiol-dependent protease normally found in lysosomes; it is activated by cathepsin D (CD) and matrix metalloproteinases. Activated CB in turn activates uPA and specific metalloproteinases. Cathepsin L (CL) is similar in specificity to CB; however, it shows little activity toward small molecular substrates. Cathepsin D, similar to CB, is a lysosomal protease; however, CD belongs to the aspartyl group of proteases.

Expression and localization of CB appear to be altered in tumors relative to normal tissue. In tumor tissue, CB is associated with the plasma membrane or is secreted. Increased expression has been demonstrated in (1) breast, (2) colorectal, (3) gastric, (4) lung, and (5) prostate carcinomas, as well as in (6) gliomas, (7) melanomas, and (8) osteoclastomas, suggesting a link with tumor development and/or progression. Altered localization of CB has been seen in various tumor tissues, such as (1) colon, (2) carcinoma, (3) thyroid cancer, (4) glioma, and (5) breast epithelial tumor. Altered expression and localization are thought to be involved in tissue invasion through ECM degradation and growth promotion. ECM degradation occurs through activation of CB and other proteases, such as MMPs and uPA. In addition to ECM degradation, CB releases growth factors such as (1) basic fibroblast growth factor (bFGF), (2) insulin-like growth factor-1 (IGF-1), (3) epidermal growth factor (EGF), and (4) TGF-β associated with the ECM.

A limited number of studies have associated high values of CB in multiple tumor types with aggressive disease. All, with one exception, are retrospective studies with low numbers of patients. In one large study (N = 1500 patients), CB was shown to be an independent prognostic marker for both relapse-free and overall survival in breast cancer patients; however, it is not as good a marker as uPA. Most data related to the prognostic value of CD are in relation to breast cancer; however, its usefulness in (1) squamous cell carcinoma (SCC) of the head and neck, (2) hepatocellular carcinoma, and (3) gastric **adenocarcinoma** has been investigated in limited studies.

Cathepsin concentrations are generally measured in tissue extracts by ELISA or directly in the tissues by immunohistochemistry.

Hormones

With the introduction of specific RIA methods for a particular hormone 50 years ago, hormones were used as tumor markers to monitor the treatment of cancer patients. This application has proved more useful with the introduction and use of monoclonal antibody-based immunoassays.

The production of hormones in cancer involves two separate routes. First, the endocrine tissue that normally produces it produces excess amounts of a hormone. Second, a hormone may be produced at a distant site by a nonendocrine tissue that normally does not produce the hormone. The latter condition is called **ectopic syndrome**. For example, the production of adrenocorticotropic hormone (ACTH) is normotropic by the pituitary and is ectopic by the small cell of the lung. Consequently, elevation of a given hormone is not diagnostic of a specific tumor because a hormone may be produced by a variety of cancers.

Multiple endocrine neoplasia (MEN) syndromes (MEN-1, MEN-2A, and MEN-2B) are familial disorders inherited in an autosomal dominant fashion that are manifested by both benign and malignant tumors. Various polypeptide hormones, such as (1) ACTH, (2) calcitonin, (3) gastrin, (4) glucagon, (5) insulin, (6) secretin, and (7) vasoactive intestinal polypeptide, may be produced by the pancreatic islet cell, by pituitary tumors found in MEN-1, and by **medullary thyroid cancer** found in MEN-2A and -2B, as well as in familial medullary thyroid cancer (FMTC), a variant of MEN-2A. Examples of hormones that are used as tumor markers are listed in Table 20-4. Of these, (1) ACTH, (2) calcitonin, and (3) human chorionic gonadotropin (CG) are discussed in greater detail in the following section.

Adrenocorticotropic Hormone

ACTH is a polypeptide hormone with 39 amino acids and an MW of 4500 Da that is produced by corticotropic cells of the anterior pituitary gland (see Chapter 40). In 1928, a patient who had the signs and symptoms of what is now known to be cortisol excess was described as having a small cell carcinoma of the lung. A small number of these carcinomas have been known to produce pro-ACTH, the precursor to ACTH. This precursor has (1) an MW of 22,000 Da, (2) 5% bioactivity, and (3) most of the immunoactivity of ACTH. Traditional RIA assays measure precursors pro-ACTH and pro-opiomelanocortin (POMC), as well as the intact molecule

TABLE 20-4 Hormones as Tumor Markers

Hormone	Type of Cancer
ACTH	Cushing syndrome, lung (small cell)
Antidiuretic hormone	Lung (small cell), adrenal cortex, pancreatic, duodenal
Bombesin	Lung (small cell)
Calcitonin	Medullary thyroid
Gastrin	Glucagonoma
Growth hormone	Pituitary adenoma, renal, lung
CG	Embryonal, choriocarcinoma, testicular (nonseminoma)
Human placental lactogen	Trophoblastic, gonads, lung, breast
Neurophysins	Lung (small cell)
Parathyroid hormone	Liver, renal, breast, lung, various
Prolactin	Pituitary adenoma, renal, lung
Vasoactive intestinal peptide	Pancreas, bronchogenic, pheochromocytoma, neuroblastoma

and ACTH fragments that may be beneficial for detection of ectopic ACTH-producing tumors, whereas reactivity of the immunometric assay depends on the antibodies used and may measure ACTH as well as its precursors.

Elevated plasma concentrations of ACTH could be the result of pituitary or ectopic production. A high concentration of ACTH (>200 ng/L) is suggestive of ectopic origin. Failure of dexamethasone to suppress cortisol is also indicative of ectopic production. About half of the ectopic production of ACTH is a result of small cell carcinoma of the lung. Other conditions that elevate ACTH concentrations have been reported, including (1) pancreatic, (2) breast, (3) gastric, and (4) colon cancer, and benign conditions, such as (1) chronic obstructive pulmonary disease, (2) mental depression, (3) obesity, (4) hypertension, (5) diabetes mellitus, and (7) stress. The value of ACTH in monitoring therapy is still unknown.

Calcitonin

Calcitonin is a polypeptide with 32 amino acids and an MW of about 3400 Da; it is produced by the C cells of the thyroid (see Chapter 39). Normally, calcitonin is secreted in response to increased serum calcium. It inhibits the release of calcium from bone and thus lowers the serum calcium concentration. The serum half-life is about 12 minutes. The concentration in healthy individuals is less than 0.1 μg/L. An elevated concentration is usually associated with medullary carcinoma of the thyroid.

Approximately 75% of medullary thyroid cancer (MTC) cases are sporadic, and 25% are familial. Most familial MEN-2A, MEN-2B, and FMTC cases are the result of mutations of the RET proto-oncogene, a receptor tyrosine kinase, and almost all develop MTC. Calcitonin is most useful for diagnosing sporadic MTC or for identifying the index case in familial MTC; genetic testing has supplanted calcitonin for screening family members of the index case. Calcitonin is also used for monitoring MTC. Provocative testing with intravenous administration of calcium and/or pentagastrin produces increased calcitonin concentrations and is used to increase the sensitivity and specificity of MTC detection. Microscopic or occult malignancy has been detected in patients who have a negative radioisotopic scan and normal thyroid glands on physical examination.

In practice, calcitonin concentrations appear to correlate with indicators of the extent of disease, such as tumor volume and tumor involvement in local and distant metastases. Calcitonin is useful for monitoring treatment and detecting the recurrence of disease.

Calcitonin concentrations are also elevated in some patients with carcinoid tumors and cancers of the (1) lung, (2) breast, (3) kidney, and (4) liver. The usefulness of calcitonin as a tumor marker in these malignancies, however, has not been proved. Calcitonin elevation has been reported in other nonmalignant conditions, such as (1) pulmonary disease, (2) pancreatitis, (3) hyperparathyroidism, (4) pernicious anemia, (5) Paget's disease of bone, and (6) pregnancy.

Human Chorionic Gonadotropin (CG)

Elevated CG concentrations are seen in (1) pregnancy, (2) trophoblastic disease, and (3) germ cell tumors. CG is a useful tumor marker for tumors of the placenta (trophoblastic tumors) and for some tumors of the testes. It is also useful for diagnosing and monitoring pregnancy (see Chapter 44).

Biochemistry

Human chorionic gonadotropin is a glycoprotein secreted by the syncytiotrophoblastic cells of the healthy placenta. It consists of two dissimilar α- and β-subunits and has an MW of 45,000 Da. The α-subunit is common to several other hormones such as (1) luteinizing hormone (LH), (2) follicle-stimulating hormone (FSH), and (3) thyroid-stimulating hormone (TSH). The β-subunit is unique to CG, and the 28 to 30 amino acids making up the carboxyl terminal are antigenically distinct. Additional serum forms, including hyperglycosylated (CGh) and nicked CG (CGn) and the urine form CGβ core fragment (CGβcf), have relevant clinical utility.

Production of the two CG subunits is under separate genetic control. Trophoblastic tumors of placental and germ cell origin primarily produce intact CG, and differential production of the subunits, primarily the free β-subunit, has been observed in nontrophoblastic cancer patients. CG assays with a detection limit <2 IU/L, cross-reactivity with LH <2%, and equimolar recognition of CG and CGβ (or a separate assay for CGβ) are desired for tumor marker use.

Clinical Applications

Patients with trophoblastic tumors typically have elevated concentrations of CG (>1 million IU/L). They are also elevated in 70% of those with nonseminomatous testicular germ cell tumors and less frequently in those with seminoma. Elevated serum concentrations of CG are found in 45% to 60% of (1) biliary and (2) pancreatic cancers and in 10% to 30% of many other cancers, including (3) bladder, (4) renal, (5) prostate, (6) liver, (7) colorectal, (8) non–small cell lung, (9) breast, and (10) head and neck cancers, as well as (11) hematological malignancies. Most neuroendocrine tumors produce CGβ,

TABLE 20-5 Oncofetal Antigens as Tumor Markers

Name	Nature	Type of Cancer
AFP	Glycoprotein, 70 kDa, 4% CHO	Hepatocellular, germ cell (nonseminoma)
Oncofetal antigen	80 kDa	Colon
Carcinofetal ferritin	Glycoprotein, 600 kDa	Liver
CEA	Glycoprotein, 22 kDa, 50% CHO	Colorectal, gastrointestinal, pancreatic, lung, breast
Pancreatic oncofetal	Glycoprotein, 40 kDa	Pancreatic
Squamous cell antigen	Glycoprotein, 44 to 48 kDa	Cervical, lung, skin, head and neck (squamous)
Tennessee antigen	Glycoprotein, 100 kDa	Colon, gastrointestinal, bladder
Tissue polypeptide antigen	Cytokeratins 8, 18, 19	Various (breast, colorectal, ovarian, bladder)

CHO, Carbohydrate.

and carcinoid tumors produce CGα. Elevations have also been reported in benign conditions such as (1) cirrhosis, (2) duodenal ulcer, and (3) inflammatory bowel disease.

In practice, CG is most useful for monitoring treatment and progression of trophoblastic disease. Concentrations of CG correlate with tumor volume. A patient with an initial CG concentration greater than 400,000 IU/L is considered at high risk for treatment failure. After surgical removal of the tumor, CG concentration is expected to decline. The normal half-life of serum CG is about 12 to 20 hours. Slowly decreasing or persistent concentrations of CG may indicate the presence of residual disease. During chemotherapy, weekly CG measurement is recommended. After remission is achieved, yearly CG measurement is recommended to detect relapse. The detection limit of the assay is important, because any residual CG activity may indicate the presence of a tumor.

In addition to its usefulness in identifying patients with trophoblastic tumor, CG together with AFP also is useful in detecting nonseminomatous testicular tumor. Its concentrations correlate with tumor volume and disease prognosis. The hyperglycosylated form of CG may aid in the early detection of new or recurrent active trophoblastic malignancy and may discriminate quiescent gestational trophoblastic disease from active gestational trophoblastic neoplasia/choriocarcinoma. Because CG does not cross the blood-brain barrier, the normal cerebrospinal fluid-to-serum ratio is 1:60. Higher concentrations in cerebrospinal fluid may indicate metastases to the brain. Furthermore, response to therapy for patients with central nervous system metastasis may be observed by monitoring the CSF CG concentration.

Analytical Methods

Measurement of serum CG improved greatly in the 1970s as assay specificity was improved by use of an antibody to the β-subunit of CG that had little cross-reactivity with other glycoprotein hormones. Currently, most CG assays use an immunometric ("sandwich") format. An CG assay measures the intact (whole) molecule only when an antibody for the α-subunit and an antibody for the β-subunit are used in the immunometric format. A total β-CG assay measures both intact CG and free β-subunits. As a tumor marker, a total β-CG assay is preferred because many cancer patients produce notable amounts of free β-subunit. World Health Organization (WHO) international reference reagents (IRRs) have been developed for CG isoforms, including (1) intact CG, (2) nicked CG, (3) CGβ, (4) nicked CGβ, (5) CGβcf, and (6) CGα. Studies with these preparations have indicated that varying specificity of these variants in commercial CG assays contributes to methodological differences. To date, none of the commercially available CG assays have been approved by the U.S. Food and Drug Administration (FDA) for use as a tumor marker assay. Heterophile antibodies and antianimal antibodies such as human antimouse antibodies (HAMAs) are known to cause false-positive or false-negative results in immunoassays, including those for CG. Urine CG testing, among other approaches, helps to distinguish true positives from assay interference.

Oncofetal Antigens

Oncofetal antigens are proteins produced during fetal life. These proteins are present in high concentration in the sera of fetuses and decrease to low concentrations or disappear after birth. In cancer patients, these proteins often reappear, revealing that certain genes are reactivated as the result of the malignant transformation of cells.

Discovery of the oncofetal antigens AFP and CEA in the 1960s revolutionized the modern era of tumor markers. Oncofetal antigens that have been used as tumor markers are listed in Table 20-5.

α-Fetoprotein

AFP is a marker for hepatocellular and germ cell (nonseminoma) carcinoma. AFP was found first in the sera of mice with liver cancer and later in the sera of humans with hepatocellular carcinoma. It is a glycoprotein with a molecular mass of 70 kDa. It consists of a single polypeptide chain and is 4% carbohydrate. AFP is synthesized in large quantities during embryonic development by the fetal yolk sac and liver. It is one of the major proteins in the fetal circulation, but its maximum concentration is about 10% that of albumin. AFP is closely related both genetically and structurally to albumin and has extensive homologies in amino acid sequence. As albumin synthesis increases during later fetal development, AFP concentrations in fetal serum begin to decline. They finally reach the trace concentrations found in normal adults 18 months after birth.

Clinical Applications

The serum AFP concentration is less than 10 μg/L in healthy adults. The use of AFP for detecting fetuses with neural tube defects is discussed in Chapter 45. In addition to pregnancy, elevated concentrations of serum AFP are associated with benign liver conditions, such as hepatitis and cirrhosis. Most patients with these benign diseases (95%) have AFP concentrations less than 200 μg/L.

Except in the pregnant patient, AFP concentrations greater than 1000 μg/L are indicative of cancer. At these concentrations of AFP, about half of hepatocellular carcinomas may be detected. However, because the serum concentration of AFP correlates with the size of the tumor, detection of hepatocellular carcinoma is more useful at earlier stages, when the tumor is small enough to be resectable (<5 cm), than when the tumor is large. To detect small tumors, the cutoff for AFP is typically set at a low concentration; a cutoff point of 10 to 20 μg/L has been recommended. However, at this concentration, hepatitis and cirrhosis must be considered as possible causes of elevation. Screening for hepatocellular carcinoma has been instituted in high-incidence areas, such as (1) Africa, (2) China, (3) Taiwan, (4) Japan, and (5) Alaska.

AFP is also useful for determining prognosis and for monitoring therapy for hepatocellular carcinoma. The concentration of AFP is a prognostic indicator of survival. Elevated AFP concentrations (>10 μg/L) and serum bilirubin concentrations greater than 2 mg/dL are associated with a decreased survival time.

Differential binding of AFP to the lectin LCA forms the basis of the AFP-L3% test for hepatocellular carcinoma that was cleared by the FDA for clinical use in 2005. Total AFP has been separated into three glycoforms: (1) AFP-L1, (2) AFP-L2, and (3) AFP-L3, based on reactivity to LCA. The L1 fraction of total AFP is present in patients with chronic hepatitis and liver cirrhosis, and it constitutes the majority of total AFP in nonmalignant liver disease. AFP-L1 has low reactivity with LCA. AFP-L2 is mostly derived from yolk sac tumors and has an intermediate affinity to LCA. AFP-L3 is produced by cancer cells and has an additional α-1-6-fucose residue attached at the reducing terminus of N-acetylglucosamine. AFP-L3% is calculated as the proportion of measured AFP-L3 to total AFP.

The AFP-L3% test is indicated for use in risk assessment for the development of hepatocellular carcinoma in patients who have chronic liver disease. A cutoff of 10% is used, and those patients with chronic liver disease and an elevated AFP-L3% have a sevenfold increased risk of developing hepatocellular carcinoma within 21 months. The test is useful for early detection, particularly in the AFP range of 20 to 200 μg/L, as has been shown in patients with hepatitis C–related cirrhosis. In practice, although AFP-L3% is useful in detection and prognosis, it typically is used only when AFP concentrations are elevated.

The AFP concentration is a good indicator for use in monitoring therapy and the change in clinical status. Elevated AFP concentration after surgery may indicate incomplete removal of the tumor or the presence of metastasis. Falling or rising AFP concentration after therapy may reveal the success or failure of the treatment regimen. A notable increase in AFP concentration in patients considered free of metastatic tumor may indicate the development of metastasis.

The combination of measuring the concentration of both AFP and CG is useful in classifying and staging germ cell tumors. Germ cell tumors may be predominantly one type of cell or may be a mixture of (1) seminoma, (2) yolk sac, (3) choriocarcinomatous elements (embryonal carcinoma), and (4) teratoma. Serum concentrations of AFP are elevated in yolk sac tumors, whereas CG is elevated in choriocarcinoma. Both are elevated in embryonal carcinoma. In seminomas, AFP is not elevated, whereas CG is elevated in 10% to 30% of patients who have syncytiotrophoblastic cells in the tumor. Neither marker is elevated in teratoma. One or both of the markers are elevated in about 90% of patients with nonseminomatous testicular tumor. Elevations were noted in less than 20% of patients with stage I disease, in 50% to 80% with stage II disease, and in 90% to 100% with stage III disease. These markers correlate with tumor volume and the prognosis of disease.

The combined use of these markers is useful in monitoring patients with germ cell tumors: elevation of either marker indicates recurrence of disease or development of metastasis. The success of chemotherapy can be assessed by calculating the decrease in concentration of both markers using the half-lives of AFP (5 days) and CG (12 to 20 hours).

Analytical Methods

Serum AFP is determined by immunometric assay on many automated immunoassay systems. A reference material for AFP (First WHO International Standard [IS]) is available from the National Institute for Biological Standards and Control (NIBSC/ http://www.nibsc.org/; accessed September 9, 2013) in the United Kingdom. AFP is reported primarily in units of ng/mL (μg/L) and kIU/L. One international unit (IU) of AFP is equivalent to 1.21 ng. A detection limit of 1 ng/mL is recommended for clinical use. AFP-L3% is measured using a microfluidics-based instrument that utilizes immunochemical and electrophoretic techniques. (Wako Diagnostics, Richmond, Va; http://www.wakodiagnostics.com/; accessed on September 9, 2013).

Carcinoembryonic Antigen

CEA is a marker for (1) colorectal, (2) gastrointestinal, (3) lung, and (4) breast carcinoma. CEA was discovered by Gold and Freeman in 1965 and was known initially as the Gold "antigen." Rabbits were immunized with extracts of human colon cancer tissue, and the resultant antisera were absorbed with extracts of normal human colon. Some antisera reacted with the tumor extracts but not with the extracts of normal tissue. The antigen, which was also found in embryonic tissue, was named carcinoembryonic antigen.

Biochemistry

CEA is a glycoprotein with a molecular mass of 150 to 300 kDa; it contains 45% to 55% carbohydrate. It is a single polypeptide chain consisting of 641 amino acids, with lysine in the N-terminal position. The heterogeneity of CEA has

been demonstrated with the use of isoelectric focusing electrophoresis to separate the variants.

CEA consists of a large family of related cell surface glycoproteins. CEA proteins are encoded by about 10 genes located on chromosome 19. Up to 36 different glycoproteins have been identified in the CEA family. The major proteins are CEA and nonspecific cross-reacting antigen (NCA). The domain structures of (1) CEA, (2) NCA 50, and (3) the heavy chain of IgG are very similar. Thus, CEA is part of the **immunoglobulin gene "superfamily**."

Clinical Applications

CEA is elevated in a number of cancers at varying percentages, such as (1) colorectal—70%, (2) lung—45%, (3) gastric—50%, (4) breast—40%, (5) pancreatic—55%, (6) ovarian—25%, and (7) uterine—40% carcinomas.

CEA testing may be useful as an adjunct to clinical staging. Persistently elevated concentrations that are 5 to 10 times the upper reference limit strongly suggest the presence of colon cancer but may be associated with other cancers. In colon cancer, CEA concentrations correlate with the stage of disease. High pretreatment CEA concentrations are associated with greater likelihood of developing metastasis.

After successful initial therapy, CEA concentrations decline. During remission, CEA concentrations are stable. Rising CEA concentrations may indicate recurrence of disease. The lead time from CEA elevation to clinical recurrence is about 5 months. A repeat laparotomy is performed to confirm the relapse, which is detected in 90% of cases. In monitoring metastatic colon cancer, CEA is useful for following patients throughout therapy and the clinical course of the disease.

CEA is also useful for monitoring (1) breast, (2) lung, (3) gastric, and (4) pancreatic carcinomas. In breast cancer, elevated CEA is associated with metastatic disease. Early or localized breast cancer does not show CEA elevation and CEA is less sensitive than CA 15-3 and CA 27.29. CEA is most useful for monitoring metastatic breast cancer during therapy and for detecting the development of bone or lung metastasis. An increasing serum CEA concentration may reflect treatment failure when measurable disease is not present. In lung cancer, CEA determination is helpful in diagnosing non–small cell lung carcinoma (>65% of patients have elevated CEA) and in monitoring disease.

Analytical Methods

As with AFP, most assays use the immunometric format for determination of serum CEA. Polyclonal and monoclonal antibodies and combinations of the two types have been used in CEA immunoassays.

In the healthy population, the upper limit of CEA is about 3 μg/L for nonsmokers and 5 μg/L for smokers. Because the concentration of CEA measured is method dependent, values should always be compared by using the same method. When methods are changed, all patients who are being monitored should be tested in parallel with the use of both old and new methods. CEA may be elevated in patients with benign conditions, such as cirrhosis (45%), pulmonary emphysema (30%), rectal polyps (5%), benign breast disease (15%), and ulcerative colitis (15%).

Cytokeratins

The **cytokeratins** are a group of approximately 20 proteins that make up the cytoskeletal intermediate filaments of epithelial cells and cells of epithelial origin. The cytokeratins are divided into two groups: type 1 is smaller and acidic, and type 2 is larger and neutral to basic. As discussed below, clinically useful members of this family are (1) tissue polypeptide antigen (TPA), (2) tissue polypeptide-specific antigen (TPS), and (3) cytokeratin 19 fragments (CYFRA 21-1).

Tissue Polypeptide Antigen

The discovery of TPA preceded that of AFP and CEA, but TPA is not a specific tumor marker. It was found later that TPA could be identified by antibodies that react with cytokeratins 8, 18, and 19. TPA is produced by both normal and cancerous cells. Elevated serum concentrations of TPA are related to the proliferative activity and turnover of cells, allowing it to be used as a proliferation marker. In pregnancy, TPA increases throughout gestation. After pregnancy, the concentration returns to normal after 5 days. TPA is also elevated in inflammatory disease and in cancer; thus it is not useful for diagnosis. In monitoring of metastatic disease, TPA is useful when combined with CEA and CA 15-3 in breast cancer, with CEA and CA 19-9 in colon cancer, and with CA 125 in ovarian cancer. TPA may be helpful in the differentiation of cholangiocarcinoma (in which TPA concentration is elevated) from hepatocellular carcinoma (in which TPA is not elevated).

Tissue Polypeptide-Specific Antigen

TPS is an antigenic site on cytokeratin 18 that is specifically recognized by the M3 monoclonal antibody. This epitope has been proposed as a specific marker of cell proliferation and is detectable in serum with the use of a specific immunoassay. TPS appears to correlate with proliferation activity of lung tumors, irrespective of histology and tumor volume, and TPS concentrations increase with advancing stage. Elevated concentrations of TPS correlate with a poorer outcome.

CYFRA 21-1

CYFRA 21-1 is elevated in all types of lung cancer, although it is most sensitive for non–small cell lung cancer, primarily SCC. Concentrations of CYFRA 21-1 positively correlate with advancing stage and are useful in monitoring the disease course and in providing postsurgical follow-up. In non–small cell lung cancer patients, CYFRA 21-1 has been shown to independently correlate with (1) decreased survival, (2) nodal status, and (3) tumor stage. Blood concentrations are not affected by smoking status and may be increased in (1) renal failure, (2) liver cirrhosis, and (3) benign pulmonary disease. CYFRA 21-1 immunoassays use two monoclonal antibodies—BM 19.21 and KS 19.1—to detect cytokeratin 19 fragments.

TABLE 20-6 Mucin Tumor Markers

Name	Antigen and Source	Antibody	Type of Cancer
CA 125	Glycoprotein, >200 kDa, OVCA 433	OC 125	Ovarian, endometrial
Episialin (MUC1)			
• CA 15-3	Glycoprotein, 400 kDa, membrane-enriched BRCA	DF3 and 115D8	Breast, ovarian
• CA 549	High-MW glycoprotein	BC4E549, BC4N154	Breast, ovarian
• CA 27.29	High-MW glycoprotein	B27.29	Breast
MCA	350 kDa glycoprotein	b-12	Breast, ovarian
DU-PAN-2	Mucin, 1000 kDa peptide epitope	DU-PAN-2	Pancreatic, ovarian, gastrointestinal, lung

BRCA, Breast cancer.

TABLE 20-7 Blood Group Antigen–Related Cancer Markers

Name	Antigen and Source	Antibody	Type of Cancer
CA 19-9	Sialylated Le^{xa}, SW-1116 colon CA	19-9	Pancreatic, gastrointestinal, hepatic
CA 19-5	Le^{a} and sialylated Le^{ag}	19-5	Gastrointestinal, pancreatic, ovarian
CA 50	Sialylated Le^{a} and afucosyl form	C50	Pancreatic, gastrointestinal, colon
CA 72-4	Sialylated Tn	B27.3, cc49	Ovarian, breast, gastrointestinal, colon
CA 242	Sialylated CHO	C242	Gastrointestinal, pancreatic

CHO, Carbohydrate.

Squamous Cell Carcinoma Antigen (SCCA)

SCCA is a glycoprotein previously referred to as tumor-associated antigen 4. Subfractions of SCCA have been separated by isoelectric electrophoretic focusing into neutral and acidic fractions. Molecular weights range from 42,000 to 48,000 Da. Both malignant and nonmalignant squamous cells have been shown to contain the neutral fraction, whereas the acidic fraction is found mainly in malignant cells. The acidic fraction is the one released into the blood circulation.

SCCA is elevated in a variety of SCCs, including those of the (1) cervix, (2) lung, (3) skin, (4) head, (5) neck, (6) digestive tract, (7) ovaries, and (8) urogenital tract. In general, the concentration of SCCA is proportional to advancing stages of cancer. It is not useful for screening because only a small percentage of patients with early stages of cancer show elevated serum SCCA concentrations. High pretreatment SCCA concentrations appear to be associated with a poor prognosis. SCCA is useful in detecting recurrence of cancer and in monitoring treatment and disease progression.

Healthy, nonpregnant women have SCC antigen concentrations below 1.5 µg/L. Serum SCC antigen concentrations may be elevated (>1.5 µg/L) in certain benign conditions, including (1) pulmonary infection, (2) skin disease, (3) renal failure, and (4) liver disease. SCC antigen is also present in saliva, sweat, and respiratory secretions.

Carbohydrate Markers

Carbohydrate-related tumor markers may be (1) antigens on the tumor cell surface, or (2) secreted by the tumor cells. Monoclonal antibodies against these antigens have been developed. These markers have been found to be clinically useful as tumor markers and tend to be more specific than naturally secreted markers, such as enzymes and hormones. Biochemically, they are high-molecular-weight **mucins** (Table 20-6) or blood group antigens (Table 20-7).

Mucins

CA 15-3 and CA 27.29 assays detect a high-molecular-weight glycoprotein mucin expressed by the mammary epithelium known as episialin; thus they are used as markers for breast carcinoma. Episialin, also known as polymorphic epithelial mucin (PEM), is a product of the MUC1 gene and is a transmembrane protein with a 69 amino acid cellular domain and an extracellular domain of 20 amino acid tandem repeats. In breast cancer, MUC1 is upregulated and glycosylation is decreased and incomplete, exposing epitopes on the core polypeptide background. Assays for CA 15-3 and CA 27.29 use different antibodies that detect overlapping epitopes on the episialin molecule.

Mucins discussed in greater detail below include (1) CA 15-3, (2) CA 27.29, and (3) CA 125.

CA 15-3

CA 15-3 is detected by a murine monoclonal antibody (MAb) DF3 produced against a membrane-enriched extract of a human breast cancer metastatic to liver. The antibody binds in the tandem repeat region of the peptide core and is carbohydrate independent. Another monoclonal antibody, 115D8, was developed against the human milk fat globule membrane. This antibody does not bind in the tandem repeat region and is carbohydrate dependent.

In healthy subjects, the upper limit of CA 15-3 concentrations is 25 kU/L. When this cutoff is used, 5.5% of normal individuals, 23% of patients with primary breast cancer, and 69% of those with metastatic breast cancer have elevated

CA 15-3 concentrations. Elevated CA 15-3 concentrations are also found in other malignancies, including pancreatic (80%), lung (71%), breast (69%), ovarian (64%), colorectal (63%), and liver (28%) cancers. CA 15-3 is also reported to be elevated in benign disease, including benign liver disease (42%) and benign breast disease (16%).

CA 15-3 should not be used to diagnose primary breast cancer because the incidence of elevation is fairly low (23%). It is most useful in monitoring therapy and disease progression in metastatic breast cancer patients. A significant change of at least 25% correlates with disease progression in 90% of patients, and regression is noted in 78%. No change is correlated with disease stability in 60%.

Two antibodies are used in CA 15-3 immunoassays. The MAb 115D8 is attached to a solid support, whereas MAb DF3 is labeled. Assays using alternative antibodies against the same common antigen are also available for clinical use.

CA 27.29

CA 27.29 is recognized by a monoclonal antibody, B27.29, which is produced against an antigen in ascites of patients with metastatic breast carcinoma. It has been approved by the FDA for clinical use for detecting recurrent breast cancer in patients with stage II or stage III disease and for monitoring response to therapy in patients with stage IV (metastatic) disease. The assay provides similar information to that used for CA 15-3.

Immunoassays for CA 27.29 immunoassay have both competitive and sandwich formats that incorporate the B27.29 monoclonal antibody. Assays that use alternative antibodies against the same common antigen are also available for clinical use.

CA 125

CA 125 is a marker for monitoring ovarian cancer. It is a high-molecular-mass (>200 kDa) glycoprotein recognized by the monoclonal antibody OC 125. It contains 24% carbohydrate and is expressed by epithelial ovarian tumors and other pathological and normal tissues of müllerian duct origin. The molecule has been cloned and designated CA 125/MUC 16. Its physiological function is unknown.

Bast and associates developed the MAb OC 125 using a cell line (OVCA 433) from a patient with a serous papillary cystadenocarcinoma of the ovary. The OC 125 clone was selected for its reactivity with the OVCA 433 cell line and for its lack of reactivity with a B-lymphocyte line from the same patient.

Clinical Applications

The primary FDA-indicated use for CA 125 is to monitor response to therapy in patients with epithelial ovarian cancer. The second FDA-indicated use is to detect residual or recurrent disease in patients who have undergone first-line therapy and would be considered for second-look procedures. However, second-look laparotomy is now considered controversial except for use in clinical trials, or when surgical findings would alter disease management. In a healthy population, the upper limit of CA 125 is 35 kU/L. CA 125 is elevated in nonovarian carcinoma, including (1) endometrial, (2) pancreatic, (3) lung, (4) breast, (5) colorectal, and (6) other gastrointestinal tumors. Also, CA 125 is useful for determining the prognosis of patients with endometrial carcinoma. It is elevated in women in the follicular phase of the menstrual cycle and with benign conditions such as (1) cirrhosis, (2) hepatitis, (3) endometriosis, (4) pericarditis, and (5) early pregnancy. It cannot be used to differentiate ovarian cancer from other malignancies. CA 125 is not useful in screening asymptomatic populations for ovarian cancer, but screening is recommended in at-risk women with a family history of hereditary ovarian cancer, in conjunction with pelvic examination and ultrasound testing. Strategies to improve the clinical usefulness of CA 125 for screening/early detection of ovarian cancer to achieve needed high sensitivity and very high specificity include (1) combining with transvaginal sonography, (2) assessing changes in concentrations measured over time, and (3) using multimarker panels.

In ovarian carcinoma, CA 125 is elevated in (1) 50% of patients with stage I disease, (2) 90% with stage II, and (3) more than 90% with stages III and IV. The concentration of CA 125 correlates with tumor size and staging. CA 125 is also useful in differentiating benign from malignant disease in patients with palpable ovarian masses. This differentiation is important because surgical intervention for malignant ovarian masses is far more extensive than that for benign masses. A preoperative CA 125 concentration less than 65 kU/L is associated with a significantly greater 5-year survival rate (42%) when compared with a concentration greater than 65 kU/L (5%). Postoperative CA 125 concentrations and rate of decline are also predictors of survival. The half-life of CA 125 is normally 4.8 days. A group of patients with a CA 125 half-life of 22 days responded poorly to chemotherapy as compared with another group with a CA 125 half-life of 9 days.

After chemotherapy, CA 125 concentrations provide an indication of disease prognosis. A decrease in the CA 125 concentration by a factor of 10 after the first cycle of chemotherapy is indicative of response. Persistent elevation of CA 125 concentration after three cycles of chemotherapy indicates a poor prognosis.

Analytical Methods

An immunoradiometric assay for CA 125 was first developed that and manufactured by Centocor, Inc. (now Fujirebio Diagnostics, http://www.fdi.com/; accessed on September 9, 2013); it incorporated the OC 125 antibody for both capture and detection, allowing recognition of multiple CA 125 determinants. A second-generation assay (CA 125II) typically uses the monoclonal antibody, M11, as the capture antibody and OC 125 as the conjugate antibody. Other FDA-cleared assays for CA 125, which employ antibodies other than the OC 125 and M11 antibodies, are available on automated immunoassay platforms. Results from different assays are not interchangeable, and individual patients should be monitored with a single assay.

Other Ovarian Cancer Biomarkers

Human epididymis protein 4 (HE4) and OVA1 (Vermillion, Inc., Austin, Tex) are other ovarian cancer markers discussed in the following section.

HE4

The gene for HE4, Homo sapiens epididymis specific, WFDC2, was initially discovered with the use of microarrays to be overexpressed in epididymal tissue and later in ovarian cancer tissue.[7] Tumor expression is histologically dependent, with most serous and endometrioid tumors expressing HE4 and only 50% clear cell and 0% mucinous tumors. The protein is characterized as part of the four-disulfide core protein family and contains whey acid protein domains (WAPs). These proteins typically are secreted and are protease inhibitors, although this function has not been ascribed to HE4; its physiological role is unknown and studies have shown that HE4 is not specific for ovarian tumors.

At the HE4 cutoff of 150 pMol/L, covering 95% of healthy women, 79% of women with ovarian cancer have elevated concentrations. HE4 is elevated in other cancers, including (1) breast—13%, (2) endometrial—26%, (3) gastrointestinal—16%, and (4) lung—42%, as well as in (5) benign gynecological—7% and (6) other benign disease—24%. The assay is FDA cleared for monitoring recurrence or progressive disease in patients with epithelial ovarian cancer. Results comparing HE4 and CA 125 to distinguish women with ovarian cancer from normal women or those with benign processes appear to depend on the population studied, although combining the two markers may allow more accurate prediction of cancer than use of the individual markers. An algorithm incorporating HE4 and CA 125 has been reported to successfully classify women with a pelvic mass as at high or low likelihood for malignancy at the time of surgery. This algorithm was accurate in classifying a high percentage (93.8%) of women with cancer as high risk. The algorithm, termed the Risk of Malignancy Index (ROMA has been cleared for use by the FDA. HE4 may also have usefulness as a marker in endometrial cancer.

HE4 is measured by an enzyme immunoassay, with 2H5 as the capture antibody and 3D8 as the detector antibody (Fujirebio Diagnostics; http://www.fdi.com/; accessed on September 9, 2013). This assay is not recommended for patients with mucinous or germ cell ovarian cancer.

OVA1

Based on the proteomics biomarker discovery approach using mass spectrometry, Zhang and colleagues[14] identified several proteins that, when combined with CA 125, provide diagnostic value for ovarian cancer as the OVA1 test. It is considered the first in vitro diagnostic multivariate index assay proteomic diagnostic for cancer (Vermillion, Inc.; http://www.vermillion.com/; accessed on September 9, 2013). The OVA1 test is a qualitative serum test that combines five immunoassay results—(1) CA 125, (2) prealbumin (transthyretin), (3) apolipoprotein A1 (apo A1), (4) transferrin (Tfr), and (5) β2M (beta-2-microglobulin)—into a single numerical score. Its use is indicated for women who meet the following criteria: (1) older than age 18, (2) ovarian adnexal mass present for which surgery is planned, and (3) not yet referred to an oncologist. The OVA1 test is an aid in further assessment of the likelihood that malignancy is present when the physician's independent clinical and radiological evaluation does not indicate malignancy. The addition of OVA1 to the presurgical clinical assessment improved the sensitivity of predicting malignancy from 72% to 92% for non–gynecological oncologist (GO) patients and from 78% to 99% for GO patients.

Blood Group Antigens

Blood group carbohydrates identified by monoclonal antibodies that have been used as markers of cancer are listed in Table 20-7. CA 19-9 (sialylated Le^{xa}) is an example of blood group antigens used frequently for clinical purposes. It is a marker for gastrointestinal cancers and is used primarily in patients with pancreatic carcinoma. CA 19-9 has been approved by the FDA for quantitative measurement in serum and as an aid in monitoring pancreatic cancer patients.

The CA 19-9 carbohydrate antigen is sialylated lacto-N-fucopenteose II ganglioside; it is a sialylated derivative of the Le^a blood group antigen denoted as Le^{xa}. Expression of the antigen requires the Lewis gene product, 1,4-fucosyl transferase. CA 19-9 is synthesized by (1) normal human pancreatic and biliary ductular cells and by (2) gastric, (3) colon, (4) endometrial, and (5) salivary epithelia. In serum, it exists as a mucin—a high-molecular-mass (200 to 1000 kDa) glycoprotein complex. Patients who are genotypically Le^{a-b-} (about 5%) do not express CA 19-9.

The CA 19-9 upper reference limit is 37 kU/L, as determined from the 99th percentile of healthy subjects. This cutoff discriminates between pancreatic cancer and benign pancreatic disease with clinical sensitivities of 69% to 93% and clinical specificities of 76% to 99%. Elevated CA 19-9 concentrations (>37 kU/L) are found in patients with (1) pancreatic—80%, (2) hepatobiliary—67%, (3) gastric—40% to 50%, (4) hepatocellular—30% to 50%, (5) colorectal—30%, and (6) breast—15% cancers. Some patients (10% to 20%) with pancreatitis and other benign gastrointestinal diseases have elevated concentrations up to 120 kU/L. CA 19-9 is useful in monitoring (1) pancreatic, (2) colorectal, and (3) gastric cancers. CA 19-9 concentrations correlate with pancreatic cancer staging. At a cutoff of 37 kU/L, 67% of patients with resectable and 87% of those with unresectable pancreatic cancers have elevated concentrations. When the cutoff is raised to 1000 kU/L, 35% of patients with unresectable tumors and only 5% of those with resectable tumors have elevated CA 19-9 concentrations. CA 19-9 is also useful for establishing prognosis for pancreatic cancer at initial diagnosis, as concentrations have independent predictive value for determination of resectability and of overall survival. Elevated or increasing concentrations have been known to indicate recurrence 1 to 7 months before it is detected by radiographs or clinical findings. Unfortunately, early detection of relapse may not be useful because of the lack of effective therapy for pancreatic cancer.

Most diagnostics companies have developed a CA 19-9 immunoassay. Typically, the CA 19-9 antibody is used as both the capture and the signal antibody. Considerable differences among value assays have been noted, and assay results are not interchangeable for individual patients.

Proteins

Several proteins that have tumor marker potential are listed in Table 20-8. Included in this group of tumor markers are proteins that are not enzymes or hormones and are not high in carbohydrate content.

Immunoglobulin

Monoclonal immunoglobulin has been used as a marker for multiple myeloma for more than 100 years. Monoclonal paraproteins appear as sharp bands in the globulin region of serum electrophoretic patterns. More than 95% of patients with multiple myeloma have such an electrophoretic pattern. Appearance of nonmalignant monoclonal immunoglobulins increases with age, reaching 5% in patients older than 75 years. These nonmalignant monoclonal bands are usually lower in concentration than malignant bands and are not associated with Bence-Jones protein. Bence-Jones protein is a free monoclonal immunoglobulin light chain in the urine. The concentration of monoclonal immunoglobulin at initial diagnosis is a prognostic indicator of disease progression. During treatment, the serum concentration of urinary Bence-Jones protein may reflect the success of therapy. Lower concentrations are associated with more favorable outcomes. Serum paraproteins are discussed in Chapter 18.

Bladder Cancer Markers

It is estimated that 600,000 Americans are currently affected by bladder cancer, and approximately 70,000 new cases will be diagnosed each year. Symptoms are (1) intermittent hematuria, (2) voiding problems and (3) dysuria. The most common type of bladder cancer, transitional cell carcinoma (TCC), is treated on the basis of the extent of tumor invasion. Carcinoma in situ (stage Tis) and superficial bladder cancers (stages Ta and T1) occur on the epithelial lining and do not invade the muscle layer. Stage Ta tumors are confined to the mucosa, and stage T1 tumors superficially invade the lamina propria. Stage T2 tumors extend into the muscle layer, and T3 tumors invade beyond the muscle layer. Stage T4 tumors have metastasized to local nodes or distant organs.

Urinary Bladder Tumor Markers

Bladder cancer is detected through cystoscopy or cytology of shed cells. Noncellular tumor antigens present in urine, such as (1) NMP22, (2) complement factor-H (CFH), and (3) fibronectin, are used in a complementary manner with cystoscopy and cytology. Other markers have been evaluated as markers for bladder cancer, including (1) telomerase, (2) cytokeratins, and (3) **survivin**.

Two bladder cancer–related cellular tests that are fluorescence based have been cleared by the FDA. ImmunoCyt (Scimedx Corporation, Denville, NJ; http://www.scimedx.com/; accessed on September 9, 2013) uses three fluorescently labeled monoclonal antibodies and microscopy to identify bladder cancer markers on cells found in urine. This test appears most useful with cytology in identifying low-grade tumors. UroVysion (Abbott Molecular, Abbott Park, Ill; http://www.abbottdiagnostics.com/; accessed on September 9, 2013), a **fluorescence in situ hybridization (FISH)** technique, uses fluorescently labeled probes to detect aneuploidy (abnormal number of chromosomes) of chromosomes 3, 7, and 17, and deletion of the 9p21 locus that contains the tumor suppressor p16, which is the most common alteration seen in urothelial carcinoma.

Nuclear Matrix Protein (NMP22)

Nuclear matrix proteins (NMPs) make up the internal structure of the nucleus. Their function has been associated with regulating key reactions in the nucleus, such as DNA replication and RNA synthesis. NMPs released by the cancer cell may be different from those in normal healthy cell. In a multicenter study of 90 patients with 33 pathologically confirmed TCCs of the urinary tract, 70% of 33 recurrences had urinary NMP greater than 10 U/mL. Among patients with NMP less than 10 U/mL, 86% had no malignancy at subsequent cystoscopy.

An ELISA for the measurement of an NMP, called nuclear mitotic apparatus protein (NuMa) in urine, has been approved by the FDA for the management of patients with TCC of the urinary tract, to aid in diagnosis of symptomatic patients or those with risk factors, and to identify patients with recurrent

TABLE 20-8 Proteins as Tumor Markers

Name	Nature	Type of Cancer
β_2-Microglobulin	11 kDa	Multiple myeloma, B-cell lymphoma, chronic lymphocytic leukemia, Waldenström's macroglobulinemia
C-peptide	3.6 kDa	Insulinoma
Ferritin	450 kDa iron-binding protein	Liver, lung, breast, leukemia
HER-2/neu	97 to 115 kDa, 20% CHO	Breast
Immunoglobulin	160 to 900 kDa, 3% to 12% CHO	Multiple myeloma, lymphomas
Melanoma-associated antigen	90 to 240 kDa	Melanoma
Pancreas-associated antigen	100 kDa, 20% CHO	Pancreatic, stomach
Pregnancy-specific protein 1	10 kDa, 30% CHO	Trophoblastic, germ cell
Pro-gastrin releasing peptide	Amino acid residues 31 to 98	Small cell lung
Prothrombin precursor	Des-γ-carboxy prothrombin	Hepatocellular
Soluble mesothelin-related peptides	Mesothelin/megakaryocyte potentiating factor peptides	Mesothelioma, ovarian
Tumor-associated trypsin inhibitor	6 kDa polypeptide	Lung, gastrointestinal, ovarian

CHO, Carbohydrate.

TCC. T is test, which is called NMP22, is manufactured by Alere North America, Inc. (Princeton, NJ; http://www.alere.com/; accessed on September 9, 2013). A qualitative, immunochromatographic point-of-care version of the test is available as an aid in monitoring patients with a history of bladder cancer.

Bladder Tumor–Associated (BTA) Analytes

A qualitative, lateral flow immunoassay for BTA analytes in urine, termed the BTA stat test, detects the antigen human complement factor H–related protein (hCFHrp), which is a variant of human complement factor H (hCFH). It functions in the alternative complement pathway by interacting with complement factor C3b to prevent cell lysis. Bladder tumor–associated antigen may allow tumor cells to evade the host immune system. A multicenter trial compared the BTA stat test with voided urine cytology studies in 499 patients undergoing surveillance cystoscopy for recurrent bladder cancer. T e BTA stat test identified 40% of patients with positive cystoscopy results, and cytology detected 17%. A positive test may result in a higher degree of suspicion for recurrence. A quantitative test in ELISA format, BTA TRAK, is also available. Both tests have FDA-approved indications for use as an aid in conjunction with cystoscopy in the management of bladder cancer patients.

Soluble Mesothelin-Related Peptides (SMRPs)

Mesothelioma is a rare cancer of the mesothelial surfaces of the pleural and peritoneal cavities or the pericardium that is linked to asbestos exposure. Mesothelin is a cell surface glycoprotein expressed on mesothelial cells, and mesothelin fragments, which are soluble mesothelin-related peptides, are found in the circulation of patients with mesothelial tumor. An ELISA assay has been developed (Mesomark, Fujirebio Diagnostics; http://www.fdi.com/; accessed on September 9, 2013) that measures serum soluble molecules related to the mesothelin/megakaryocyte potentiating factor (MPF) family of proteins recognized by the monoclonal antibody OV569. T e assay also incorporates the 4H3 monoclonal antibody. T is test is approved by the FDA under the Humanitarian Device Exemption, which is used for medical devices for diseases affecting fewer than 4000 individuals a year; demonstration of effectiveness is not required. It is intended as an aid in monitoring patients who have been diagnosed with epithelioid mesothelioma. A cutoff of 1.5 nmol/L was derived from the 99th percentile of healthy subjects. In addition to patients with mesothelioma (52%), approximately 10% to 15% of patients with other cancers, such as (1) ovarian, (2) lung, (3) colon, and (4) pancreatic cancers, may have elevations in SMRP compared with 5% of individuals exposed to asbestos. SMRP increases with increasing stage of malignant pleural mesothelioma. With the use of ROC analysis, an AUC of 0.81 was obtained to distinguish malignant pleural mesothelioma patients (n = 90) from asbestos-exposed individuals (n = 66) with clinical sensitivity, specificity, and accuracy of 60%, 89%, and 73%, respectively, at a cutoff of 1.9 nmol/L. T e AUC for distinguishing malignant pleural mesothelioma from lung cancer (n = 170) was 0.82.

Des-γ-Carboxy Prothrombin (PIVKA-II)

Des-γ-carboxy prothrombin (DCP), also called PIVKA-II (proteins induced by vitamin K absence or antagonism II), is an abnormal form of prothrombin and a tumor marker for hepatocellular carcinoma. Prothrombin is a vitamin K–dependent coagulation factor produced in the liver that undergoes post-translational modification in which the 10 glutamic acid (glu) residues in the N-terminus are carboxylated to form γ-carboxy glutamic acid (gla) that is functional. T e γ-glutamyl carboxylase requires vitamin K as a cofactor, and in cases of dietary deficiency or antagonism, such as by warfarin, DCP is produced. Obstructive jaundice with an effect on vitamin K may result in increased DCP. In hepatocellular carcinoma, gene expression of the enzyme is defective, resulting in DCP.

DCP is most commonly used clinically for (1) early detection, (2) monitoring, and (3) detecting recurrence in countries with a high prevalence of hepatocellular carcinoma, such as Japan. When an ELISA was used to compare patients with hepatocellular carcinoma versus those with cirrhosis or chronic hepatitis, sensitivity for detection was 48% and specificity 96%. DCP and AFP are independent markers, and in a case control study of patients with hepatocellular carcinoma or cirrhosis, clinical sensitivity for cancer detection in early-stage disease increased to 78% compared with 53% for AFP alone and 61% for DCP alone. DCP correlates with tumor size, although it is less sensitive for detecting (1) small tumors, (2) tumor stage, and (3) prognosis. In the United States, the Wako DCP assay (http://www.wakodiagnostics.com/; accessed September 9, 2013) has been FDA cleared as an aid in the risk assessment of patients with chronic liver disease for progression of hepatocellular carcinoma. When this assay was used in a prospective study of 334 patients with hepatitis C virus (HCV) cirrhosis, the relative risk of developing hepatocellular carcinoma was 5.7 with a cutoff of 7.5 μg/L.

S-100 Proteins

T e S-100 proteins constitute a group of at least 19 related calcium-binding proteins. All contain two high-af nity and selective EF-hand calcium-binding domains. T eir physiological role is uncertain; however, some members have been associated with cancer progression, namely, (1) S-100A4, (2) S-100A2, (3) S-100A6, and (4) S-100β. S-100A4 is normally expressed in selected immune cells, with faint expression in (1) keratinocytes, (2) melanocytes, and (3) Langerhans' cells. It is not expressed in (1) breast, (2) colon, (3) thyroid, (4) lung, (5) kidney, or (6) pancreas. Expression of S-100A4 in (1) breast cancer, (2) esophageal-squamous carcinoma, and (3) gastric cancer correlates with a worse outcome and more aggressive disease and was shown to be an independent marker of prognosis in multivariate analysis. Lack of expression in normal tissue and expression in cancer tissue make it an excellent candidate for routine histological use as a cancer marker.

S-100β is routinely used as a diagnostic histological marker of melanoma and melanoma metastases. Measurement of serum concentrations of S-100β has been investigated for monitoring disease recurrence. In the absence of melanoma, serum S-100β concentrations are normally undetectable;

however, with recurrent disease, S-100β concentrations rise. With the use of an immunoassay, clinical sensitivity and specificity of 0.29 and 0.93, respectively, with diagnostic accuracy of 0.84, were obtained when a cutoff of 0.12 μg/L was used. S-100β is a more sensitive and specific marker for recurrent melanoma that is able to detect recurrence earlier than LD or alkaline phosphatase (traditional markers of melanoma recurrence). An automated assay is available on the LIAISON analyzer (DiaSorin, Inc., Stillwater, Minn; http://www.diasorin.com/; accessed on September 9, 2013).

Thyroglobulin and Antibodies

Thyroglobulin (Tg) is produced by the thyroid gland as the precursor to thyroid hormone (see Chapter 42). The primary use of Tg measurement is for monitoring patients with a diagnosis of differentiated thyroid cancer after thyroid gland ablation. Approximately two-thirds of these patients have an elevated preoperative Tg concentration. An elevated preoperative concentration of Tg confirms the tumor's ability to secrete Tg and validates the use of postoperative measurement of Tg to monitor for tumor recurrence. Postoperatively, the most sensitive time to detect residual tumor or metastasis is after TSH stimulation. In well-differentiated tumors, a tenfold increase in Tg concentrations is seen after TSH stimulation.

Antithyroglobulin antibodies have been proposed to monitor residual disease and/or recurrence. Serial anti-Tg measurements may be an independent prognostic indicator of therapy because an increase in anti-Tg antibodies may suggest recurrence of the tumor.

Immunometric assays (IMAs) and RIAs are the two main methods used for measurement of Tg (see Chapter 42). IMA assays provide the advantage of having a shorter incubation time and have been automated; however, they suffer from greater interferences. The main interferants in both assays are antithyroglobulin antibodies, which typically cause an underestimation of Tg concentrations in the IMA. Antithyroglobulin antibodies have been measured directly in all patients; if both IMA and RIA are used to measure Tg, a discordant result suggests an interference from antithyroglobulin antibodies.

Chromogranins

Chromogranins are a family of proteins that are major components of the secretory granules of most neuroendocrine cells. The granin family consists of three members: (1) chromogranin A (CgA); (2) chromogranin B (CgB); and (3) secretogranin II, III, IV, and V. Chromogranins are found in neuroendocrine cells throughout the body, including the neuronal cells of the central and peripheral nervous systems. Intracellularly located chromogranins have been suggested to play a role in the regulation of secretory granules. In addition, secreted chromogranins are proteolytically processed to form bioactive peptides. Chromogranin A has been the best studied of the chromogranins, has been shown to be widely expressed by neuroendocrine tissue, and is co-secreted by neuroendocrine cells, along with peptide hormones and neuropeptides. Their wide distribution and co-secretion make it an excellent histochemical and plasma marker of neuroendocrine tumors.

Both CgA and CgB are useful in detecting various neuroendocrine tumors, including (1) carcinoid tumor, (2) pheochromocytoma, and (3) neuroblastoma. In most cases, CgA is produced at higher concentrations than CgB; however, in some cases, CgB is positive when CgA is negative; therefore, it is recommended that both should be measured. In the case of carcinoid tumor, foregut and midgut tumors are normally functional tumors producing serotonin. CgA is as specific for the detection of both foregut and midgut carcinoid tumors. Also, the serotonin metabolite 5-hydroxyindoleacetic acid (5-HIAA) is the preferred marker in hindgut tumors, which commonly are nonfunctional. Although nonfunctional tumors have lost the ability to secrete serotonin, they retain the ability to secrete chromogranins. For detection of pheochromocytomas, CgA is at least as sensitive and specific as plasma catecholamines or urinary metanephrines.

CgA is measured by immunoassay. Depending on the assay, polyclonal or monoclonal antibodies are used. Care must be taken in choosing an assay, however, because CgA and the other chromogranins are heavily processed after release, which may render them nondetectable by the assay and may produce false-negative results. Therefore, an assay that recognizes both intact and processed molecules should be considered.

Receptors

Various receptors have found use as tumor markers. They include (1) estrogen, (2) progesterone, and (3) epidermal growth factor receptors.

Estrogen and Progesterone Receptors

Estrogen (ERs) and progesterone (PRs) receptors are used in tumor markers as indicators of breast cancer for hormonal therapy. Patients with positive estrogen and progesterone receptors tend to respond to hormonal treatment. Those with negative receptors will be treated using other therapies, such as chemotherapy. Hormone receptors also serve as prognostic factors in breast cancer. Patients positive for hormone receptors tend to have a better prognosis.

Estrogen receptors and progesterone receptors are members of the nuclear steroid hormone receptor family and are involved in hormone-directed transcriptional activation. The general structure of nuclear steroid hormone receptors, including ERs and PRs, consists of a large N-terminal domain containing (1) transcriptional activation domains, (2) a DNA-binding domain, (3) a hinge region, and (4) the hormone-binding domain at the C-terminus. Both ERs and PRs are present in a large protein complex, and upon hormone binding, some members of the complex dissociate, and the receptors bind to their respective response elements and activate transcription.

Both estrogen and progesterone have at least two separate receptors. Estrogen has ERα and ERβ, which are transcribed from separate genes. ERα and ERβ show 96% and 58% homology in their DNA- and hormone-binding domains, respectively, with a more divergent sequence in the N-terminal region. Two forms of PR—PR-A and PR-B—also have been

identified; both are transcribed from the same gene. PR-A lacks the first 165 amino acids of PR-B.

ERs and PRs are found in target tissue cells, such as (1) uterus, (2) pituitary gland, (3) hypothalamus, and (4) breast, and appear to be involved in tumor development and progression. Furthermore, ER status and PR status correlate with both prognosis and treatment response. For example, measurement of ER content in breast tumor tissue is useful in determining the probability of hormonal therapy and as a prognostic indicator. In addition, ERs and PRs are routinely measured in all newly diagnosed breast cancers. Among patients with carcinoma of the breast, 60% have tumors that are ER positive. ER-positive tumors are seven to eight times more likely to respond to endocrine therapy, such as tamoxifen. Ninety-five percent of patients with ER-negative tumors fail to respond. The greater the ER content of the tumor, the higher the response rate to endocrine therapy. As a prognostic indicator, ER positivity suggests a better 5-year outcome; however, after 5 years, ER-negative tumors have a better prognosis.

The PR assay is a useful adjunct to the assay of ERs. Because PR synthesis appears to be dependent on estrogen action, measurement of PR activity provides confirmation that all steps of estrogen action are intact. Indeed, metastatic breast cancer patients with both ER- and PR-positive tumors have a response rate of 75% to endocrine therapy, whereas those with ER-positive and PR-negative tumors have a 40% response rate. In addition, only 25% of ER-negative/PR-positive patients respond to endocrine therapy, whereas less than 5% of ER-negative/PR-negative patients respond.

Immunohistochemistry assay is used to measure steroid hormone receptors in breast tumor tissue specimens. In practice, the reader should note that the (1) classical quantitative biochemical method, (2) multiple-point dextran-coated (DCC) titration assay, and (3) enzyme immunoassays are obsolete. They have been replaced with immunohistochemical assays as they are simple and less expensive and use small amounts of tissue. In 2010, ASCO and the College of American Pathologists (CAP) collaborated to develop guidelines for estrogen and progesterone receptor analysis by immunohistochemistry in an effort to standardize and improve the quality of testing among laboratories.

Epidermal Growth Factor Receptor

The epidermal growth factor receptor (EGFR) is a prototype of a family of tyrosine kinase receptors. Natural ligands for the EGFR include epidermal growth factor and transforming growth factor-α. In cancerous tissue, these growth factors promote growth in both a paracrine and an autocrine fashion.

Several compounds have been developed that inhibit EGFR signaling by blocking ligand binding or inhibiting tyrosine kinase activity. Also, mutations in the EGFR gene that are predictive of sensitivity to these drugs have been identified; the primary example is that of the L858R mutation in EGFR. This information is useful because it allows for the appropriate selection of therapy for a subset of patients, as demonstrated in individuals with non–small cell lung cancer. The tumors of some patients undergoing this therapy eventually become resistant to this medication. It is interesting to note that these resistant tumors are characterized by a different mutation in the EGFR—the T790M mutation.

EGFR is identified in tissue by immunohistochemistry and FISH. Detection of the EGFR protein (HER1) in EGFR-expressing cells by immunohistochemistry has been approved by the FDA for use as a companion diagnostic to aid in identifying colorectal cancer patients for treatment with the EGFR inhibitors cetuximab and panitumumab. A genetic test for the KRAS gene mutation to determine which advanced colorectal cancer patients have the wild-type gene (mutation negative) is also FDA approved. Individuals with wild-type KRAS tumors are much more likely to benefit from monoclonal antibody treatments targeting the EGFR pathway than individuals whose tumor carries mutated KRAS. This is because the K-ras protein is downstream of the EGFR protein in a signaling pathway. Thus, if K-ras protein is mutated such that it is constitutively activated, treatment that blocks EGFR will not be effective, as K-ras will continue to send a signal that promotes growth and proliferation.

Circulating Tumor

Circulating tumor cells are also used as tumor markers.

A majority of all cancers are derived from epithelial cells. Under appropriate conditions, these cells break from the primary tumor and shed into the circulation. These circulating tumor cells (CTCs) are very rare (approximately 1 CTC per 5 to 10 million red blood cells and lymphocytes), but techniques are available that make it possible to (1) capture, (2) enrich, and (3) count them. Consequently, their quantification has been demonstrated to be an independent predictor of overall survival and progression-free survival in patients suffering from metastatic (1) breast, (2) colon, and (3) prostate cancers. This technology, as applied using the Veridex CellSearch platform (Veridex LLC, Raritan, NJ; https://www.cellsearchctc.com/; accessed September 9, 2013), is FDA approved for these applications.

The assay uses a combination of positive and negative selection methods to isolate circulating epithelial cells from whole blood. This allows rapid assessment of therapeutic response and hence adjustment of therapy as needed. For patients not responding to a particular line of therapy, alternative regimens have been prescribed, or dosages adjusted as needed.

The greatest demonstration of the use of this technology is seen in breast cancer patients. In metastatic breast or prostate cancer, a CTC count of five or more cells per 7.5 mL of blood is associated with a poor prognosis and is predictive of shorter progression-free survival and overall survival. The same is true in metastatic colorectal cancer with a CTC count of three or more cells per 7.5 mL of blood.

Genetic and Molecular Markers

Cancerous growth is an inheritable characteristic of cells that is thought to be the outcome of genetic changes. Multiple genetic alterations may be necessary for the transformation

of a cell from a healthy state to a cancerous one and, finally, for metastatic spread. Therefore, evaluation of chromosomal changes is now being used to establish cancer risk and to screen for cancer (see Chapters 47 and 49).

Classes of genes implicated in the development of cancer are (1) **oncogenes** (cell activation genes) and (2) tumor-suppressor genes (genes involved in the recognition and repair of damaged DNA; Table 20-9). Oncogenes are derived from proto-oncogenes that may be activated by dominant mutations, such as (1) point mutations, (2) insertions, (3) deletions, (4) translocations, or (5) inversions. Most oncogenes code for proteins that function at some stage of activation of cells for proliferation, and their activation leads to cell division. Many oncogenes are associated with hematological malignancies such as leukemia[5] and solid tumors. Tumor-suppressor genes, the other class of cancer-associated genes, have been isolated mostly from solid tumors. The oncogenicity of tumor-suppressor genes is derived from loss of the gene rather than from their activation, as with oncogenes. Deletion or monosomy (the presence of only one chromosome) may lead to loss of tumor suppressor genes. The major tumor suppressor gene, p53, functions to repair damaged DNA through apoptosis (programmed cell death). Repair is mediated by activation of the production of p21, which blocks the cell cycle in late G_1 to allow repair to take place. Loss of function of this gene caused by loss or mutation may result in an impaired DNA repair process, leading to the development of tumorigenesis.

Advances in technologies (both hardware and software), coupled with robust expansion of nucleotide and protein databases, have led to the development of new tools that allow the simultaneous interrogation of hundreds to thousands of variables simultaneously. In particular, microarray-based analyses are at the forefront of translation to clinical practice.

Oncogenes

Proto-oncogenes are normal cellular genes that are similar to tumor virus genes. Activation of proto-oncogenes is found to be associated with cancer. These genes code for products that are involved in normal cellular processes, such as growth factor signaling pathways. Overexpression of the oncogene will lead to abnormal cell growth, resulting in malignancy. Of the many proto-oncogenes recognized, only a few have been shown to be useful tumor markers. A detailed description of three representative oncogenes is presented next: (1) RAS genes, (2) HER2, and (3) BCR/ABL. Others are listed in Table 20-9.

RAS Genes

The RAS genes were first identified as being responsible for the tumorigenic properties of the Harvey (H-ras) and Kirsten (K-ras) sarcoma viruses, which produce tumors in animals, and they provided the first evidence that cellular counterparts in human cells might be involved in the development of human tumors. RAS proteins coded for by the RAS genes are located at the inner face of the plasma membrane, as well as

TABLE 20-9 Oncogenes and Tumor-Suppressor Genes

Oncogenes	Cellular Function	Representative Cancers*	Protein Function/Comments
RAS	Proliferation, cell growth	N-ras: AML, neuroblastoma K-ras: leukemia, lymphoma	GTP/GDP binding protein, p21
c-myc	Transcriptional regulation	B- and T- cell lymphoma, SCLC	Master transcriptional regulator: induces expression of ≈15% of all genes
HER2 (c-erbB2)	Receptor tyrosine kinase	Breast, ovarian, GI tumors	Plasma membrane receptor, p185; ligand binding induces dimerization
BCL2	Apoptosis	Leukemia, lymphoma	Two isoforms; antiapoptotic regulatory protein; higher protein levels in some cancers
BCR/ABL	Signal transduction protein	CML, RCC, GIST	Tyrosine kinase fusion protein resulting from Philadelphia chromosome reciprocal translocation, p185/p210
Tumor Suppressors	**Cellular Function**	**Representative Cancers***	**Chromosomal Locus**
Rb	Cell cycle regulation	Retinoblastoma, osteosarcoma, SCLC	13q14
TP53	Transcriptional regulation, apoptosis	Breast, colorectal, lung, liver, renal, bladder, sarcoma	17p13
p21(WAF1/CIP1)	Cell cycle progression	Breast, pancreatic, and multiple cancers	6p21
APC	Cell-cell interaction	Colorectal	5q21
NF1	Proliferation and cell growth, negative regulator	von Recklinghausen's disease; colorectal, melanoma, neuroblastoma	17q
WT1	Transcriptional regulation	Wilms' tumor	11p13
nm23	Metastasis-related functions	(Multiple) metastatic human cancers	17q21
BRCA1/2	Transcriptional regulation, DNA repair	Breast cancer	BRCA1: 17q; BRCA2: 13q12.3
DCC	Membrane protein of IgG superfamily	Colorectal	18q21
PTEN	Lipid kinase	Glioblastoma, endometrial, prostate	10q23

*This list is not meant to be exhaustive but merely to provide representative examples.

in other internal cellular membranes. T ey bind to guanine nucleotides and function as molecular switches that regulate mitogenic signals from growth factors to the nucleus via signal transduction pathways. T e ras proteins are activated in association with protein-tyrosine kinase receptors and are required for growth factor proliferation or differentiation of a number of cell types.

In oncology, the most important human RAS genes are NRAS and KRAS. T e NRAS gene is found on the short arm of human chromosome 1. Changes in NRAS appear to be the critical step in carcinogenesis. T e mutated NRAS gene is found in neuroblastomas and acute myeloid leukemia. In addition, it is present in (1) 95% of pancreatic cancers, (2) 40% of colon cancers, and (3) 30% of lung and bladder cancers, and in lower percentages in other tumors. T e KRAS gene is on the short arm of chromosome 12. A single point mutation at codon 12 changes a coded amino acid from glycine to valine in the p21 protein. T is mutation is by far the most frequently found in cancer, but other mutations have also been demonstrated, including those at codons 13 and 61. KRAS mutations appear to correlate with poor prognosis and shorter disease-free survival in patients with adenocarcinoma of the lung and endometrial carcinoma. Activated ras is detected by expression of the RAS gene product, p21, in cancer tissue. By immunohistochemistry, the ras protein is found not only in about 40% of colon cancers, but also in colon polyps believed to be premalignant. Higher relative intensity of staining for p21-ras may differentiate malignant from normal tissues or benign lesions in (1) breast, (2) pancreas, (3) stomach, (4) lung, (5) uterus, or (6) thyroid tissues. Expression in tissue appears to correlate with stage or grade of the tumor, but p21-ras may also be seen in some normal tissue, and other studies show no significant difference between benign and malignant tumors. Use of the p21 protein as a tumor marker in tissue or serum is not well established. Mutations of RAS oncogenes have been detected in DNA in the stool of symptomatic and asymptomatic patients with colorectal tumors, suggesting a novel, noninvasive paradigm for population screening. Several studies have underscored the importance of KRAS mutations in therapeutic regimen selection. Individuals with a diagnosis of metastatic colorectal cancer with wild-type KRAS tumors are much more likely to benefit from monoclonal antibody treatments targeting the EGFR pathway, such as cetuximab and panitumumab, than individuals whose tumor carries mutated KRAS (at codons 12 and 13). T us, KRAS mutation testing is advocated in patients suffering from metastatic colorectal carcinoma who are candidates for anti-EGFR treatments. Further, if the tumor tests positive for mutation at codon 12 or 13, the patient should not receive anti-EGFR treatment.

HER2

T e HER2/neu gene (also known as c-erbB-2, symbol ERBB2) is named for its association with neural tumors (neu). T e ERBB2 gene codes for a 185 kDa transmembrane protein expressed on epithelial cells and belongs to the EGF family of tyrosine kinase receptors. T e EGF family includes four members: (1) EGFR (also known as ErbB1/HER-1), (2) ERBB2 (HER2 or HER2/neu), (3) ERBB3, and (4) ERBB4. Members of the EGF family of receptors have the same overall structure consisting of (1) an extracellular ligand-binding domain (ECD), (2) a single transmembrane domain, and (3) an intracellular tyrosine kinase domain. T e extracellular domain undergoes proteolytic cleavage by metalloproteases, releasing the ECD (known as p105) into the blood, which is then detected. All are involved in (1) cell proliferation, (2) differentiation, and (3) survival. HER2 is normally expressed on the epithelia of numerous organs, including (1) lung, (2) bladder, (3) pancreas, (4) breast, and (5) prostate, and has been found to be elevated in cancer cells.

Amplification of ERBB2 is found in (1) breast, (2) ovarian, and (3) gastrointestinal tumors. In breast cancer, it appears to be as useful a prognostic indicator of overall survival and tumor size as ER and PR expression, but not as good as the number of lymph nodes involved in metastases. Of the three oncogenes—ERBB2, RAS, and MYC—ERBB2 has the strongest prognostic value in breast cancer. Herceptin treatment is administered only to those breast cancer patients who have HER2 amplification.

Measurement of the serum concentrations of the HER2 proteins is considered most useful in breast cancer, with some use in ovarian cancer patients. The assay is cleared by the FDA for use in follow-up and monitoring of patients with metastatic breast cancer with a HER-2 concentration >15 μg/L. Approximately 30% of patients have elevated concentrations. HER2 concentrations in breast cancer correlate with a worse prognosis and a shorter disease-free state. Elevated HER2 concentrations also correlate with (1) large tumor size, (2) lymph node positivity, and (3) a high grading score. Serum concentrations of HER2 may also be useful in monitoring the response of breast cancer patients to treatment.

Immunohistochemistry is used to detect increased tissue expression of the HER2 protein. FISH is used for detection of HER2 gene amplification. ASCO and CAP have collaborated to develop comprehensive guidelines for HER2 testing. T e ECD of HER2 in serum is detected by ELISA and automated immunoassay. Both assays use the same monoclonal antibodies, recognizing different epitopes of the ECD, which does not cross-react with any other member of the EGF family. It is important to note that no interference from the therapeutic monoclonal antibody, Herceptin, is noted with either assay.

BCR-ABL

Chronic myelogenous leukemia (CML) is a myeloproliferative disorder that results from the clonal expansion of a transformed multipotent hematopoietic stem cell. In approximately 90% of CML patients, the transforming event is the formation of the **Philadelphia chromosome**—a balanced translocation between chromosomes 9 and 22 [t(9;22)(q34;q11)] creating the BCR-ABL fusion gene. T e protein derived from this fusion is a constitutively active cytoplasmic tyrosine kinase that activates several signaling pathways, leading to (1) uncontrolled growth, (2) inhibition of apoptosis, and (3) other aspects of neoplastic transformation.

Detection of the BCR-ABL gene is useful in diagnosing CML and in directing treatment. Once detected, several tactics are then used that target the BCR-ABL gene by oligonucleotides (antisense or ribozyme based) or the BCR-ABL kinase domain by the tyrosine kinase inhibitor STI571 (also known as Gleevec, or imatinib mesylate). For example, BCR-ABL detection by reverse transcription–polymerase chain reaction (RT-PCR) is useful in monitoring minimal residual disease in patients who have undergone bone marrow transplantation. In the subset of acute lymphoblastic leukemia patients who harbor the Philadelphia chromosome, a positive RT-PCR for the BCR-ABL gene carries much higher risk of relapse compared with a negative result. In CML patients after bone marrow transplantation, positive RT-PCR results at 6 to 12 months were associated with a 26-fold elevated risk of relapse, and a positive result at 3 months was not predictive of risk. Also, the amount of BCR-ABL transcript per μg of RNA correlated with risk of relapse; less than 1% of patients with fewer than 50 transcripts per μg of RNA relapsed, as did 72% of patients with more than 50 transcripts per μg of RNA.

Tumor-Suppressor Genes

Historically, evidence of tumor-suppressor genes was derived from the study of hybrid cells of normal and malignant cells that behaved in a typical manner. It was concluded that healthy cells contained a gene that suppressed the expression of malignancy. Reversion to malignancy occurred when the cultured cells lost normal chromosomes. T e clinical usefulness of detection of mutations in tumor-suppressor genes lies not only in the diagnosis and prognosis of cancer, but also in the prediction of susceptibility when the mutation is carried in the germline, such as with the breast cancer genes BRCA1 and BRCA2. Examples of tumor suppressors are (1) RB, (2) APC, and the (3) BRCA1-2. Additional tumor suppressors are listed in Table 20-9.

Retinoblastoma Gene

Retinoblastoma (RB) is a rare tumor of children that occurs both in families and sporadically. In Knudson's two-hit hypothesis, it is considered that in the inherited form of the tumor, one mutation is present in the germline and in all cells of the body, and the other mutational event occurs somatically in one of the cells of the developing retina. RB is a tumor-suppressor gene, as it suppresses DNA synthesis. Detection of mutations in RB is useful in determining the susceptibility of an individual to development of RB in the familial form, but it is not typically used as a tumor marker.

Adenomatous Polyposis Coli (APC) Gene

One of the first events in the putative steps of progression of precursor lesions to colon cancer is loss of the APC gene in premalignant polyps. T e APC gene encodes a 300 kDa protein that may be truncated in cancer cells. T e healthy function of the APC gene product is not known, but it interacts with proteins, such as α- and β-catenin, involved in cell-cell interactions in epithelial cells. T is gene is mutated in hereditary colorectal cancer syndromes—polyposis and nonpolyposis types. In the polyposis types, hundreds and even thousands or more benign tumors (polyps) arise before the development of cancer. Among nonpolyposis types, very few polyps are seen, but the elevated risk of cancer is essentially similar. T e APC gene was detected by an interstitial deletion on chromosome 5q in a patient with hundreds of polyps. More than 80% of individuals with hereditary colorectal cancer have germline mutations in one of the APC alleles, including gross deletions or localized mutations. Hereditary forms of colorectal cancer are relatively uncommon, but somatic mutations appear to be of great importance in the development of nonhereditary colorectal cancers. More than 70% of colorectal tumors, regardless of size or histology, have a specific mutation in one of the two APC alleles, and mutation may be found in other types of tumors, including (1) breast, (2) esophageal, and (3) brain tumors. T e usefulness of loss of the APC protein for diagnosis and prognosis is the subject of ongoing investigation. However, recent evidence suggests the importance of APC functional activity for prognostic purposes, as well as for directing therapy in colorectal cancer.

BRCA1 and BRCA2

A subset of breast cancer patients have been shown to have an inherited predisposition to developing breast and ovarian cancer that is inherited as an autosomal dominant trait. Two genetic loci have been identified (1): BRCA1 on chromosome 17q, and (2) BRCA2, which localizes to 13q12-13. BRCA1 encodes an 1863 amino acid protein that plays a role in transcriptional regulation and in DNA repair. BRCA2 encodes a protein of 3418 amino acids that functions in DNA repair. T e ability to detect mutations in BRCA1 and BRCA2 in the germline permits the identification of individuals in breast cancer families who carry the mutated gene.

It is estimated that as many as 1 in 200 women in the United States may have a germline mutation in the BRCA1 gene. T is has created an ethical dilemma for (1) physicians, (2) patients and their families, (3) insurance companies, and (4) health maintenance organizations, as it is now possible to predict that an individual who carries a mutation in one of these genes will develop breast and/or ovarian cancer. For example, carriers of a BRCA1 gene mutation have an 85% risk of developing breast cancer and a 45% risk of developing ovarian cancer by the age of 85.T is leads to the following questions

(1) What should be done if an otherwise healthy individual is shown to carry a BRCA gene mutation?

(2) Should such patients undergo preventive mastectomy or oophorectomy?

and

(3) Should insurance companies and healthcare maintenance organizations charge higher rates for carriers? T is latter question has been answered with passage of the GINA legislation (**Genetic Information Nondiscriminatory Act**/ http://www.eeoc.gov/; accessed September 09, 2013) that prohibits discrimination based on genetic information.

Other Molecular Tests

Other molecular tests used to detect cancer include the (1) prostate cancer gene, or antigen 3 (PCA3), (2) single-nucleotide polymorphisms, and (3) cell-free nucleic acids.

Prostate Cancer Gene or Antigen 3 (PCA3)

Measurement of PCA3 mRNA in urine is a molecular test for prostate cancer. The PCA3 gene is also known as $PCA3^{DD3}$ or $DD3^{PCA3}$. PCA3 mRNA is noncoding, and its function is unknown. It is highly overexpressed in prostate cancer tissue compared with healthy or benign prostate tissue, which has low expression. Also, it is not detectable in healthy tissue or in tumors from (1) bladder, (2) testis, and (3) other organs. PCA3 score correlates with biopsy outcome in men undergoing a first or a repeat biopsy. Unlike PSA, PCA3 is independent of prostate volume, and PCA3 scores have been associated with both grade and extent of prostate cancer. Urine specimens for PCA3 are collected after digital rectal examination (DRE) to release prostate cells. PCA3 and PSA mRNA are quantitated using transcription-mediated nucleic acid amplification. The PCA3 mRNA copy number is normalized with the PSA mRNA housekeeping gene to generate the PCA3 score. The PCA3 assay (Hologic Gen-Probe PROGENSA; http://www.gen-probe.com/; accessed on September 9, 2013) was approved by the FDA in 2012 to help determine the need for a repeat prostate biopsy in men with a previous negative prostate biopsy result.

Single-Nucleotide Polymorphisms

The Human Genome Project identified all of the ≈25,000 transcriptional units in the human genome and determined the sequences of the 3 billion chemical base pairs that constitute human DNA (http://www.genome.gov/; accessed September 9, 2013). A byproduct of the sequencing effort was the identification of a very large number of single-nucleotide polymorphisms (SNPs; single nucleotides that differ between individuals and are inherited). These have been formalized and detailed through the efforts of the HapMap Project (http://hapmap.ncbi.nlm.nih.gov/; accessed September 9, 2013). This project is a partnership of scientists and funding agencies from Canada, China, Japan, Nigeria, the United Kingdom, and the United States to develop a public resource that will help researchers find genes associated with human disease and with response to pharmaceuticals. It has been estimated that it is possible to find one SNP in every ≈300 bases of human DNA. Most of these SNPs are present in introns, and only a relatively small number (approximately 60,000 of the 2,000,000 SNPs) are present within exons. Groups of SNPs (called haplotypes) are inherited together in blocks. Scientists are currently investigating SNPs in the hope of identifying characteristic SNPs or haplotypes that can be used for diagnostic purposes, or of determining future risk (predisposition) for developing certain diseases.

Cell-Free Nucleic Acids

Circulating DNA and RNA have been recognized since the 1970s, but it was not until the late 1980s that the neoplastic characteristics of DNA were recognized. Circulating DNA and RNA have been proposed as markers for certain types of cancer. To use circulating DNA as a cancer marker, a mechanism must differentiate normal DNA from neoplastic DNA. This is achieved by detecting mutations in circulating DNA that are present in cancer cells (e.g., ras mutations that occur in various cancers) (1) by performing microsatellite analysis of circulating DNA, (2) by detecting common cancer-causing chromosomal translocations, or (3) detecting epigenetic alterations of circulating DNA, such as altered methylation patterns. Cell-free nucleic acids have been detected in bronchial lavage fluid from lung cancer patients and in plasma from colorectal cancer patients.

Microarray-Based Markers

Microarray-based genotyping is a molecular technique used to simultaneously screen hundreds to thousands of markers per individual. It is a technology suited for applications requiring whole-genome coverage. It is associated with relatively low cost and consequently is a useful technique for large populations. The three early assays described next give a taste of the applications to cancer.

Roche Amplichip P450

The Amplichip P450 (Roche Molecular Diagnostics, http://molecular.roche.com/assays/; accessed on September 9, 2013) detects variations in P450 genes that are involved in the metabolism of many clinically prescribed drugs, including (1) β-blockers, (2) antidepressants, (3) antipsychotics, and (4) chemotherapeutic agents such as tamoxifen and cyclophosphamide.

Drugs that are metabolized through the cytochrome P450 2D6 pathway are inactivated or activated through enzymatic action of 2D6. One example is tamoxifen, which is used currently as the standard of care treatment for estrogen receptor–positive (ER+) breast cancer. Tamoxifen is a prodrug that undergoes a series of modifications leading to its activation. Clinically, endoxifen is the most important active metabolite and has been shown to have 50 to 100 times greater antitumor activity compared with tamoxifen in in vitro assays, along with higher affinity for the estrogen receptor. It is produced by the action of the cytochrome P450 2D6 enzyme in the liver.

Poor and intermediate metabolizers of 2D6 may experience suboptimal effects because of reduced endoxifen concentrations. In contrast, ultra-rapid metabolizers may experience toxic effects caused by high concentrations of the active metabolite.

Oncotype Dx

The Oncotype Dx assay (Genomic Health Inc., Redwood City, Calif); (http://www.genomichealth.com/; accessed on September 9, 2013), determines the expression of 21 genes in breast tissue. I provides an assessment of the likelihood of response to chemotherapy and of recurrence within 10 years.

MammaPrint

The MammaPrint assay (Agendia, http://www.agendia.com/; accessed on September 9, 2013) is used to assess the risk of

breast cancer recurrence. Assessment is performed on fresh frozen tumor tissue obtained during surgery, and samples are sent directly to Agendia Laboratories in T e Netherlands. T is assay measures the expression of 70 genes involved in important signal transduction pathways responsible for breast cancer metastasis.

Review Questions

1. Protein tumor markers found both in normal fetal tissue and in certain tumors are referred to as:
   a. embryonic proteins.
   b. tumor-associated antigens.
   c. oncogenes.
   d. oncofetal antigens.
2. Moderate elevation of which one of the following indicates normal pregnancy, while an extreme elevation is indicative of a trophoblastic tumor?
   a. CG
   b. HPL
   c. AFP
   d. PSA
3. Which of the following statements most correctly describes the usefulness of clinical laboratory assays for tumor markers?
   a. Tumor markers are useful in diagnosing asymptomatic patients for tumors.
   b. Tumor markers are useful for monitoring treatment.
   c. Tumor markers are diagnostic for cancer in all cases.
   d. Tumor markers are highly specific.
4. An example of a blood group antigen that may be elevated in pancreatic cancer is:
   a. CA 125.
   b. CA 15-3.
   c. CA 19-9.
   d. PSA.
5. A genetic tumor marker that, when mutated, loses its ability to stop cell division is referred to as a(n):
   a. tumor-suppressor gene.
   b. proto-oncogene.
   c. oncofetal antigen.
   d. repair process gene.
6. T e greatest usefulness of a tumor marker is its:
   a. use in the evaluation of progression of disease after initial therapy.
   b. use in the diagnosis of the presence of a tissue-specific tumor in an asymptomatic individual.
   c. sensitivity and specificity in assessment of the presence of a tumor.
   d. diagnostic ability in all cases of cancer.
7. A molecular test for prostate cancer involves measurement of:
   a. circulating tumor cells specific for prostate.
   b. the cell-free nucleic acid that contains a methylated region of PCA3.
   c. elevated prostate-specific antigen in serum.
   d. PCA3 in urine.
8. An elevated serum concentration of calcitonin is usually associated with:
   a. parathyroid gland tumors.
   b. medullary carcinoma of the thyroid.
   c. small cell lung carcinoma.
   d. trophoblastic tumors.
9. In an individual with a poorly differentiated tumor, the tissue of origin test measures, to determine the primary tumor site, is/are:
   a. gene expression of many genes compared with known tumor genes using microarrays
   b. immunoassay results using specific antibodies against many different cell surface receptors
   c. circulating tumor cell numbers
   d. risk percentage of the primary tumor site using a multivariate index assay
10. T e primary FDA-indicated use for CA 125, a high-molecular-weight mucin, is for assessment of:
    a. human breast cancer that has become metastatic to liver.
    b. women with ovarian cancer and to distinguish them from normal women or those with benign processes.
    c. response to therapy in patients with epithelial ovarian cancer.
    d. metastatic cancer with bone or liver involvement.

CHAPTER

21

Kidney Function Tests—Creatinine, Urea, and Uric Acid

Edmund J. Lamb, Ph.D., F.R.C.Path., and Christopher P. Price, Ph.D., F.R.C.Path.

Objectives

1. Define the following:
   Creatinine Uric acid
   Urea Gout
2. Diagram the pathway that results in the formation of creatinine.
3. State the clinical usefulness of measuring serum and urine creatinine.
4. State the principle of the Jaffe reaction and list five interferences that affect this method.
5. List and describe three enzymatic assays used to measure creatinine in serum.
6. Describe "compensated assays" in relation to the measurement of creatinine.
7. Diagram the catabolic pathway that results in the formation of urea.
8. State the clinical usefulness of measuring serum urea; list the causes of increased and decreased serum urea.
9. Describe the urease approach for measuring urea in serum; list one interference that affects this method.
10. Convert serum urea nitrogen given in mg/dL to urea nitrogen in mmol/L.
11. Diagram the pathway that results in the formation of uric acid.
12. State the clinical usefulness of measuring serum uric acid.
13. List the causes of hyperuricemia; explain the pathogenesis of gout and urinary tract uric acid stones.
14. Compare and contrast primary and secondary gout.
15. List the causes of hypouricemia.
16. Describe the uricase method of measuring uric acid in serum; list two interferences that affect this method.

Key Words and Definitions

BUN (blood urea nitrogen) Obsolete term used to report results of a urea assay, particularly in the United States.

Creatinine A nonprotein nitrogen compound derived from the spontaneous hydrolysis of creatine or the cyclization of phosphocreatine; creatinine production is relatively constant, is related to muscle mass, and is used as a marker of the glomerular filtration rate of the kidneys.

Fanconi syndrome A rare recessive disorder characterized by pancytopenia, bone marrow hypoplasia, and patchy brown skin discoloration due to deposition of melanin, as well as multiple congenital anomalies of the musculoskeletal and genitourinary systems.

Gout A group of disorders of purine metabolism due to primary (inherited) or secondary causes such as chronic kidney disease.

Hyperuricemia An excess of uric acid or urates in the blood with many causes; it is a prerequisite for the development of gout and may lead to renal disease.

Hypouricemia Decreased uric acid concentration in the blood, secondary to a number of underlying conditions such as severe hepatocellular disease and defective renal tubular reabsorption.

Jaffe reaction The reaction of creatinine with alkaline picrate to form a colored compound; this creatinine assay is subject to numerous interferences.

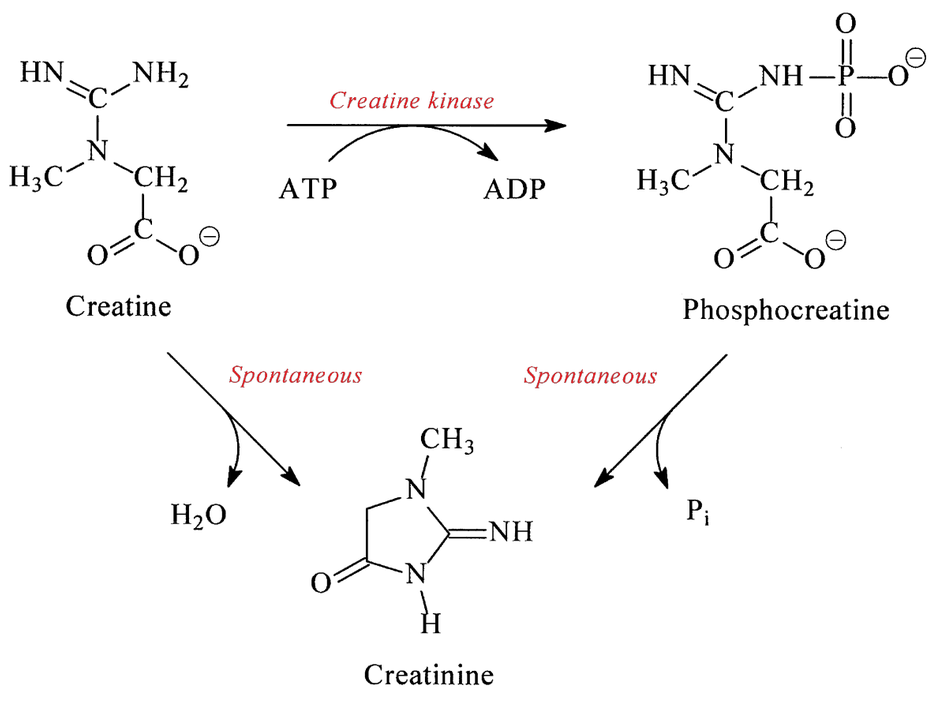
Urea The major nitrogen-containing metabolic product of protein catabolism in humans.

Urease methods Enzymatic assays that initially involve the hydrolysis of urea by urease to generate ammonia, which is quantified by a variety of methods.

Uremia The entire constellation of signs and symptoms of chronic renal failure; also known as azotemia.

Uric acid A nitrogenous compound derived from the catabolism of purine nucleosides.

Uricase methods A group of enzymatic assays that initially involve oxidation of uric acid by uricase to eventually produce a chromogen that is spectrophotometrically measured to determine uric acid concentration.



Creatinine, urea, and uric acid are nonprotein nitrogenous metabolites that are cleared from the body by the kidney after glomerular filtration. Measurements of plasma or serum* concentrations of these metabolites are commonly used as indicators of kidney function and other conditions.

Creatinine

Creatinine (MW 113 Da) is the cyclic anhydride of creatine that is produced as the final product of decomposition of phosphocreatine. It is excreted in the urine; measurements of plasma creatinine and its renal clearance are used as diagnostic indicators of kidney function (see Chapter 35).

Biochemistry and Physiology

Creatine is synthesized in the (1) kidneys, (2) liver, and (3) pancreas by two enzymatically mediated reactions. In the first, transamidation of arginine and glycine forms guanidinoacetic acid. In the second reaction, methylation of guanidinoacetic acid occurs with S-adenosylmethionine as the methyl donor. Creatine is then transported in blood to other organs, such as muscle and brain, where it is phosphorylated to phosphocreatine, a high-energy compound.

Interconversion of phosphocreatine and creatine is a particular feature of the metabolic processes of muscle contraction. A proportion of the free creatine in muscle (thought to be between 1% and 2%/d) spontaneously and irreversibly converts to its anhydride waste product—creatinine. Thus the amount of creatinine produced each day is relatively constant and is related to the muscle mass. In health, the concentration of creatinine in the bloodstream is also relatively constant, although dietary meat intake may influence the value. Creatinine is present in all body fluids and secretions and is freely filtered by the glomerulus. Although it is not reabsorbed to any great extent by the renal tubules, a small but significant tubular secretion occurs.

*Concentrations of creatine, urea, and uric acid in serum and plasma are equivalent: "serum" has been used throughout this chapter.

Clinical Significance

Serum creatinine concentration is maintained within narrow limits predominantly by glomerular filtration. Consequently, both serum creatinine concentration and its renal clearance ("creatinine clearance") have been used as markers of the glomerular filtration rate (GFR). The application and limitations of these tests are discussed in Chapter 35.

Analytical Methodology

Serum creatinine is commonly measured using chemical or enzymatic methods.[5,9,11] Other methods, including isotope-dilution mass spectrometry (IDMS) and high-performance liquid chromatography (HPLC), have also been used. Most laboratories use adaptations of the same assay for measurements in both serum and urine.

Chemical Methods: The Jaffe Reaction

Most chemical methods used to measure creatinine are based on its reaction with alkaline picrate. As was first described by Jaffe in 1886, creatinine reacts with picrate ion in an alkaline medium to yield an orange-red complex.

A serious analytical problem with the **Jaffe reaction** is its lack of specificity for creatinine. For example, many compounds have been reported to produce a Jaffe-like chromogen, including (1) ascorbic acid, (2) blood-substitute products, (3) cephalosporins, (4) glucose, (5) guanidine, (6) ketone bodies, (7) protein, and (8) pyruvate. The degree of interference from these compounds is dependent on the specific reaction conditions chosen. The effects of ketones and ketoacids are probably of greatest significance clinically, although this determination is highly method dependent. Thus reports on acetoacetate interference vary from a negligible increase to an increase of 3.5 mg/dL (310 μmol/L) in the apparent creatinine concentration at an acetoacetate concentration of 8 mmol/L. Bilirubin is a negative interferant with the Jaffe reaction. The addition of buffering ions, such as borate and phosphate, together with surfactant, has been used to minimize the effects of this interference. In addition, ferricyanide—O'Leary method—has been added that oxidizes bilirubin to biliverdin, hence reducing its interference. Noncreatinine chromogens do not generally contribute to measured urinary creatinine concentration.

The greatest success in terms of common usage and specificity has been seen in the use of a kinetic measurement approach in combination with careful choice of reactant concentrations. In general, manual methods have traditionally been equilibrium methods, with 10 to 15 minutes allowed to complete the color development at room temperature. Kinetic assays have been developed to provide more (1) specific, (2) faster, and (3) automated analyses. Early studies of interferences in the kinetic methods identified two types of noncreatinine chromogens. In one group, the rate of adduct formation is very rapid, and such formation occurs in the first 20 seconds after mixing of the aliquots of reagent and sample. Acetoacetate is an example of this type of interferant. In the second group, the rate of adduct formation does not become significant until 80 to 100 seconds after mixing. The "window" between 20 and 80 seconds therefore was a period in which the rate signal that

was being observed could be attributed predominantly to the creatinine-picrate reaction. This improvement of specificity in the kinetic assays was achieved by selecting times for rate measurements 20 to 80 seconds after initiation of the reaction (mixing). This approach has been implemented with various automated instruments, and kinetic assays are now widely used to measure creatinine concentrations in body fluids.

Extensive literature describes the choice of reactant concentrations and reading intervals, as well as the choice of wavelength and reaction temperature. Brief comments follow.

Picrate Concentration

The Jaffe reaction is pseudo first order with respect to picrate up to 30 mmol/L, and most methods employ a concentration between 3 and 16 mmol/L. At concentrations above 6 mmol/L, the rate of color development becomes nonlinear, so a two-point fixed interval rather than a multiple data point approach is required.

Hydroxide Concentration

The initial rate of reaction is pseudo first order with respect to hydroxide concentrations greater than 0.5 mmol/L. However, at 500 mmol/L, degradation of the Jaffe complex is increased. Furthermore, at hydroxide concentrations greater than 200 mmol/L, the blank absorbance is increased significantly.

Wavelength

Although the absorbance maximum of the Jaffe reaction is between 490 and 500 nm, improved method linearity and reduced blank values have been reported at other wavelengths, with the choice varying with hydroxide concentration.

Temperature

The rate of Jaffe complex formation and the absorptivity of the complex are temperature-dependent with measurable differences observed even between 25 °C and 37 °C. Consequently, temperature control is an important component of assay reproducibility.

"Compensation"

As a result of the reaction with noncreatinine chromogens, Jaffe methods often have historically overestimated true serum creatinine concentrations at physiological concentrations by up to 20% compared with HPLC or IDMS methods. In an attempt to adjust for this, some manufacturers have introduced so-called "compensated" Jaffe assays, in which a fixed concentration is automatically subtracted from each result. For example, Roche Diagnostics Ltd. (Lewes, Sussex, United Kingdom) has realigned its assays on the Cobas Integra and Hitachi systems by −0.20 mg/dL and −0.32 mg/dL (−18 and −28 μmol/L), respectively. Such assays produce lower results more closely aligned with IDMS reference measurement procedures at concentrations within the reference interval. However, the purveyors make an assumption that the noncreatinine chromogen interference is a constant between samples; this is clearly an oversimplification, especially when adult and pediatric samples are compared.

Enzymatic Methods

Enzymes from a number of metabolic pathways have been investigated for the enzymatic measurement of creatinine. All methods involve a multistep approach leading to a photometric equilibrium (Figure 21-1). Primarily three approaches may be used and are described in the following sections.

Creatininase

Creatininase (EC 3.5.2.10; creatinine amidohydrolase) catalyzes the conversion of creatinine to creatine. The creatine is then detected with a series of enzyme-mediated reactions involving (1) creatine kinase, (2) pyruvate kinase, and (3) lactate dehydrogenase, with monitoring of the decrease in absorbance at 340 nm (see Figure 21-1, A). Initiating the reaction with creatininase allows for the removal of endogenous creatine and pyruvate in a preincubation reaction. The kinetics of the reaction is analytically problematic, and 30-minute incubation is required to allow the reaction to reach equilibrium. This shortcoming has been overcome by a kinetic approach but with a further reduction in the ability of the method to detect creatinine. Consequently, this approach is not widely used.

Creatininase and Creatinase

An alternative approach has involved the use of creatinase (EC 3.5.3.3; creatine amidinohydrolase) that yields sarcosine and urea, with the former measured by further enzyme-mediated steps using sarcosine oxidase (EC 1.5.3.1). This produces (1) glycine, (2) formaldehyde, and (3) hydrogen peroxide (see Figure 21-1, B), and the latter is detected and measured by a variety of methods. Care must be taken, however, because of interference (e.g., by bilirubin) in the final reaction sequence. This problem has been minimized by adding potassium ferricyanide (with limited success) or bilirubin oxidase. The potential interference caused by ascorbic acid has been overcome by the inclusion of ascorbate oxidase (l-ascorbate:oxygen oxidoreductase; EC 1.10.3.3). The influence of endogenous intermediate creatine and urea has been minimized by adding a preincubation step and then initiating the reaction with creatininase. This system has been incorporated in a point-of-care testing device using polarographic detection. An alternative detection system involves measurement of the reduction of nicotinamide adenine dinucleotide by formaldehyde in the presence of formaldehyde dehydrogenase (see Figure 21-1, C).

Creatinine Deaminase

Creatinine deaminase (EC 3.5.4.21; creatinine imino-hydrolase) catalyzes the conversion of creatinine to N-methylhydantoin and ammonia. Early methods concentrated on the detection of ammonia using glutamate dehydrogenase or the Berthelot reaction. An alternative approach involves the enzyme N-methylhydantoin amidohydrolase (see Figure 21-1, D).

Dry Chemistry Systems

Several multilayer dry reagent methods have been described for the measurement of creatinine using enzyme-mediated reactions. An early "two-slide" approach employed creatinine deaminase, with the ammonia diffusing through a semipermeable and

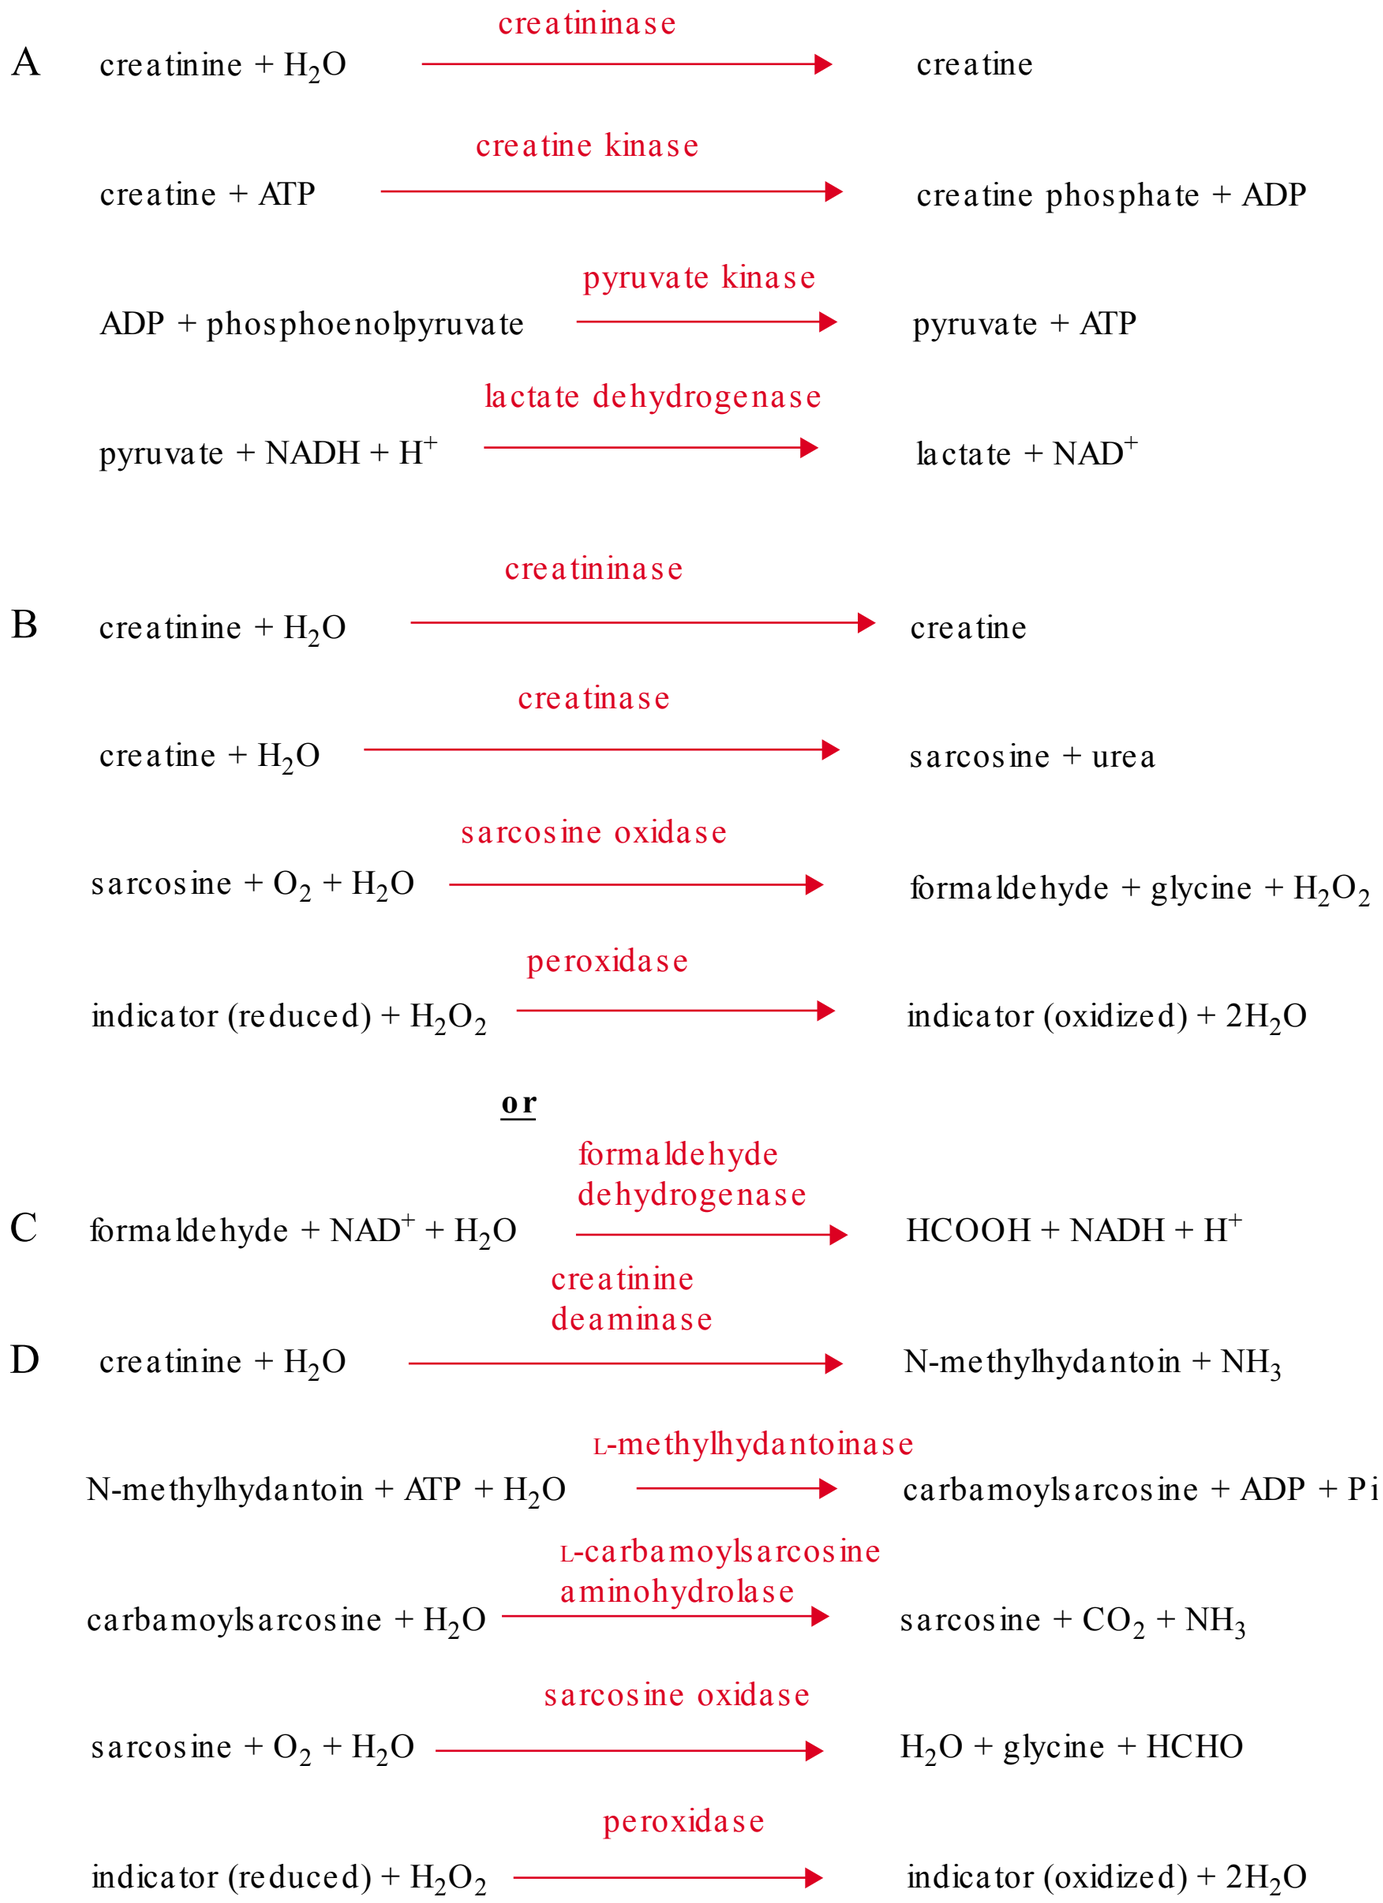


Figure 21-1 Determination of creatinine using a variety of enzymatic methods. For further details, see text.

optically opaque layer to react with bromophenol blue to give an increase in absorbance at 600 nm. A second multilayer film lacking the enzyme was used to quantitate endogenous ammonia, enabling blank correction. A later single-slide method used the creatininase-creatinase reaction sequence. Lidocaine metabolites have been reported to interfere with this method. The creatinine deaminase system described above has also been used and adapted for use as a point-of-care testing device (see Figure 21-1, D). In all cases, the color produced in the film is quantified by reflectance spectrophotometry.

Other Methods

A definitive method employing IDMS was described by Welch in 1986.[13] Gas chromatography–IDMS (GC-IDMS) is now accepted as the method of choice for establishing the true concentration of creatinine in serum because of its excellent specificity and low imprecision. Three GC-IDMS methods have been approved by the Joint Committee for Traceability in Laboratory Medicine (JCTLM) as reference measurement procedures for serum creatinine.[5] With these procedures, creatinine must be derivatized before GC analysis because of its polarity. In addition, a cation exchange cleanup step is necessary before GC analysis because creatine is derivatized into the same chemical species as creatinine.

Quality Issues and Preanalytical Considerations With Creatinine Methods

The method used for measurement of creatinine is complex by virtue of the number of variants of the Jaffe reaction and the introduction of enzymatic procedures that overcome the limitations of the former. Although enzymatic methods are more expensive, they are used in dry chemistry systems

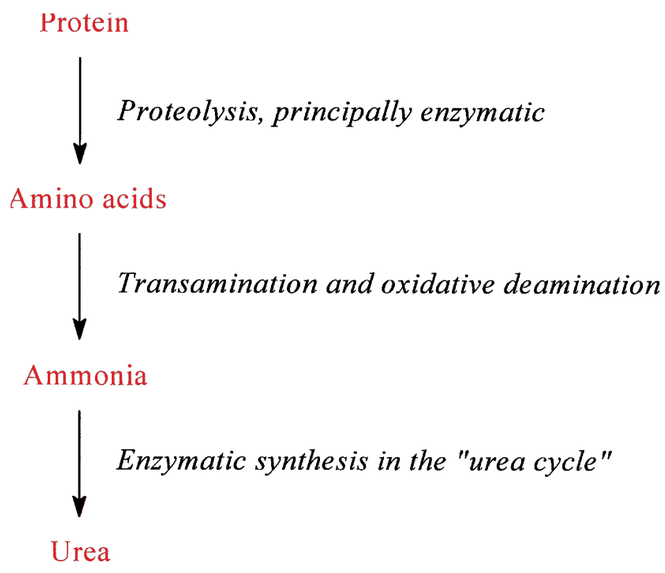
(with their lower reagent requirement), including some point-of-care testing devices. Kinetic Jaffe approaches predominate in wet chemistry analytical systems. Any laboratorian assessing a new creatinine method (e.g., as part of an analyzer purchase) should review the data for that method on common interferences. Despite criticism of the Jaffe methods, adequate correlation has been noted invariably between them and enzymatic procedures, with differences likely to be due as much to calibration as to interference.

Creatinine in serum or urine is stable for at least 7 days at 4 °C, and serum creatinine is stable during long-term frozen storage (at −20 °C and below) and after repeated thawing and refreezing. However, it should be noted that delayed separation (beyond 14 hours) of serum from erythrocytes leads to a significant increase in apparent serum creatinine concentration using some kinetic Jaffe (but not enzymatic) assays. Creatinine concentration is increased in blood after meals containing cooked meat because of the conversion of creatine to creatinine; ideally, blood for serum creatinine measurement should be obtained in the fasting state. Clearly, this latter problem will affect both enzymatic and Jaffe creatinine methods.

Different methods for assaying serum creatinine have varying degrees of accuracy and imprecision. Mean within-individual biological variation for serum creatinine has been reported as 4.3%, indicating a desirable analytical performance goal of <2.2%. Intralaboratory imprecision at a concentration of 88 μmol/L varies between approximately 2.0% and 8.4%. [5] Clearly, many laboratories do not meet desirable and even minimum performance standards. Proficiency studies demonstrate that although between-laboratory coefficients of variation (CVs) of approximately 3% are achievable within method groups, overall between-laboratory agreement across methods is much poorer. Further, interlaboratory and within-laboratory agreement deteriorates as serum creatinine concentration nears the reference interval; the exponential relationship between serum creatinine and GFR means that imprecision at lower creatinine concentrations contributes to greater error in GFR estimation than is seen at higher creatinine concentrations.

Over the past decade, appreciation of chronic kidney disease (CKD) as a major public health issue[3,6,7] and of its identification with the use of GFR-estimating equations has led to increased focus on the measurement of creatinine. Creatinine-based estimates of GFR (see Chapter 35) will clearly vary, depending on how accurate the creatinine measurement is that is used in the calculation. The more a method overestimates "true" creatinine, the greater will be the underestimation of GFR, and vice versa. Standardized serum matrix reference materials (SRM 967) with established creatinine concentrations (0.80 mg/dL [71 μmol/L] and 4.00 mg/dL [354 μmol/L]) have been prepared by the National Institute of Standards of Technology (NIST) and have been included in a list of higher order reference materials by the JCTLM. The material was value-assigned with the use of mass spectrometry and was issued in 2007.[2] This material, in combination with GC-IDMS reference methodology, was used by reagent manufacturers to restandardize their methods,[8] and by the end of 2009, most clinical laboratory methods had calibration traceable to the reference measurement procedure and standard.[4]

Although undoubtedly desirable, it must be recognized that standardization is only one part of the problem. Standardization does not solve the problem of different reactivity with noncreatinine chromogens across different patient samples, which will be resolved only by the use of highly specific creatinine methods such as the enzymatic methods.



Reference Intervals

Reference intervals for serum creatinine are method dependent. A systematic review of creatinine reference intervals from methods whose calibration was traceable to the reference IDMS procedure proposed adult reference intervals of 0.72 to 1.18 mg/dL (64 to 104 μmol/L) in men and 0.55 to 1.02 mg/dL (49 to 90 μmol/L) in women.[1] These data were derived using an enzymatic (Roche Diagnostics Ltd.) assay. Reference interval data for children may be found in the same publication. Serum creatinine concentration in patients with untreated end-stage renal disease (ESRD) may exceed 11 mg/dL (1000 μmol/L).

Urinary creatinine excretion is higher in men (14 to 26 mg/kg/d, 124 to 230 μmol/kg/d) than in women (11 to 20 mg/kg/d, 97 to 177 μmol/kg/d). Creatinine excretion decreases with age. Typically, for a 70-kg man, creatinine excretion will decline from approximately 1640 to 1030 mg/d (14.5 to 9.1 mmol/d) with advancing age from 30 to 80 years. Measurement of urinary creatinine excretion has been found to be a useful indication of the completeness of a timed urine collection. In addition, creatinine excretion is often used as a method of normalizing the urinary excretion of analytes, that is, excretion of the test analyte (in millimoles or grams) is divided by the total amount of creatinine (in millimoles or grams) excreted in the same urine specimen. This is method provides a rough correction for volume differences between patient specimens. Similarly, expressing the concentration of a substance as a ratio to the creatinine concentration is a useful method of adjusting for urinary concentration differences in random ("spot") urine samples.

Urea

Catabolism of proteins and amino acids results in the formation of **urea**, which is predominantly cleared from the body by the kidneys.

Biochemistry and Physiology

Urea is the major nitrogen-containing metabolic product of protein catabolism in humans, accounting for more than 75% of the nonprotein nitrogen eventually excreted. The biosynthesis of urea from amino acid nitrogen–derived ammonia is carried out exclusively by hepatic enzymes of the urea cycle. During the process of protein catabolism, amino acid nitrogen is converted to urea in the liver by the action of the so-called urea cycle enzymes (Figure 21-2).

More than 90% of urea is excreted through the kidneys, with losses through the gastrointestinal tract and skin accounting for most of the remaining minor fraction. Consequently, kidney disease is associated with accumulation of urea in blood. An increase in blood urea concentration characterizes the uremic (azotemic) state. Urea is neither actively reabsorbed nor secreted by the tubules but is filtered freely by the glomeruli. In a healthy kidney, 40% to 70% of the highly diffusible urea moves passively out of the renal tubule and into the interstitium, ultimately to re-enter blood. The back-diffusion of urea is also dependent on urine flow rate, with less entering the interstitium in high-flow states (e.g., pregnancy) and vice versa. Consequently, urea clearance generally underestimates GFR.

Clinical Significance

Measurement of blood and serum urea has been used for many years as an indicator of kidney function. However, it is now generally accepted that creatinine measurement provides better information in this respect. Serum and urinary urea measurement, however, may still provide useful clinical information in particular circumstances, and measurement of urea in dialysis fluids is widely used to assess the adequacy of renal replacement therapy. Several extrarenal factors influence the circulating urea concentration, limiting its value as a test of kidney function. For example, serum urea concentration is increased by (1) a high-protein diet, (2) increased protein catabolism, (3) reabsorption of blood proteins after gastrointestinal hemorrhage, (4) treatment with cortisol or its synthetic analogues, (5) dehydration, and with (6) decreased perfusion of the kidneys (e.g., heart failure). In these prerenal situations, the serum creatinine concentration may be within its reference interval. In obstructive postrenal conditions such as (1) malignancy, (2) nephrolithiasis, and (3) prostatism, both serum creatinine and urea concentrations will be increased, However, in these situations, a greater increase in serum urea than in creatinine is often seen because of increased back-diffusion. These considerations give rise to the principal clinical utility of serum urea, which lies in its measurement in conjunction with that of serum creatinine and subsequent calculation of the urea-to-creatinine ratio, which has been used as a crude discriminator between prerenal and postrenal **uremia**.

Measurement of urinary urea has little place in clinical diagnosis. However, it does provide a crude index of overall nitrogen balance and may be used as a guide to replacement in patients receiving parenteral nutrition. With an average protein diet, urinary excretion expressed as urea nitrogen is 12 to 20 g/d.

Although the term **blood urea nitrogen** (or **BUN**) continues to be used for ordering the serum urea test, this terminology is incorrect and obsolete because blood is rarely the sample that is analyzed for urea. The long-established habit of reporting and expressing results of a urea assay in units of urea nitrogen appears to be strongly entrenched in the United States, although the SI system recommends reporting of urea, expressed in mmol/L. Thus, students of clinical chemistry need to know the conversion factors for urea to urea nitrogen. Because 60 g (1 g MW) of urea contains 28 g (2 g atomic weight) of nitrogen, the factor is 0.467 for converting urea mass units to those of urea nitrogen, and 2.14 for converting urea nitrogen mass units to those of urea. The factor for converting urea nitrogen in mg/dL to urea in mmol/L is 0.357.

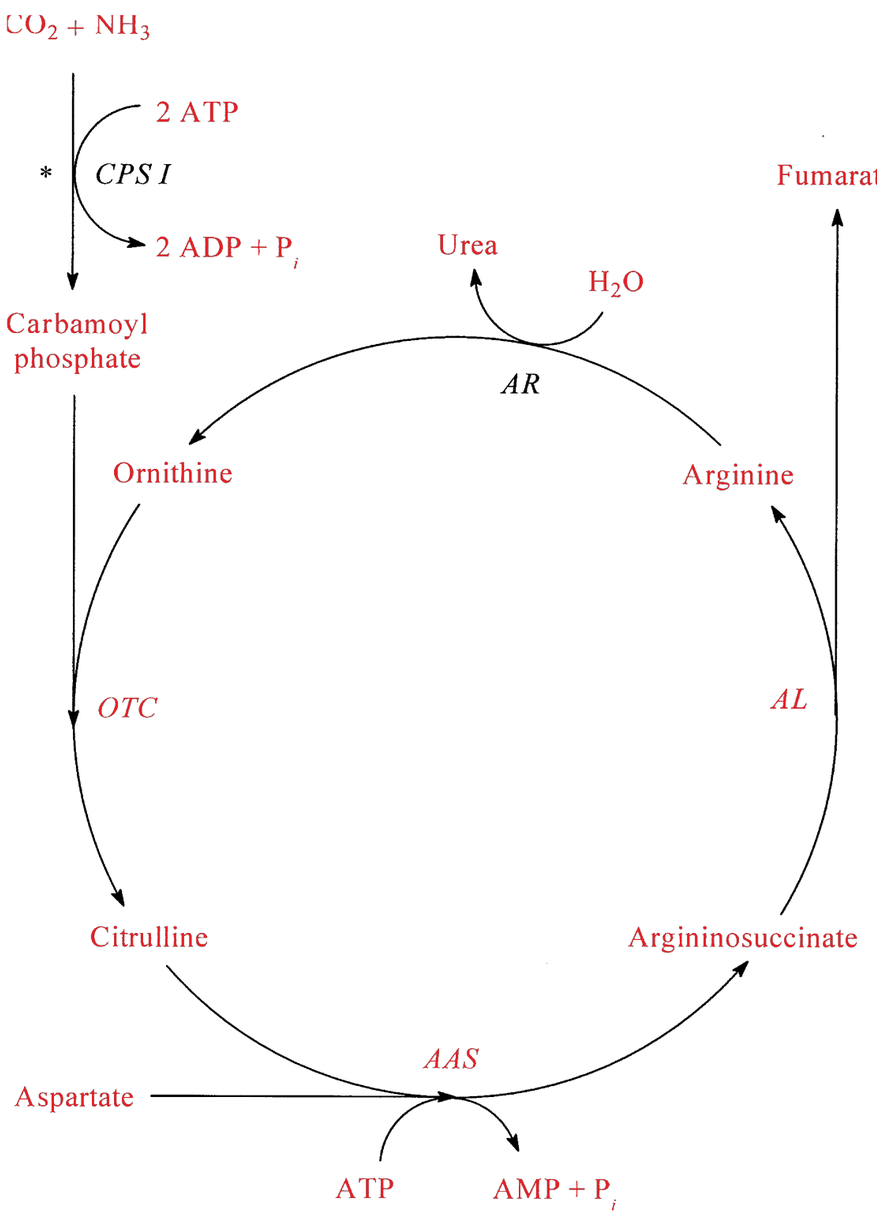


Figure 21-2 The urea cycle pathway. *N-acetylglutamate as a positive allosteric effector. AAS, Argininosuccinate synthetase; ADP, adenosine diphosphate; AL, argininosuccinate lyase; AMP, adenosine monophosphate; AR, arginase; ATP, adenosine triphosphate; CPS I, carbamoyl phosphate synthetase I; OTC, ornithine transcarbamylase; P_i, inorganic phosphate.

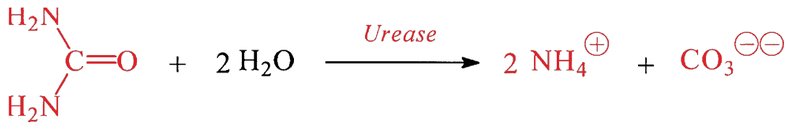
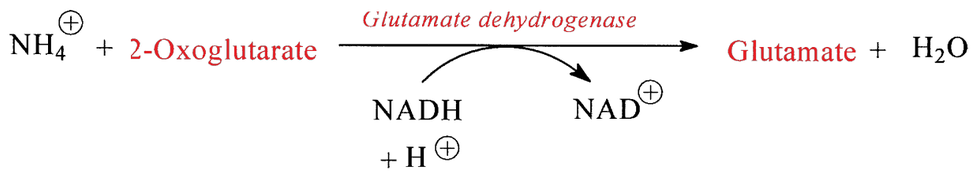
Analytical Methodology



Both chemical and enzymatic methods are used to quantify urea in body fluids.[12]

Chemical Methods

Most chemical methods for urea are based on the Fearon reaction, in which molecules of diacetyl condense with those of urea to form the chromogen diazine, which absorbs strongly at 540 nm. Because diacetyl is unstable, it is usually generated in the reaction system from diacetyl monoxime and acid. Although once widely used, the method has largely been superseded by enzymatic approaches.



Enzymatic Methods

Enzymatic methods for the measurement of urea are based on preliminary hydrolysis of urea with **urease** (urea amidohydrolase, EC 3.5.1.5; main source jack bean meal) to generate ammonia, which is then quantified. This approach has been used in (1) equilibrium photometric, (2) kinetic photometric, (3) conductimetric, and (4) dry chemistry systems.

Urea

Spectrophotometric approaches to ammonia quantitation include the Berthelot reaction and the enzymatic assay with glutamate dehydrogenase (l-glutamate:NAD[P] oxidoreductase [deaminating], EC 1.4.1.3). This latter approach has been accepted as a reference method and has been adapted to many analytical platforms.

For serum assays, the reaction system contains urease, so that the addition of sample containing urea starts the reaction. A decrease in absorbance resulting from the glutamate dehydrogenase reaction is monitored at 340 nm. In another example of a coupled-enzyme assay system for urea, ammonia produced from urea by urease then reacts with glutamate and adenosine triphosphate in the presence of glutamine synthetase (EC 6.3.1.2). Adenosine diphosphate produced in this second enzymatic reaction is then measured in a third and fourth step using pyruvate kinase (EC 2.7.1.40) and pyruvate oxidase (EC 1.2.3.3), respectively, thus generating peroxide. In the final step, peroxide reacts with phenol and 4-aminophenazone, catalyzed by horseradish peroxidase (donor:hydrogen-peroxide oxidoreductase; EC 1.11.1.7), to yield a quinone-monoamine dye that is quantified spectrophotometrically.

Methods for the measurement of urea using dry chemistry systems have been described using the urease approach and a variety of detection methods. In one approach, a semipermeable membrane separates the first stage of the reaction involving urease, and ammonia is detected by using a simple pH indicator reaction. Urea has also been measured by means of a conductimetric method in which a sample and a urease-containing reagent are incubated in a conductivity cell with the rate of change of conductivity monitored as urea is converted to an ionic species. With a potentiometric approach, an ammonium ion-selective electrode is employed, and urease is immobilized on a membrane; this principle has been applied in some point-of-care testing devices.

The specificity of all methods is generally acceptable, particularly for the urease–glutamate dehydrogenase procedure; however, endogenous ammonia interference must be expected when the protocol employs the sample to initiate the reaction. This may be relevant in (2) aged samples, (2) some urines samples, and (3) particular metabolic disorders. Typically, within-run CVs of less than 3.0% with between-day values of less than 4.0% are achievable in the concentration range of 14 to 20 mg/dL (5.0 to 7.0 mmol/L). Given the high intrinsic biological variation of serum urea, this is well within desired standards of analytical performance.

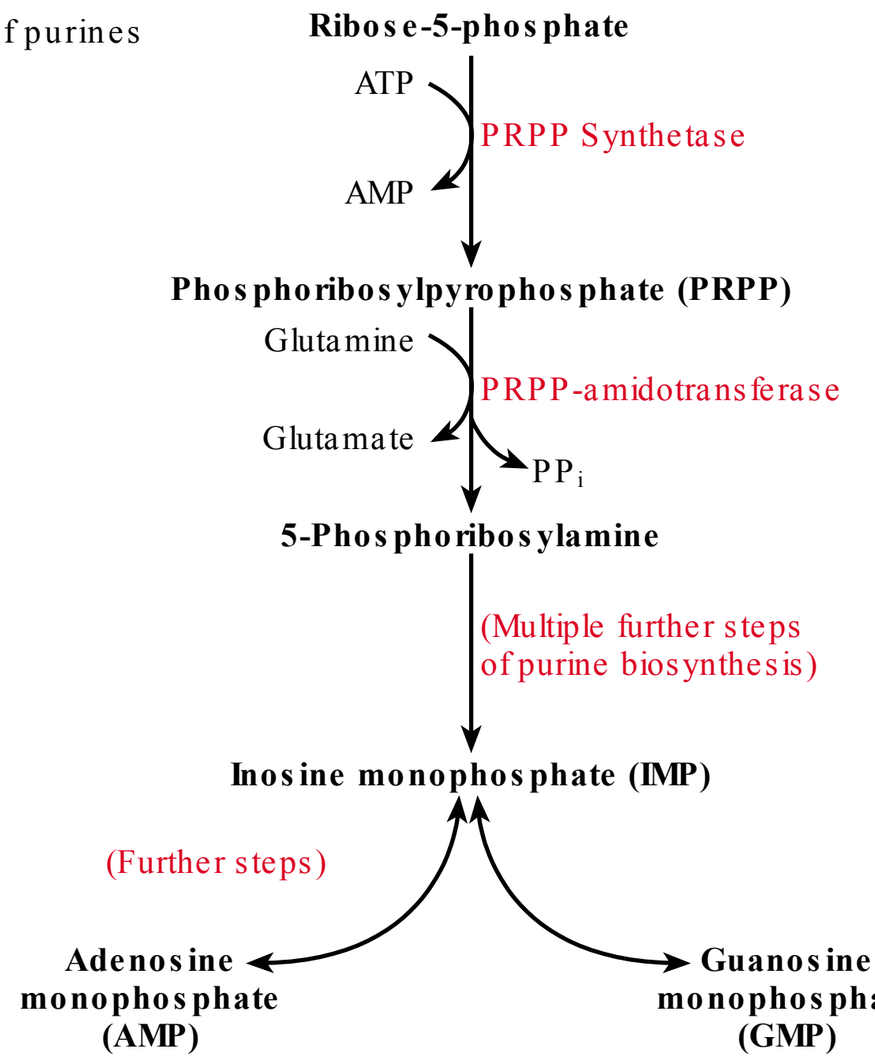
Reference Intervals

The reference interval for blood urea nitrogen in healthy adults is 6 to 20 mg/dL (2.1 to 7.1 mmol/L). In adults older than 60 years of age, the reference interval is 8 to 23 mg/dL (2.9 to 8.2 mmol/L). Serum concentrations tend to be slightly lower in children and in pregnancy and slightly higher in males than in females. Serum urea concentrations in a patient with untreated ESRD typically reach 108 to 135 mg/dL (40 to 50 mmol/L).

Uric Acid

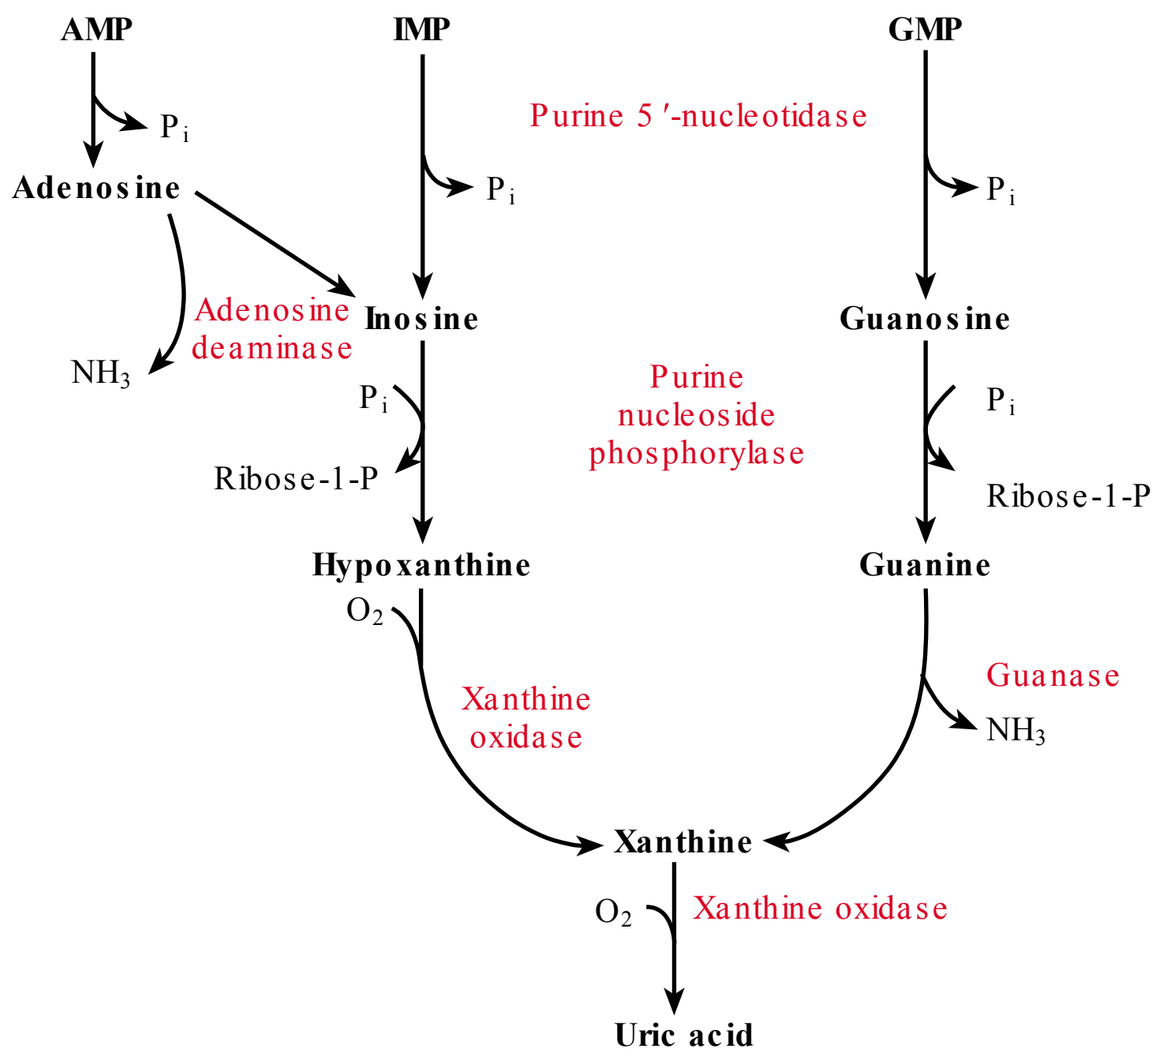
Uric acid is a nitrogenous compound (2,6,8-trihydroxypurine) that is present as the principal nitrogenous component of the excrement of reptiles and birds. It is found in small amounts in mammalian urine, and its salts occur in the joints in gout.

Biochemistry and Physiology



In humans, uric acid is the major product of catabolism of the purine nucleosides adenosine and guanosine (Figure 21-3). Purines from catabolism of dietary nucleic acid are converted to uric acid directly. The bulk of purines excreted as uric acid arise from degradation of endogenous nucleic acids. The daily synthesis rate of uric acid is approximately 400 mg. Dietary sources contribute another 300 mg. In men consuming a purine-free diet, the total body pool of exchangeable urate is estimated at 1200 mg. In women it is estimated to be 600 mg. By contrast, patients with gouty arthritis and tissue deposition of urate may have urate pools as large as 18,000 to 30,000 mg. Overproduction of uric acid may result from increased synthesis of purine precursors.

Renal handling of uric acid is complex and involves four sequential steps: (1) glomerular filtration of virtually all the uric acid in capillary plasma entering the glomerulus; (2) reabsorption in the proximal convoluted tubule of about 98% to 100% of filtered uric acid; (3) subsequent secretion of uric acid into the lumen in the distal portion of the proximal tubule; and (4) further reabsorption in the distal tubule. The net urinary excretion of uric acid is 6% to 12% of the amount filtered.



Clinical Significance

More than 20 inherited disorders of purine metabolism giving rise to both hyperuricemias and hypouricemias have been recognized to date. Most are very rare, and the diagnosis requires support from a specialist purine laboratory. Symptoms that should raise suspicion include (1) kidney failure or stones in a child or young adult, (2) "gravel" in an infant's diaper, (3) unexplained neurological problems in an infant, child, or adolescent, and (4) gout presenting in a man or woman younger than 30 years of age.

Hyperuricemia

Hyperuricemia is most commonly defined by serum uric acid concentrations greater than 7.0 mg/dL (0.42 mmol/L) in men or greater than 6.0 mg/dL (0.36 mmol/L) in women. The major causes of hyperuricemia are summarized in Box 21-1. Asymptomatic hyperuricemia is frequently detected through biochemical screening. Long-term follow-up of asymptomatic hyperuricemic patients is undertaken because many are at risk for kidney disease that may develop as a result of hyperuricemia and hyperuricuria; few of these patients ever develop the clinical syndrome of gout.

Serum uric acid is measured predominantly in the investigation and management of gout as a result of a primary hyperuricemia or of other conditions or treatments that give rise to secondary hyperuricemias.

Gout

Gout occurs when monosodium urate precipitates from supersaturated body fluids. The deposits of urate are responsible for the clinical signs and symptoms. Gouty arthritis may be associated with urate crystals in joint fluid and with deposits of crystals (tophi) in tissue surrounding the joint. These deposits also may occur in other soft tissue. Wherever they occur, they elicit an intense inflammatory response consisting of polymorphonuclear leukocytes and macrophages. The big toe (first metatarsophalangeal) joint is the classic site for gout. Gout is a condition characterized by occasional attacks and long periods of remission. It is important to appreciate that the serum uric acid concentration is often normal during an acute attack. Kidney disease associated with hyperuricemia may take one or more of several forms: (1) gouty nephropathy with urate deposition in renal parenchyma, (2) acute intratubular deposition of urate crystals, and (3) urate nephrolithiasis.

Gout is classified as primary or secondary. Primary gout is associated with "essential" hyperuricemia, which has a polygenic basis. In more than 99% of cases, the cause is uncertain, but the condition is probably due to a combination of (1) metabolic overproduction of purines (25% of patients have increased phosphoribosylpyrophosphate [PRPP]-amidotransferase [EC 2.4.2.14] activity), (2) decreased renal excretion (80% of patients show decreased renal tubular secretion of uric acid), and (3) increased dietary intake. Very rarely, primary gout is attributable to inherited defects of enzymes in the pathways of purine metabolism. The Lesch-Nyhan syndrome is characterized by complete deficiency of hypoxanthine-guanine phosphoribosyl transferase (HGPRT, EC 2.4.2.8), the major enzyme of the purine salvage pathways (see Figure 21-3). This is X-linked genetic disorder is manifested clinically by (1) mental retardation, (2) abnormal muscle movements, and (3) behavioral problems (self-mutilation and pathological aggressiveness). Patients may present in the first weeks of life with (1) crystalluria, (2) acute kidney failure, (3) gout, (4) hyperuricemia, (5) hyperuricuria, and (6) greatly decreased activities of HGPRT in primarily erythrocytes and fibroblasts. Also, intracellular concentrations of PRPP and rates of purine synthesis are increased. Neurological symptoms of this syndrome may be related to decreased availability of purines to the developing brain, which has limited capacity for de novo purine synthesis. It relies therefore on the purine salvage pathways to supply it with most of the purine nucleotides that it requires. DNA technology has been applied to prenatal diagnosis in the first trimester using chorionic biopsy material. HGPRT assays on cultured fibroblasts obtained by amniocentesis may be used in the second trimester. Partial deficiency of HGPRT (severe X-linked gout) presents in adolescence or early adulthood as (1) early gout, (2) kidney failure, or (3) nephrolithiasis. Increased concentrations of intracellular PRPP with consequent increased uric acid concentrations have been known to occur as a result of mutations in PRPP synthetase (EC 2.7.6.1; PRPP synthetase superactivity), which is also inherited as an X-linked recessive trait. An autosomal dominant familial juvenile hyperuricemic nephropathy has also been recognized. Glucose-6-phosphatase deficiency leads to hyperuricemia as a result of both overproduction and underexcretion of uric acid.

Secondary gout is a result of hyperuricemia attributable to several identifiable causes. Renal retention of uric acid may occur in acute or chronic kidney disease of any type or as a consequence of administration of drugs. Diuretics, in particular, are implicated in the latter instance. Organic acidemia—caused by increased acetoacetate in diabetic ketoacidosis or by lactic acidosis—may interfere with tubular secretion of urate. Increased nucleic acid turnover and a consequent increase in catabolism of purines may be encountered in rapid proliferation of tumor cells and in massive destruction of tumor cells when therapy with certain chemotherapeutic agents is provided.

BOX 21-1 Causes of Hyperuricemia

- **Increased Formation**
  - *Primary*
    - Idiopathic
    - Inherited metabolic disorders
  - *Secondary*
    - Excess dietary purine intake
    - Increased nucleic acid turnover (e.g., leukemia, myeloma, radiotherapy, chemotherapy, trauma)
    - Psoriasis
    - Altered ATP metabolism
    - Tissue hypoxia
    - Preeclampsia
    - Alcohol
- **Decreased Excretion**
  - *Primary*
    - Idiopathic
  - *Secondary*
    - Acute or chronic kidney disease
    - Increased renal reabsorption
    - Reduced secretion
    - Lead poisoning
    - Preeclampsia
    - Organic acids (e.g., lactate, acetoacetate)
    - Salicylate (low doses)
    - Thiazide diuretics
    - Trisomy 21 (Down syndrome)

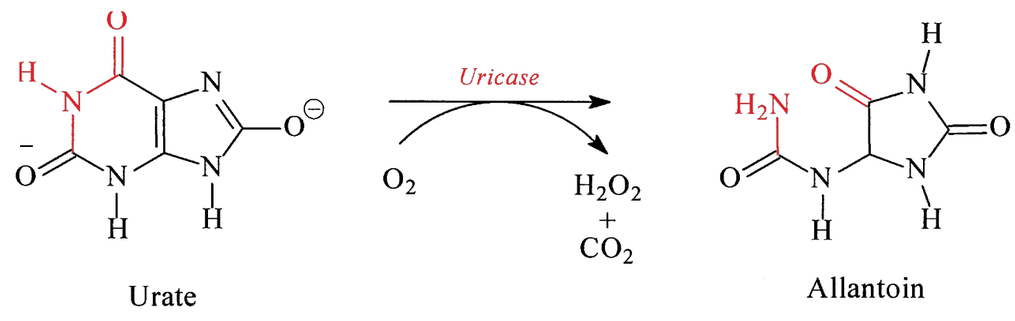
Management of an acute attack of gout generally involves the use of nonsteroidal anti-inflammatory drugs (NSAIDs). Patients should be advised to avoid (1) foods that have high purine content (e.g., liver, kidneys, red meat, sardines) and (2) drugs that affect urate excretion (thiazide diuretics and salicylates). Specific pharmacological interventions include the use of uricosuric drugs (e.g., probenecid, sulfinpyrazone), which enhance renal excretion of uric acid by blocking carriers in the tubular cells that mediate reabsorption, or the xanthine oxidase inhibitor allopurinol. Measurement of urinary uric acid excretion facilitates selection of appropriate treatment in this context. Patients excreting less than 600 mg/d (3.6 mmol/d) of uric acid are candidates for treatment with uricosuric drugs, which are contraindicated in patients with urate stones or kidney failure. Conversely, patients excreting more than 600 mg/d (3.6 mmol/d) are candidates for treatment with allopurinol. T e NSAIDs azapropazone and tiaprofenic acid have a uricosuric effect and so have a place in both long-term and short-term management of gout. For patients treated for gout, a target concentration of <6.0 mg/dL (<0.36 mmol/L) has been recommended.[14]

About one in five patients with clinical gout also has urinary tract uric acid stones. Although serum and urinary uric acid should be measured in stone formers, many uric acid stone formers do not demonstrate hyperuricuria or hyperuricemia. However, this may reflect the use of reference intervals derived in a purine-rich, westernized society. T e cause of uric acid stone formation also involves the passage of persistent acid urine with loss of the postprandial alkaline tide. Undissociated uric acid (pK_a = 5.57) is relatively insoluble. Above pH 5.57, it exists predominantly as its more soluble urate ion, and at pH 7.0, it is greater than 10 times more soluble. T us in patients with urinary pH persistently less than 6.0, normal urinary concentrations of uric acid will produce supersaturation. T us measurement of urinary pH throughout the day is often useful. Pure uric acid stones account for approximately 8% of all urinary tract stones and, unlike many of the calcium-containing stones, are radiolucent. Allopurinol is the mainstay of treatment for uric acid stones. Hyperuricuria is also a risk factor for calcium stone formation. Consequently, attempts to increase urinary pH with potassium alkaline salts may be counterproductive as a result of increased calcium stone formation.

Hypouricemia

Hypouricemia is defined as a condition whereby serum urate concentrations are less than 2.0 mg/dL (0.12 mmol/L). It is much less common than hyperuricemia. It may be secondary to any of a number of underlying conditions. Examples include (1) severe hepatocellular disease with reduced purine synthesis or xanthine oxidase activity and (2) defective renal tubular reabsorption of uric acid. Defective reabsorption may be congenital, as in generalized **Fanconi syndrome**, or acquired. T e reabsorption defect may be acquired acutely as a result of injection of radiopaque contrast media or chronically because of exposure to toxic agents. Overtreatment of patients with hyperuricemia with allopurinol or uricosuric drugs and cancer chemotherapy with 6-mercaptopurine or azathioprine (inhibitors of de novo purine synthesis) may also cause hypouricemia. Very rarely, hypouricemia may occur as the result of an inherited metabolic defect. Hypouricemia in combination with xanthinuria is rarely encountered and suggests a deficiency of xanthine oxidase, either in isolation or as part of combined molybdenum cofactor deficiency (sulfite oxidase/xanthine oxidase deficiency).

Analytical Methodology



Common techniques for measuring uric acid in body fluids include (1) phosphotungstic acid (PTA), (2) uricase, and (3) HPLC-based methods.[10]

Phosphotungstic Acid Methods

T ese methods are based on the development of a blue reaction chromogen (tungsten blue) as PTA is reduced by urate in an alkaline medium. Absorbance of the chromogen in the reaction mixture is measured at wavelengths of 650 to 700 nm. PTA methods are subject to many interferences, and efforts to modify them have had little success in improving their specificity.

Uricase Methods

Uricase methods are more specific than PTA approaches. Uricase ([urate:oxygen] oxidoreductase; EC 1.7.3.3; main sources Aspergillus f avus, Candida utilis, Bacillus *f*astidiosus, and hog liver) isused as a single step or as the initial step in oxidizing uric acid. Uricase acts on uric acid to produce allantoin, hydrogen peroxide, and carbon dioxide.

Uricase methods became feasible and popular as a result of the availability of high-quality, low-cost preparations of the bacterial enzyme. Preliminary precipitation of protein is not required. Generally, only (1) guanine, (2) xanthine, and (3) a few other structural analogs of uric acid act as alternative substrates, and then only at concentrations improbable in biological fluids.

T e reaction is executed in either the kinetic or equilibrium mode with the decrease in absorbance measured with a spectrophotometer at 293 nm. T is forms the basis of a proposed reference procedure but requires a high-quality spectrophotometer with a narrow bandpass, which is rarely included in automated analyzers. Most current enzymatic assays for uric acid in plasma involve a peroxidase system coupled with one of a number of oxygen acceptors to produce a chromogen. For example, one method measures hydrogen peroxide with the aid of horseradish peroxidase and an oxygen acceptor to yield a chromogen in the visible spectrum. Oxygen acceptors that have been used for

this purpose include (1) 4-aminophenazone and a substituted phenol, (2) 3-methyl-1-benzothiazoline hydrazone (MBTH), 2,2′-azino-di-(3-ethyl-benzothiazoline)-6-sulfonate (ABTS), and (3) o-dianisidine.

Although many combinations of oxygen acceptor and phenol have been described, the choice should be guided by minimization of interference and sufficient absorbance to ensure a precise method. Use of a substituted phenol yielding a highly absorbing product helps to reduce potential interference by reducing the sample volume requirement. The major interferants that should be minimized are ascorbic acid and bilirubin. For example, some methods use ascorbate oxidase to eliminate ascorbic acid. Aminophenazone with a substituted phenol or with the addition of ferricyanide has been used to minimize bilirubin interference. It has also been shown that unknown metabolites in plasma of patients with kidney failure, thought to be phenolic compounds, will interfere by competing with the reagent phenol, resulting in low recovery of urate. A phenolic derivative has been used to minimize this interference, thereby generating a higher absorbing product and reducing the sample volume.

Devices that use uricase in a dry reagent format to measure uric acid have also been described. For example, a multilayer film system employs uricase and peroxidase separated by a semi-permeable membrane from a leuco dye that is oxidized to form a colored product. A cellulose matrix pad system employs uricase, peroxidase, and MBTH as oxygen acceptors. In addition, this method needs only a diluted plasma sample, which helps to reduce interferences. Ascorbic acid, however, is a significant interferant. A third system incorporates separation of plasma from red cells and uricase, peroxidase, and a substituted phenol to measure uric acid. All three systems employ a reflectance meter system to facilitate accurate and precise quantitation of the color change.

HPLC Methods

HPLC methods with ion exchange or reversed-phase columns have been used to separate and quantify uric acid. The column effluent is monitored at 293 nm to detect the eluting uric acid. (1) HPLC methods are specific, (2) mobile phases are simple, and (3) retention time for uric acid is less than 6 minutes. Because of these multiple attributes, HPLC has been used to develop reference methods for measuring uric acid. A proposed definitive method for the assay of uric acid in plasma uses IDMS.

Reference Intervals

When an enzymatic method is used, the reference interval for uric acid has been reported to be 3.5 to 7.2 mg/dL (0.208 to 0.428 mmol/L) for males and 2.6 to 6.0 mg/dL (0.155 to 0.357 mmol/L) for females. The concentration of serum uric acid increases gradually with age, rising about 10% between the ages of 20 and 60 years. A rise in women is noted after menopause, when uric acid reaches concentrations similar to those in men. During pregnancy, serum uric acid concentrations fall during the first trimester and until about 24 weeks of gestation. At that time, concentrations begin to rise and eventually exceed nonpregnant concentrations.

An alternative approach to the interpretation of serum uric acid concentrations is to consider the degree of hyperuricemia in relation to the risk of developing gout; men with plasma uric acid concentrations exceeding 9.0 mg/dL (0.540 mmol/L) are approximately 150 times more likely to have coexisting gouty arthritis than are men with uric acid concentrations less than 6.0 mg/dL (0.360 mmol/L).

Urinary uric acid excretion in individuals on a diet containing purines is 250 to 750 mg/d (1.5 to 4.5 mmol/d). Excretion may decrease by 20% to 25% on a purine-free diet to less than 400 mg/d.

Review Questions

1. The plasma concentration of creatinine is maintained within narrow limits predominantly by:
   a. the constant catabolism of purines.
   b. the constant rate of protein metabolism.
   c. the glomerular filtration rate.
   d. an individual's diet.
2. Symptoms of gout are caused by:
   a. decreased renal perfusion as in heart failure.
   b. precipitation of excessive uric acid in joints and the urinary tract.
   c. a low-protein diet.
   d. liver dysfunction as in hepatitis.
3. The main nitrogen-containing compound that accounts for more than 75% of excreted nonprotein nitrogen is:
   a. uric acid.
   b. creatinine.
   c. creatine.
   d. urea.
4. A deficiency of the enzyme xanthine oxidase due to severe hepatocellular disease will lead to:
   a. increased urea concentration.
   b. decreased creatinine concentration.
   c. hypouricemia.
   d. hyperuricemia.
5. During protein breakdown, the amino acid nitrogen groups are converted to urea through the urea cycle in which of the following?
   a. Liver
   b. Kidneys
   c. Heart
   d. GI tract
6. Compensated Jaffe assays for creatinine assessment:
   a. add a fixed value to the assay result to compensate for interferants.
   b. subtract a fixed value from each result to compensate for noncreatinine interference.
   c. use a special formula that involves body mass and urine production to "normalize" creatinine results.
   d. involve averaging of values to remove possible discrepancies between two samples obtained at different times of the day.

7. A value of 8.4 mg/dL of urea converts to what in mmol/L?
   a. 2.99
   b. 29.9
   c. 3.92
   d. 39.2
8. Ascorbic acid and bilirubin are interferants in which of the following assays?
   a. Jaffe reaction and uricase methods
   b. Jaffe reaction only
   c. Jaffe reaction, urease methods, and uricase methods
   d. Urease methods only
9. In the uricase method of uric acid measurement, the main interferants that must be minimized are:
   a. phenol and bilirubin.
   b. ascorbic acid and bilirubin.
   c. endogenous ammonia and oxidizing agents.
   d. ketone bodies and protein.
10. Uric acid is:
   a. the major product of protein catabolism.
   b. a derivative of muscle creatine.
   c. a metabolite of urinary nitrogen.
   d. the major product of purine catabolism.

CHAPTER

22 Carbohydrates

David B. Sacks, M.B., Ch.B., F.R.C.Path.

Objectives

1. Define the following:
   Carbohydrate
   Gluconeogenesis
   Glycogen
   Glycogen storage disease
   Glycogenesis
   Glycogenolysis
   Glycolysis
   Glycoprotein
   Hypoglycemia
   Ketone
   Monosaccharide, disaccharide, and polysaccharide
2. Provide two examples each of a monosaccharide, a disaccharide, and a polysaccharide; describe the chemical structure of each.
3. Summarize the regulation of glucose concentration in the blood, including two hormones involved in this process.
4. Explain the relationship between glucose, lactate, and pyruvate.
5. Discuss the brain's dependence on glucose, including how the brain is affected in a hypoglycemic state and the alternative energy source used.
6. State the blood glucose concentration at which hypoglycemia is typically diagnosed.
7. List three causes of fasting hypoglycemia and three causes of postprandial (nonfasting) hypoglycemia; describe the 72-hour fast test for diagnosing hypoglycemia.
8. List two causes of hypoglycemia in persons with type 1 diabetes.
9. Compare glucose values in fasting whole-blood, capillary, and venous blood specimens; state the reasons for the discrepant values.
10. State the effects of glycolysis on glucose in uncentrifuged blood; list two ways in which glycolysis can be inhibited.
11. Describe the hexokinase method for measurement of glucose in blood; state the specimen requirements and the principle of the reaction, and list the known interferences.
12. Describe the glucose oxidase method for measurement of glucose in blood; state the specimen requirements and the principle of the reaction, and list the known interferences.
13. Describe the chemical reaction used to assess lactate concentration in blood; describe the chemical reaction used to assess pyruvate concentrations in blood.
14. State the specimen collection and storage requirements for blood lactate and pyruvate analyses.
15. Analyze and resolve case studies regarding carbohydrate disorders; correlate the results of carbohydrate analysis with carbohydrate disorders.

Key Words and Definitions

Aldehyde An organic compound with a carbonyl group (a carbon atom double-bonded to an oxygen) at the end of the carbon chain bonded to hydrogen and an R group (usually an alkyl group).

Carbohydrate Aldehyde or ketone derivatives of polyhydroxy alcohols composed of carbon, hydrogen, and oxygen in a ratio of 1:2:1.

Cori cycle The mechanism by which lactate produced by muscles is carried to the liver, converted back to glucose via gluconeogenesis, and returned to the muscles.

Diabetes Control and Complications Trial (DCCT) A medical study of diabetic patients conducted in the United States and Canada in 1983-1993 by the National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK).

Diabetes mellitus A group of metabolic disorders of carbohydrate metabolism in which glucose is underutilized, producing hyperglycemia.

Glucagon A protein hormone that maintains blood glucose concentration by increasing blood glucose through glycogenolysis.

Gucagonoma A type of islet cell tumor of the alpha cells of the pancreas that secretes glucagon; some are malignant.

Glucose A six-carbon monosaccharide derived from the breakdown of carbohydrates in the diet or in body stores; also can be endogenously synthesized from protein or the glycerol moiety of triglyceride.

Glycogen An extensively branched polysaccharide containing many glucose residues and found particularly in muscle and liver cells for glucose storage.

Glycogen storage disease A group of rare inborn errors of metabolism caused by defects in specific enzymes or transporters involved in the metabolism of glycogen.

Key Words and Definitions—cont'd

Hypoglycemia An abnormally diminished concentration of glucose in the blood.

Idiopathic postprandial syndrome Repeated occurrence of the clinical manifestations of hypoglycemia after meals.

Insulin A protein hormone from the pancreas that maintains blood glucose concentration by decreasing blood glucose through cellular uptake.

Ketone An organic compound that has a carbonyl group (carbon atom double-bonded to an oxygen atom) at any position other than at the end of the carbon chain.

Lactate An intermediary product in glucose metabolism that accumulates in the blood predominantly when tissue oxygenation is decreased, as during strenuous exercise; an increased blood lactate concentration is called lactic acidosis.

Oral glucose tolerance test (OGTT) The most common kind of glucose tolerance test in which glucose is ingested by a fasting patient and their concentration of plasma glucose measured over time.

Pyruvate An organic acid formed from glucose through glycolysis.

Stereoisomer One of a group of compounds differing only in the spatial arrangement of their atoms.

Whipple's triad A collection of three criteria suggesting a patient's symptoms result from hypoglycemia.

Carbohydrates, including sugar and starch, are widely distributed in plants and animals. They perform multiple functions, such as serving as structural components in RNA and DNA (ribose and deoxyribose sugars) and providing a source of energy (glucose). **Glucose** is derived from (1) the breakdown of carbohydrates in the diet (grains, starchy vegetables, and legumes) or in body stores (glycogen), and (2) endogenous synthesis from protein or from the glycerol moiety of triglycerides. When energy intake exceeds expenditure, the excess is converted to fat and glycogen for storage in adipose tissue and liver or muscle, respectively. When energy expenditure exceeds caloric intake, endogenous glucose formation occurs from the breakdown of carbohydrate stores and from noncarbohydrate sources (e.g., amino acids, lactate, glycerol).

The glucose concentration in the blood is maintained within a fairly narrow interval under diverse conditions (feeding, fasting, or severe exercise) by hormones such as (1) **insulin**, (2) **glucagon**, and (3) epinephrine. Measurement of glucose is one of the most commonly performed procedures in (1) hospital laboratories, (2) other healthcare chemistry laboratories, (3) point-of-care applications, and (4) home-use meters The most frequently encountered disorder of carbohydrate metabolism is high blood glucose concentration due to **diabetes mellitus**, which affects approximately 9% of the U.S. adult population. The incidence of **hypoglycemia** (low blood glucose) is unknown but is low (excluding patients who use exogenous insulin to control blood glucose).

Chemistry of Carbohydrates

Carbohydrates are **aldehyde** or **ketone** derivatives of polyhydroxy (more than one –OH group) alcohols or compounds that yield these derivatives on hydrolysis.

Monosaccharides

A monosaccharide is a simple sugar that consists of a single polyhydroxy aldehyde or ketone unit and is unable to be hydrolyzed to a simpler form. The backbone is made up of several carbon atoms. Sugars containing three, four, five, six, and seven carbon atoms are known as trioses, tetroses, pentoses, hexoses, and heptoses, respectively. One of the carbon atoms is double-bonded to an oxygen atom to form a carbonyl group. An aldehyde has the carbonyl group at the end of the carbon chain, whereas if the carbonyl group is at any other position, a ketone is formed (Figure 22-1). The simplest carbohydrate is glycol aldehyde, the aldehyde derivative of ethylene glycol. The aldehyde and ketone derivatives of glycerol are, respectively, glyceraldehyde and dihydroxyacetone (see Figure 22-1). Monosaccharides are termed aldoses and ketoses according to the position of the carbonyl group (Figure 22-2).

Compounds that are identical in composition and differ only in spatial configuration are called **stereoisomers**. The carbon atoms in the unbranched chain are numbered 1 to 6, as shown by the numbers at the left of the formula for d-glucose in Figure 22-2. The designation d- or l- refers to the position

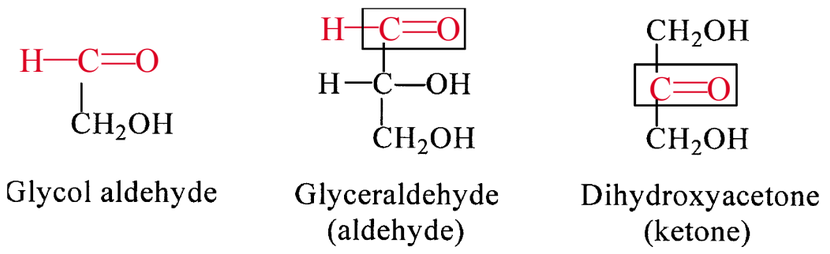

Figure 22-1 Three-carbon carbohydrates.

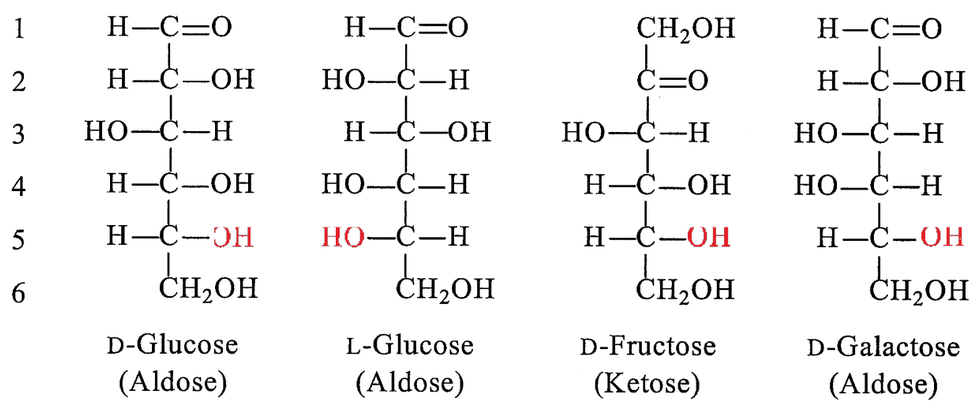

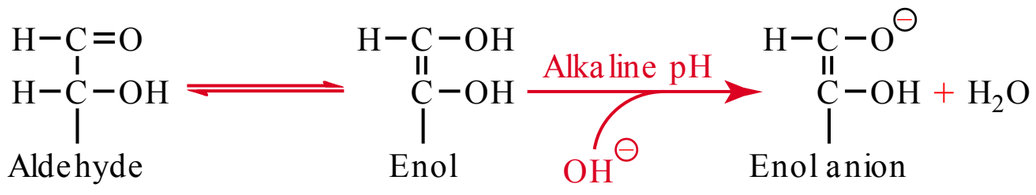

Figure 22-2 Typical six-carbon sugars.

of the hydroxyl group on the carbon atom adjacent to the last (bottom) CH_2OH group. In general, designations of d- and l- for a sugar molecule refer to the stereoisomeric forms of the highest-numbered asymmetrical carbon atom.* By convention, the d-sugars are written with the hydroxyl group on the right, and the l-sugars are written with the hydroxyl group on the left (see Figure 22-2). Most sugars in the human body are of the d-configuration. Several different structures exist, depending on the relative positions of the hydroxyl groups on the carbon atoms.

The formula for glucose can be written in the form of aldehyde or enol, a short-lived reactive species. Shift to the enol anion is favored in alkaline solution, as follows:

The presence of a double bond and a negative charge in the enol anion makes glucose an active reducing substance that is oxidized by relatively mild oxidizing agents, such as cupric ($Cu2^+$) and ferric ($Fe3^+$) ions. Glucose in hot alkaline solution readily reduces cupric ions to cuprous ions. The color change has been used as a presumptive indication for the presence of glucose; for many years, blood and urine glucose concentrations were measured using this approach. Some other sugars also reduce cupric ions in alkaline solution; these are collectively referred to as reducing sugars.

The aldehyde group reacts with the hydroxyl group on carbon 5, represented by a symmetrical ring structure and depicted by the Haworth formula, in which glucose is considered as having the same basic structure as pyran (Figure 22-3). In this formula, the plane of the ring is considered to be perpendicular to the plane of the paper, with the heavy lines pointing toward the reader. Hydroxyl groups in position 1 are then below the plane (α-configuration) or above the plane (β-configuration). A six-member ring sugar containing five carbons and one oxygen is a derivative of pyran and is called a pyranose. When linkage occurs with formation of a five-member ring containing four carbons and one oxygen, the sugar has the same basic structure as furan and is called a *f*uranose. Fructose is shown in two cyclical forms. Fructopyranose is the configuration of the free sugar, and fructofuranose occurs whenever fructose exists in combination with disaccharides and polysaccharides, as in sucrose and inulin.

Disaccharides

Two monosaccharides join covalently by an O-glycosidic bond, with loss of a molecule of water, to form a disaccharide. The chemical bond between the sugars always involves the aldehyde or ketone group of one monosaccharide joined to an alcohol group (e.g., maltose) or an aldehyde or ketone group (e.g., sucrose) of the other monosaccharide (Figure 22-4). The most common disaccharides are as follows:

Maltose = glucose + glucose
Lactose = glucose + galactose
Sucrose = glucose + fructose

*Although the d and l designations are used in this chapter, readers should be aware that in the Cahn-Ingold-Prelog system, a series of rules determine configurations. In this new system, the symbols R and S are used to designate configurations.

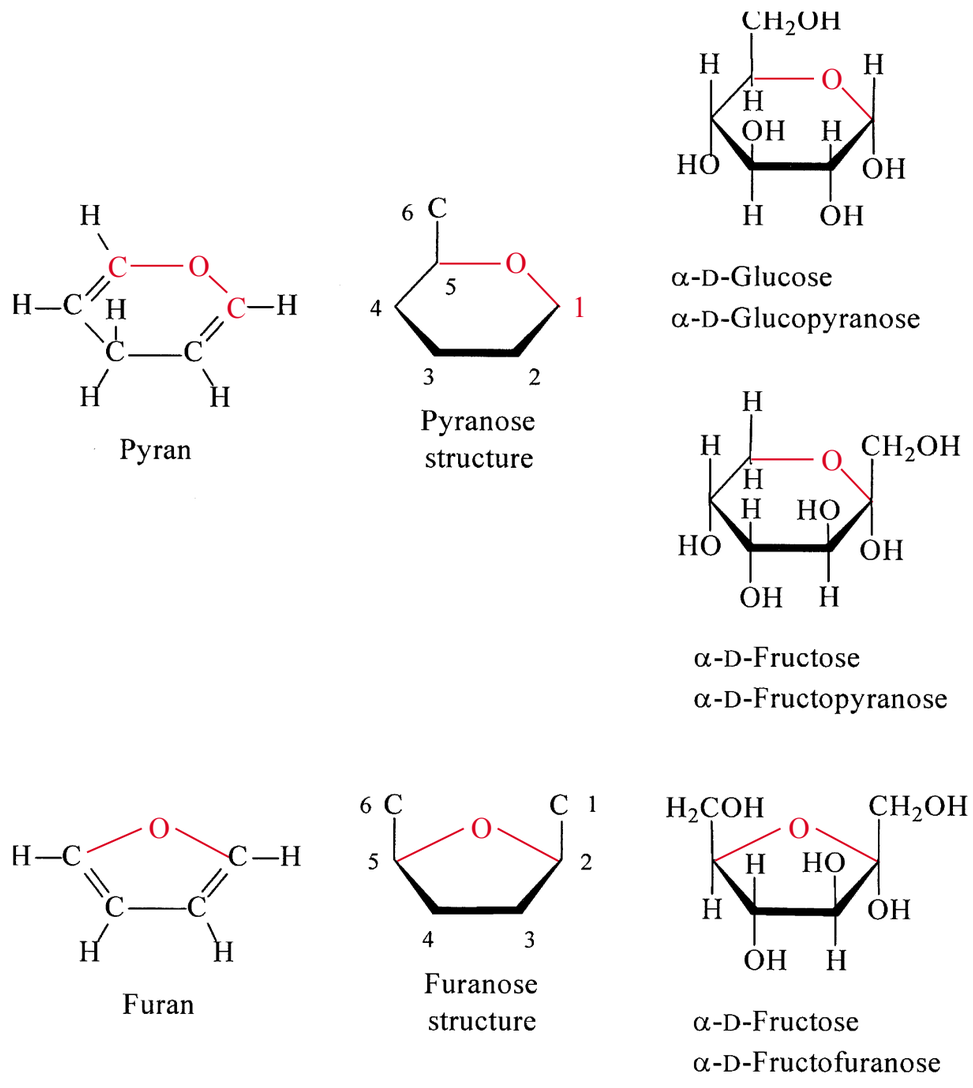

Figure 22-3 The Haworth formula for sugars.

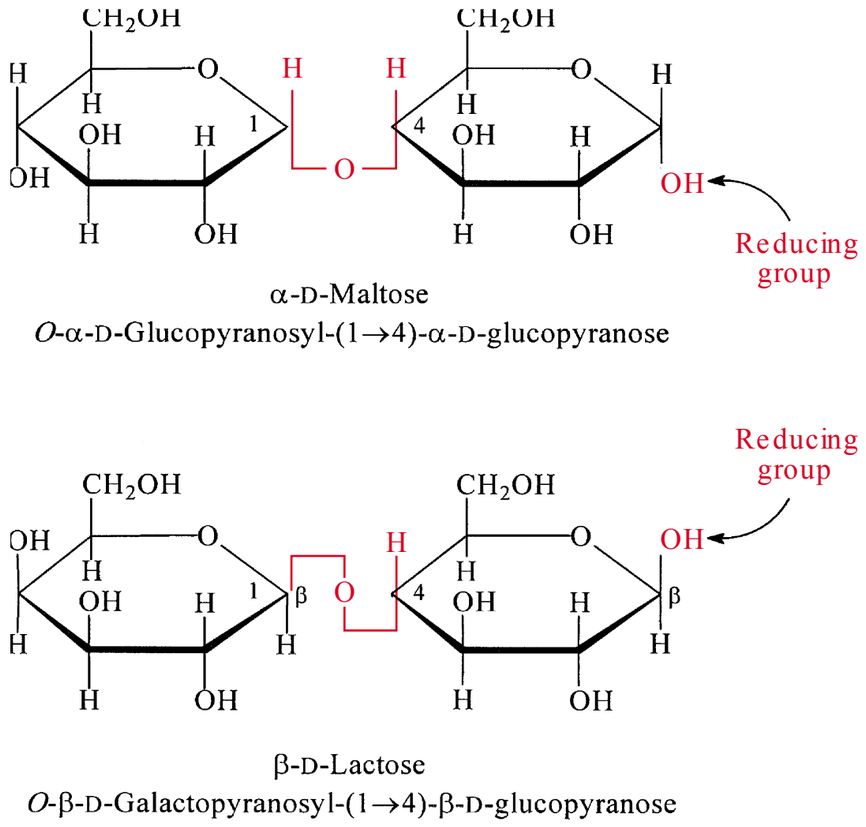

Figure 22-4 Structural formulas of disaccharides.

If the linkage between two monosaccharides is between the aldehyde or ketone group of one molecule and a hydroxyl group of another molecule (as in maltose and lactose), one potentially free ketone or aldehyde group remains on the second monosaccharide. Consequently, the second glucose residue can be oxidized and is capable of existing in α- or β-pyranose form. Thus the disaccharide is a reducing sugar, but its reducing power is only approximately 40% of the reducing power of the two single monosaccharides added together. Alternatively, if the linkage between two monosaccharides involves the aldehyde or ketone groups of both molecules (as in sucrose), a nonreducing sugar is formed because no free aldehyde or ketone group remains.

Polysaccharides

The linkage of multiple monosaccharide units results in the formation of polysaccharides. The major storage carbohydrates are starch in plants and glycogen in animals, both of which form granules inside cells. Polysaccharides also provide structural support. For example, the polysaccharide cellulose is used by plants, whereas chitin is the principal component of the exoskeleton of arthropods (insects and crustacea).

Starch and Glycogen

Most starches are composed of a mixture of amyloses and amylopectins. Amylose consists of one long unbranched chain of glucose units linked together by α-1,4-linkages, with only the terminal aldehyde group free. In amylopectin, most of the units are joined by α-1,4-links, but α-1,6-glycosidic bonds also exist every 24 to 30 residues, producing sidechains. Amylopectin contains up to 1 million glucose residues. The structure of **glycogen** is similar to that of amylopectin, but branching is more extensive and is evident every 8 to 12 glucose residues. These branches enhance the solubility of glycogen and allow the glucose residues to be more readily mobilized. Glycogen is most abundant in the liver and also is found in skeletal muscle. The difference in structure between amylose and amylopectin is important in selection of the appropriate starch substrate for amylase determinations (see Chapter 19). The rate of hydrolysis is affected by structural differences in the starch.

Cellulose

Cellulose is an important structural polysaccharide in plants. It is an unbranched polymer of glucose residues joined by β-1,4-linkages. The β-configuration facilitates the formation of long straight chains, producing fibers of high tensile strength. The β-1,4-linkages are not hydrolyzed by α-amylases. Because humans do not have cellulases, they are unable to digest vegetable fiber.

Glycoproteins

Many integral membrane proteins have oligosaccharides covalently attached to the extracellular region, forming glycoproteins. In addition, most proteins that are secreted, such as (1) antibodies, (2) hormones, and (3) coagulation factors, are glycoproteins. The number of attached carbohydrate residues varies among proteins and constitutes 1% to 70% of the weight of the glycoprotein. The oligosaccharides are attached by O-glycosidic linkages to the sidechain oxygen of serine or threonine residues or by N-glycosidic linkages to the sidechain nitrogen of asparagine residues.

One of the biological functions of the carbohydrate chains is to regulate the life span of proteins. Loss of sialic acid residues from the ends of oligosaccharide chains on erythrocytes results in the removal of red blood cells from the circulation. Carbohydrates have also been implicated in cell-cell recognition, in secretion, and in targeting of proteins to specific subcellular domains.

Biochemistry and Physiology[6]

Glucose is the primary energy source for the human body. After absorption (see Chapter 38), the metabolism of all hexoses proceeds according to the body's requirements. This metabolism results in (1) energy production by conversion to carbon dioxide and water, (2) storage as glycogen in the liver or as triglyceride in adipose tissue, or (3) conversion to keto acids, amino acids, or protein.

The complete picture of intermediary metabolism of carbohydrates is complex and is interwoven with the metabolism of lipids and amino acids. For details, readers should consult a biochemistry textbook.

Regulation of Blood Glucose Concentration

The concentration of glucose in the blood is regulated by a complex interplay of multiple pathways that are modulated by several hormones. Glycogenesis is the name for the conversion of glucose to glycogen, the most important storage polysaccharide in liver and muscle. The reverse process, namely, the breakdown of glycogen to glucose and other intermediate products, is termed glycogenolysis. The formation of glucose from noncarbohydrate sources, such as (1) amino acids, (2) glycerol, or (3) lactate, is termed gluconeogenesis. The conversion of glucose or other hexoses into lactate or **pyruvate** is called glycolysis. Further oxidation to carbon dioxide and water occurs through the Krebs (citric acid) cycle and the mitochondrial electron transport chain coupled to oxidative phosphorylation, which generates the adenosine triphosphate (ATP) that provides chemical energy for many bodily processes. Oxidation of glucose to carbon dioxide and water also occurs through the hexose monophosphate shunt pathway, which produces the reduced form of nicotinamide-adenine dinucleotide phosphate (NADPH).

Hypoglycemia[4]

Hypoglycemia is a blood glucose concentration below the fasting value, but the definition of a specific limit is difficult. The most widely used cutoff is 50 mg/dL (2.75 mmol/L), but some authors suggest 60 mg/dL (3.50 mmol/L). A transient decline may occur 1.5 to 2 hours after a meal, and it is not uncommon for plasma glucose concentration as low as 50 mg/dL (2.75 mmol/L), to be observed 2 hours after ingestion of an oral glucose load. Similarly, extremely low fasting blood glucose values may be occasionally noted without symptoms or evidence

of underlying disease. Hypoglycemia is rare in persons who do not have drug-treated diabetes mellitus.

Symptoms of hypoglycemia vary among individuals, and none is specific. Epinephrine produces the classic signs and symptoms of hypoglycemia, namely, (1) trembling, (2) sweating, (3) nausea, (4) rapid pulse, (5) light-headedness, (6) hunger, and (7) upper abdominal discomfort. T ese autonomic symptoms are nonspecific and may be noted in other conditions, such as (1) hyperthyroidism, (2) pheochromocytoma, or even (3) anxiety. Although controversial, some investigators have proposed that a rapid decrease in blood glucose concentrations may trigger the symptoms even though the blood glucose itself may not reach hypoglycemic values, whereas gradual onset to a similar glucose concentration may not produce symptoms.

T e brain is completely dependent on blood glucose for energy production under physiological conditions, and approximately half of the glucose used in resting adults is found in the CNS. Very low concentrations of plasma glucose (<20 or 30 mg/dL (1.10-1.65 mmol/L) cause severe CNS dysfunction. During prolonged fasting or hypoglycemia, ketones may be used as an energy source. T e broad spectrum of symptoms and signs of CNS dysfunction vary from (1) headache, (2) confusion, (3) blurred vision, (4) dizziness, (5) seizures, (6) loss of consciousness, and (6) even death. T ese symptoms are known as neuroglycopenia. Restoration of plasma glucose usually produces prompt recovery, but irreversible damage may occur.

T e age of onset of hypoglycemia is a convenient way to classify the disorder, but some overlap occurs among the various groups. For example, some glycogen storage disorders may arise in the third decade of life, and hormone deficiencies may occur in childhood.

Hypoglycemia in Neonates and Infants

Neonatal blood glucose concentrations are much lower than those of adults (mean, <35 mg/dL/1.93 mmol/L) and decline shortly after birth when liver glycogen stores are depleted. Glucose concentrations as low as 30 mg/dL (1.65 mmol/L) in a term infant and 20 mg/dL 1.10 mmol/L) in a premature infant may occur without clinical evidence of hypoglycemia. T e more common causes of hypoglycemia in the neonatal period include (1) prematurity, (2) maternal diabetes, (3) gestational diabetes mellitus (GDM), and (4) maternal toxemia. Hyperglycemia in these cases is usually transient. Hypoglycemia with onset in early infancy is usually less transitory and may be due to inborn errors of metabolism or ketotic hypoglycemia; this type of hypoglycemia usually develops after fasting or a febrile illness.

Fasting Hypoglycemia in Adults

Hypoglycemia results from a decreased rate of hepatic glucose production or an increased rate of glucose use. Symptoms suggestive of hypoglycemia are fairly common, but hypoglycemic disorders are rare. However, true hypoglycemia usually indicates serious underlying disease and may be life threatening. An exact threshold for the establishment of hypoglycemia is not always possible, and values as low as 30 mg/dL (1.65 mmol/L) may be encountered in healthy, premenopausal women during the classic test—a 72-hour fast. Symptoms usually begin at plasma glucose concentrations below 55 mg/dL 3.03 mmol/L), and impairment of cerebral function begins when glucose is less than 50 mg/dL (2.75 mmol/L).

T e 72-hour fast should be conducted in a hospital. During the fast, the patient should be allowed a liberal intake of calorie-free and caffeine-free f uids. Samples typically are drawn every 6 hours for analysis of plasma glucose, insulin, C-peptide, and proinsulin. When plasma glucose concentration is 60 mg/dL (3.30 mmol/L) or less, analyses are performed every 1 to 2 hours. T e fast should be concluded when plasma glucose concentration falls to a predetermined concentration (such as 45 mg/dL/2.47 mmol/L or less) or the patient exhibits signs or symptoms of hypoglycemia, or after 72 hours. Most patients with true hypoglycemia show an abnormally low value within 12 hours of beginning a fast. Women exhibit significantly lower glucose concentrations than men. Low plasma glucose alone is not sufficient to establish the diagnosis, and the absence of signs or symptoms of hypoglycemia during the fast excludes the diagnosis of a hypoglycemic disorder as the cause of such symptoms.

More than 100 causes of hypoglycemia have been reported. Drugs are the most prevalent cause, and many widely used drugs, including (1) propranolol, (2) salicylates, and (3) disopyramide, produce hypoglycemia. Oral hypoglycemic agents, which have long half-lives (35 hours for chlorpropamide), are the most frequent cause of drug-induced hypoglycemia and may be directly measured in blood or urine. Surreptitious administration of insulin is detected by the discovery of low C-peptide concentrations with increased insulin concentrations.
